1. Ocean.—From data already given in section second, we shall probably not err if we estimate the surface of the whole ocean and its branches at 144,473,000 square miles. It is not so easy to arrive at a safe conclusion with regard to its mean depth. Laplace and later investigators seem to believe that the depths of the ocean may be in proportion to the elevation of the land, and the ratio of their respective areas. Mrs Sommerville states, that although it is probable that profound cavities of small extent exist in the bed of the ocean, its mean depth does not exceed the mean height of the continents and islands above its level. According to Lagrange, the velocity of the tidal wave is a function of the depth of the channel through which it moves; and recent investigations respecting the velocity of the tidal wave in these seas, would lead us to infer that the mean depth of the sea around the coasts of England is about 120 feet, on those of Scotland 360 feet, on the western coast of Ireland 2000 feet, and in the main Atlantic 50,000 feet, or a little more than nine miles and a half. The examination of the co-tidal lines on Whewell's charts would lead to the conclusion that no considerable extent of the ocean has a greater depth than the Atlantic. If the depths of the ocean are indeed proportional to the elevation of the land, in the ratio of their respective surfaces, the greatest profundity of the oceanic abyss would be about fifteen miles, and its mean depth, at a distance from the land, would vary from one to five miles. If we assume four miles as its mean depth, this would give 577,892,000 cubic miles as the volume of the whole waters of the globe; or, if we reckon it five miles in depth, the mass of waters would equal 722,365,000 cubic miles.

Waves.

The waters of the ocean are in perpetual movement, from the effects of winds, currents, and the tides. The effect of winds in agitating the ocean is chiefly confined to its surface. The most powerful waves in the free sea only rise to the height of a few feet; and it is highly probable, that in the profound depths of the ocean, there reigns a perpetual stillness, unruffled by any movement, except in as far as general currents may disturb the tranquillity of the waters. The surface, acted upon by strong gales, is thrown into long ridgy waves, which rise with an uniform swell, and maintain the same velocity for considerable distances, the top curling in foaming surges, which are precipitated on the undulating surface below, often to the great danger of the navigator. No region of the ocean is subject to more violent oscillations of this nature than that portion of the Atlantic termed the Bay of Biscay, when agitated by a smart gale of westerly wind. Geometry has been applied to measure the velocity of waves, and Lagrange estimates, that where the depth is not very great, the velocity will be the same as a heavy body would acquire in descending from a height equal to half the depth of the water, and that the velocity of the wave is in the duplicate ratio of the depth of the channel in which the water moves. It is believed, however, that the wildest tempest in the open sea does not agitate the water at the depth of an hundred feet; but when waves meet with resistance, as when they dash upon lofty cliffs, we have known them rise apparently in one unbroken mass to the height of two hundred feet.

Cur

There are other movements of the waters of the ocean, termed *currents*. The most general currents are produced by the movement of the waters perpetually setting from the polar regions towards the equator, and the progression of the tropical seas towards the west. Both are chiefly caused by the centrifugal force of the earth's diurnal rotation. This produces a culmination of water towards the equator, and thus a current is generated towards the part of the earth in most rapid motion; but the water accumulated there passes off before the influence of the trade-winds; and the strength of the western current is increased by the mobility of the particles of water preventing the fluid immediately acquiring the velocity of that portion of the earth over which it arrives in its progression towards the equator, by which it will appear to have a motion from east to west, or in an opposite direction to the earth's rotation. The higher density of the sea, when it has been cooled by the polar ices, will increase its tendency to displace the lighter waters, which are forced westward by the constant pressure of the trade-winds, and the other causes already mentioned. The currents from the north have been well described by Martens, Scoresby, and other navigators. The set of the current from the antarctic regions has been illustrated by the voyages of Cook, La Pérouse, Flinders, and others. The equatorial current becomes very apparent in the Atlantic and in the Pacific, between the parallels of 30° on each side of the equator. According to the best observers, it has a mean velocity of nine or ten miles per day in the open sea. In the Atlantic it produces that remarkable movement of the waters termed *the gulf-stream*. This current passes between the West Indian islands, and sweeps along the northern coasts of South America, from Cumana to the isthmus of Darien; from thence it stretches toward Cape Catoche in Yucatan, and, after wheeling through the Mexican Gulf, it rushes through the channel between Cuba and Florida, passing between the Bahamas and the United States of North America towards Newfoundland. In the latter part of its course it can be distinctly traced, not only by its effect on the dead reckoning of ships, but by the superior temperature of its waters, which betray its tropical origin, and by its greater depth; for it appears in a long succession of ages to have hollowed out for itself a submarine channel. In the Bahama Channel it has a breadth of fifteen leagues, and its waters have, in latitude 42°, a temperature of 71° Fahrenheit, whilst that of the adjacent sea beyond its influence is only 63°. The gulf-stream flows with diminished velocity as it proceeds northward, until it is lost on the banks of Newfoundland, where it encounters the great current from the arctic regions. This vast sub-marine bank, indeed, probably owes its origin to the deposition of the solid particles borne along by both currents, at the point where their opposing forces meet; and there can be little

Pola rents

Equa curr

doubt that the *eastern* movement of the waters of the Northern Atlantic is the resultant of the compound motion of these mighty oceanic streams. It has been computed from the average velocity of both, that the waters of the Atlantic, between the parallels of 10° and 43° north, perform a circuit of about 3800 nautical leagues in thirty-four months. The retrograde current preserves a general easterly direction after leaving Newfoundland; but it reaches considerably farther north, for its influence frequently throws on our western shores the trees and ligneous fruits of the Antilles; but the great body of it is deflected to the southward at the Azores, partly by the influence of the polar current from the north; and then sending a branch to enter the Straits of Gibraltar, gives rise to that dangerous current which has been described by Major Rennell as the cause of the frequent shipwrecks on the African coast within the Canary Islands, when the mariner, by reckoning, considers himself as far to the westward of Teneriffe.

Another branch of the great western current of the Atlantic appears to be deflected by the peculiar form of South America, from the latitude of Pernambuco, along the eastern coasts to Cape Horn; and, doubling that promontory, it finds its way into the Pacific. There is also a general western current in the Great Pacific. Ships are carried by this with great celerity from Acapulco to the Philippine Islands; but, in returning, it is found advisable to sail northwards, for the benefit of the variable winds and of the polar currents. In the Southern Pacific, the polar currents, being little interrupted by land, proceed with less deviation from their course than those in the northern hemisphere; and hence they carry icebergs nearer to the tropical regions than we ever find to the north of the equator. The western motion of the waters of the Pacific is interrupted and broken by the vast chain of islands, shoals, and sub-marine banks which stretch from China to New Zealand. The general direction is changed or modified by the form of these lands; and the vast mass of New Holland is one cause of those dangerous currents around its shores which were noticed by Cook, La Pérouse, and Flinders. The weakened force of the general current in the Indian seas permits its interruption by the variable direction of the *monsoons;* but the current which always sets from Australia towards the Bay of Bengal seems to be produced by the modifying influence of the south polar current on the general equatorial current when weakened by the interruption of islands. The direction of this current, finding obstacles to its progress in a north-west direction, and being resisted by the banks and islands which stretch between Cape Comorin and Madagascar, is deflected to the south-west, forming the current in the Mozambique Channel, and thence sweeping round the Cape of Good Hope in a powerful stream, not less than forty-three leagues in breadth. The entrance into this current may be ascertained by the sudden increase in the temperature of the water to eight degrees beyond that of the adjacent ocean. It is probably to this current that the vast shoal off the Cape, known by the name of the Aguillas Bank, is to be attributed. It appears to round off upon both sides, forming a bank forty leagues in breadth, and 160 leagues from east to west.

The strong current through Bass's Straits, separating New Holland from Van Diemen's Land, is but a part of the general western current; but in its passage through the intricate channels between the islands, reefs, and shoals of the ocean north of Australia, it is divided and modified in a thousand different ways. There is another current less easily accounted for. On the western coast of Africa, about thirty leagues from the land, a strong current appears to set eastward in the Gulf of Guinea, and often draws ships far off their southern course. It seems to be a species of eddy, produced by resistance to the polar current caused by the sudden contraction of the Atlantic from the form of the opposite coasts of America and Africa. These currents may be considered as general; but there are other currents which, though special, are remarkably constant. Of these we may notice the perpetual current which sets into the Mediterranean through the Straits of Gibraltar. It occupies the middle of the Straits. On either shore a less powerful and less extensive current alternates with the tides; but there is a constant and powerful influx from the Atlantic into the Mediterranean. A perpetual current sets out of the Baltic to the Northern Ocean; and here also smaller counter-currents are found on the coasts of Sweden and Jutland. Another considerable local current perpetually sets from the Black Sea in the Mediterranean. The causes of these peculiarities we shall afterwards explain.

Tides.

Besides the motions already described, the waters of the ocean are subject to alternations in the level of its surface in any particular place several times a day. The rising of the water is termed *flood*, the fall is named *ebb-tide.* The connection between the tides and the moon were long observed before any theory was proposed to account for them. Descartes ascribed the flood to the pressure of the moon on the earth's atmosphere; but Kepler first suggested that it might arise from the attraction exerted by the moon; and this theory was confirmed and enlarged by Newton, who showed how well the general phenomena might be explained on the principle of universal gravitation. The theory and the phenomena are given under the article ASTRONOMY; to which we refer for the explanation of the two floods and two ebbs daily, how the united influence of the sun and moon causes the two spring and two neap-tides during each lunation; and why the highest tides of all take place about the equinoxes, when the sun and moon are on the equator, and in *perigee.*

The phenomena of the tides accord well with the theory in the open sea; but in the vicinity of land, amongst numerous islands, or in deep inland basins, their regularity is affected by various causes, as the occurrence of strong gales in particular directions, the form of points of land, of banks, and shoals, and the mechanical influence of narrow channels. Thus the tides of the German Ocean take twelve hours to reach London bridge; and consequently the time of high-water there is just as a new flood is commencing in that sea. The usual rise of the tides in mid-ocean is about three or four feet; but on the coasts of Britain, especially in the mouths of rivers, the attraction of the land raises them far higher. Thus, at Chepstow, the tide rises from forty-five to sixty feet; and it is recorded that once, from the influence of a strong gale blowing at the same time into Bristol Channel, the rise was seventy feet. In the river of Annapolis, which falls into the bay of Fundy, on the coast of America, the spring-tides have been known to reach the surprising height of 120 feet. In such cases the flood-tide often rushes in with a vast mass, like a huge wave, several feet above the general surface, which is termed a *bore*, and is dangerous to ships that may have been stranded on the receding of the tide. Something similar is often seen in our smaller rivers, and on such extensive flat sands as those in Morecamb Bay on the coast of Lancashire, and in the Solway Frith. In narrow straits the tide runs with great velocity, such as no ship can stem even with the most favourable breeze. In the embouchure of the Mersey, the ebb-tide has a rate of five or six miles an hour. In the Pentland Frith, between Caithness and the Orkney Islands, the spring-tides have a velocity of nine miles an hour.

Whirlpools.

Whirlpools appear to be occasioned by currents meeting with sub-marine obstacles, which throw them into gyration. When the movement is rapid, the centre is the most depressed portion of the rotating circle, and objects drawn within it are submerged in that point. Several small whirlpools, capable of whirling round a boat, are seen among the Orkney Islands. That of Coryvrechan, in the narrow channel between Scarba and Jura, in the Western Islands, is caused by a rock of a conical form rising abruptly from the bottom, where the depth is 600 feet, and reaching to within ninety feet of the surface. This obstruction, in a tortuous rocky channel, causes a succession of eddies; and when the flood-tide sets in, with a fresh breeze in the opposite direction, the eddying waters rise in short heavy waves, which are highly dangerous to boats, and even to decked vessels.

The Malström on the coast of Norway, near the island of Moskoe, is a whirlpool of a similar kind, the perils of which are probably much exaggerated. The flood-tide setting from the south-west amongst the Laffoden Isles, especially when it meets with a strong gale from the north-west, produces a great agitation of the waves, and a whirlpool is formed, the roaring of which is heard at the distance of many miles. Its agitated vortices are dangerous to vessels, and it is said that seals and whales, when caught within its eddies, are unable to extricate themselves from destruction.

It is now well ascertained that Charybdis, in the Strait of Messina, owes its terrors to the imagination of seamen in the infancy of navigation, and all its celebrity to poetic fancy.

Colour of the sea.

The sea, when viewed near land, has its colour affected by the nature of the bottom. Where the bottom is sandy, and the depth not very considerable, it has a greenish tint; and this is the general hue of the German Ocean; but when viewed out of soundings, the colour of the ocean is generally of a beautiful deep blue. This may be considered as the natural hue of a deep column of water, from which only the most refrangible colours reach the eye of the spectator placed on a ship's deck; and the greenish tint is produced by the mingling of this hue with the yellowish tint of the sandy bottom. Sometimes partial colours are observed in the ocean. Captain Cook and other navigators describe a brown colour of the sea, produced by myriads of minute mollusca and crustacea. In the Greenland seas, the waters in which the whales chiefly delight are streaked with green. This colour appears in broad streams in the sea; and, when examined by Scoresby, was found to be produced by innumerable medusæ and minute crustacea, the olive-green water containing sixty-four in one cubic inch. Captain Horsburgh mentions a milky appearance of the sea, observed in a passage from China to Australia, which was occasioned by minute globular bodies linked together, and doubtless forming some species of *beroe* or *medusa*. The occasional red colour of the sea on the coast of Brazil and of China is believed to proceed from minute mollusca which float in myriads in the waters at certain seasons of the year. Ehrenberg asserts that the name of *Red Sea* has been given to that gulf from the prevalence of a species of *oscillatoria*.

Phosphorescence of the sea.

The phosphorescence of the sea is a very brilliant appearance which the ocean and arms of the sea frequently assume. It is best seen when a vessel is in brisk motion through the waves, or when a boat is impelled by oars through a calm sea. We have seen this appearance so brilliant that we could distinguish letters in a book by its phosphorescence in the wake of a ship, where it will sometimes form a line of pale lambent light several hundred yards in length. We have also seen from the deck, by its light, the hour on a watch, when in other situations on the deck we could not distinguish the features of the seamen. When the hand is immersed in luminous water, we have found the shining particles adhering to the fingers; and on examining such water in a globular glass vessel by transmitted light, we scarcely ever failed to observe in it several minute animals of the genera *medusa* and *beroe*. These animals appeared to have the power of emitting light by their own efforts, as the water, when left at rest, shone by fits. On counting their number in a glass of water, and suddenly dashing it on the deck, in a dark night, it was observed that the number of luminous points generally coincided with that of the animals in the water, and never exceeded it. We have found these animals in sea-water, from 60° to 37° north latitude, in the Atlantic, and in innumerable bays; and believe that they are very general in the ocean.

The dependence of the phosphorescence of the sea on living animals was long ago asserted by Captain Cook and Sir Joseph Banks. In the voyage from the Canaries to Rio de Janeiro they drew a net through luminous water, and caught a large medusa, which shone brilliantly when taken on board; they obtained from it also three minute *crustacea*, about one tenth the size of the glow-worm, which also were very luminous in the dark. Banks named the first *Medusa pellucens*, and the most brilliant of the second *Cancer fulgens*. Other naturalists have enlarged the list of marine luminous animals, which includes occasional instances amongst the larger fishes.

Temperature of the sea.

A considerable number of experiments have been made on the temperature of the ocean by Ellis, Piron, Flinders, Parry, Ross, and others; but the results are not uniform. Ellis found in the Atlantic that the temperature remained stationary at 50° at depths a little exceeding a mile. Piron, who had sounded to greater depths, found it to decrease with the depth. The mean temperature of the ocean at the surface, and at a distance from land, is higher than that of the atmosphere with which it is in contact; but it is generally lower than the air at mid-day, and higher than the atmosphere at midnight. The ocean over a bank is colder than where it is of great depth. This is ascribed to cold currents being forced upwards by the obstruction; but whatever be the cause, the fact is important, as it may enable a seaman to recognise his approach to land when the atmosphere is obscure and his reckoning doubtful, as was first remarked by Mr Williams.

Saltness of the ocean.

The Southern Ocean, receiving less fresh water than the Atlantic, is rather salter, as is also the Mediterranean; but the Baltic, White and Black Seas, from the size of the rivers they receive, are fresher. According to Marcet their specific gravities are as follows:

Mediterranean	1·02930
Southern Ocean	1·02882
Northern Ocean	1·02829
Arctic Frozen Ocean	1·02664
White Sea	1·01901
Baltic	1·01523
Euxine	1·01418

Sea-water has a mean specific gravity of 1·0280 to distilled water as 1·0000. The late Dr John Murray published an admirable analysis of sea-water, 10,000 parts of which afforded him

Muriate of soda	245·04
Muriate of magnesia	28·63
Muriate of lime	0·00
Sulphate of magnesia	17·04
Sulphate of soda	2·66
Sulphate of lime	9·72
	303·9

Dr Murray detected no trace of muriate of lime, which Lavoisier has stated as high as 20·38, and Pfaff at 31·25. In reflecting upon these discrepancies, he was led to conclude that several of the products obtained may be the results of the mutual decomposition of the salts during the processes for separating them from the water; thus the sulphates of magnesia and of lime would be decomposed by muriate of soda, and when both are obtained from sea-water, we should regard them as results of decomposition. The real ingredients of sea-water would thus be,

Muriate of soda	220·01
Muriate of magnesia	33·16
Sulphate of soda	42·08
Muriate of lime	7·84
	303·9

This doctrine he has happily applied to explain the activity of several mineral waters, the analysis of which only affords inert ingredients.

The saline contents of the ocean do not appear to vary considerably; they, however, increase as we approach to the equator, from $\frac{1}{35}$ to $\frac{1}{24}$, as is proved by the increase of density. The numerous experiments of Bladh of Sweden proved that the specific gravity of the waters of the Atlantic on both sides of the equator increase as they recede from the poles. This table was republished by Kirwan in the Geological Essays, with a reduction of the specific gravity to temperature 62° Fahrenheit. The longitudes of Bladh are from the meridian of Teneriffe.

Latitude.		Longitude.		Sp. Gr. at 68°.	Sp. Gr. at 62°.

Dr Traill has published the results of some experiments on water taken up in different parts of the Atlantic, from 53° to 6° N., which also show a progressive increase in the specific gravity of the ocean towards the equator, and likewise as the depth increases.

Lat. 47° 47′ N.	Long. 10° 40′ W.	surface	1·0277
Ditto	Ditto	40 fathoms	1·0280
37° 0′	9°	surface	1·0281

8° 20′	56°	surface	1·0267

This last was apparently affected by the waters of the Orinoco, though out of sight of land.

ce.

The phenomena of sea-ice have been admirably described by Scoresby, who divides it into two kinds, *field* and *mountain ice*. Field-ice has a thickness of from two to three or four fathoms. He mentions single fields 100 miles in length and fifty in medial breadth, with a general elevation above the water of from four to six feet. When the ice is of smaller extent it is termed a *floe*. Mr Scoresby found the specific gravity of ice to sea-water to be as 8 to 8·97, or nearly as 8 to 9, so that ice floats in sea-water with $\frac{1}{9}$th above water; and a field which has six feet above water will have forty-eight feet below it, if the ice be of uniform thickness. When a field or floe is exposed to the dashing of the waves, especially to what is called a ground-swell, it is speedily broken up; but the pieces are apt to collect into what is termed a *pack*, when from the mast-head no opening can be discovered in it. In smaller collections it forms *patches*. The ice is *loose* or *open* when ships can pass between the fragments of floes or packs. By the collision of pieces of ice, the fragments are often heaped on the larger portions, and form *hummocks*, which are thus sometimes raised thirty feet above the general level of the ice. Some ocean-ice is whitish and porous. This affords only a brackish water; for though freezing separates the salt from the ice, the salt water is retained in its pores, and the water yielded is not potable; but ice which looks blackish whilst swimming has a solid consistence, a beautiful beryl-green hue in the air, and when melted affords a potable water, a fact of great importance to navigators in high latitudes. Sea-ice assumes different appearances, according as it is formed in smooth or in rough water. The first process in freezing is the formation of minute prisms; when these form in smooth water, they speedily unite into sheets of ice, which in twenty-four hours of keen frost will attain a thickness of two or three inches, and in forty-eight hours will be able to bear the weight of a man. This sort often forms in the interstices of fields, and is termed *bay-ice*. It sometimes increases to three feet in thickness. When the congelation takes place in rougher water, the crystals of ice accumulate, rendering the water sluggish; and this is termed by sailors *sludge*. When the motion of the waves prevents the concretion into larger masses, it forms what sailors term *pancakes*, which generally attain the thickness of a foot. Both these sorts of ice are termed *young ice*, to distinguish them from the more solid *field-ice*. They often rapidly form around ships engaged in the whale fishery, till no open water can be seen from the mast-head; and they often disappear, from the effects of gales or currents, with an almost magical celerity. The heaviest ice is liable to disruption by the waves, especially when detached from the shores, and when the fields are carried by currents into the open sea. Through the openings thus produced, Scoresby penetrated in one voyage as far north as 81° 30′ N. between Spitzbergen and Greenland; and at another time reached the long-lost eastern coast of Greenland, which he surveyed to the extent of 800 miles. The drifting of fields of ice is a proof of the existence of currents from the circumpolar regions. Scoresby mentions that he has seen a field drift 100 miles to the south in a month, although the wind had been very variable during that time. When ice-fields drift they often acquire a rotatory motion, which brings them into collision with other fields; the crushing of the weaker ice is attended with an awful noise; and the utmost presence of mind in the mariner is often required to extricate his vessel from the encounter of such irresistible forces. *Mountain-ice* or *Iceberg* is the term applied to those enormous masses of ice that are more common in Baffin's Bay than in any other part of the northern seas, and are also very frequent in the Great Southern Ocean. It is now generally believed that they are glaciers originally formed on the cliffs of lofty islands or in abrupt valleys, where their lower part being undermined by the waves, in process of time they thus become detached from the land, and float about, as impelled by currents. Some of the icebergs seen in Davis' Straits have an area of five or six square miles, rise 100 feet above the surface, and are aground in water of 100 fathoms; from which data we calculate, that such enormous masses weigh more than two thousand millions of tons. Icebergs assume most fantastic shapes, as may be seen in Captain Ross's and Captain Parry's Voyages. Large icebergs can only be produced where there is deep water close to the cliffs on which they are formed; and this is probably the reason why they abound in Davis' Straits. In the Southern Ocean icebergs have been said occasionally to be 200 feet above the surface, and Forster describes them as composed of layers of different coloured ice. It is dangerous to approach some icebergs, still more to make fast to them; for sometimes they suddenly split into a thousand pieces, with a thundering explosion, as if they were of unannealed glass; at other times they suddenly lose their equilibrium, and are overturned by the wasting of the submerged parts, whilst the upper portion has lost little of its weight. Icebergs have been wafted by currents and storms far from their native seats. Occasionally they have been encountered in the Atlantic, in latitude 40° north; but in the southern hemisphere they have been frequently seen as low as 35°. The *Ice-blink* is one of those singular effects of extraordinary refraction, by which the existence of open water is often recognised, though it really be beyond the limits of direct vision.[1]

Ice-blink.

The polar ices appear to be subject to periodical increase and diminution, depending on causes not yet perfectly understood. One of the last and most remarkable disruptions of the arctic ice is that described by Scoresby. That able philosopher has traced the usual boundary of the firm ice in close and open seasons; and during one of those periodical disruptions, in which more than two thousand square leagues of ice had broken up, he was enabled to penetrate through the boundary, which had seemingly remained undisturbed for four centuries. Large, however, as this quantity disrupted seems, it is a very small part of the whole polar ices. Leslie computed that a total eclipse of the sun for a single hour deprives our planet of as much heat as would be capable of melting a circle of ice 500 miles in diameter and 150 feet in thickness, which he estimates to be sixty times the extent of what is annually melted in the Greenland Seas; yet the effect of a total eclipse of the sun does not cool the atmosphere more than 3° of the thermometer. We cannot, then, ascribe any important influence on our climate to the melting of this portion of the polar ices.

Inland seas.
Baltic.

2. INLAND SEAS.—A few of the inland seas yet remain to be noticed. We begin with the *Baltic*. This sea differs from the arms of the ocean already mentioned, by its comparative freshness, by its want of tides, and by its sending a current continually into the German Sea. Its freshness arises from the number and size of the rivers it receives, in proportion to its extent. It is a narrow, irregular sea, the extreme length of which is about 1200 miles, with a mean breadth of about 140 miles. This will not give an area of 70,000 square miles, and its mean depth is only about sixty fathoms. Yet it receives forty considerable rivers, and the waters of innumerable lakes, which are the drainage of a country five times as extensive as its whole surface. The immense influx of fresh water into such a small basin, from which evaporation is but slow for a large portion of the year, sufficiently accounts both for its deficiency of salt and for the out-going current. The want of regular tides in the Baltic is a consequence of the same causes that operate in all confined collections of water having narrow communications with the ocean, viz. that the moon must act almost equally on all parts of its surface at the same time, and the oceanic tidal-wave, obstructed by the sinuosities of the narrow channel, only penetrates a little way into the three passages which lead into the Baltic.

Mediterranean.

The *Mediterranean* is the noblest and most remarkable inland sea on the face of our earth. A strong current is perpetually setting into the Mediterranean through the Straits of Gibraltar, especially in the centre; and although there be an eddy on each side, this reflux is far inferior to the quantity flowing in from the Atlantic. This inland sea, which is 2350 miles in length, with a breadth varying from 100 to 650 miles, covers an area of about 1,000,000 of square miles. Its depth is much more considerable near the Straits than that of the adjacent Atlantic. The fine hydrographical chart of Don Vincente Tofiño de San Miguel, republished in this country with additions by Captain W. H. Smyth, R. N., shows, that from the longitude of Cape Trafalgar, where the Atlantic is from fifty to sixty fathoms, the channel deepens as we proceed upwards, until, a little within Gibraltar, it is a thousand fathoms deep, and soon after is beyond soundings. It is also very deep towards its eastern extremity. Between Sicily and Africa its depth varies from a hundred to thirty fathoms; so that there exists in that part of the sea a submarine chain or shoal, which may be considered as an extension of the rock-formations of Italy and Sicily, with deep water on either hand. Besides the perpetual current from the Atlantic, it receives the surplus waters of the Euxine, by the constant stream passing through the strait of the Dardanelles. These immense additions appear necessary to supply the enormous evaporation from its surface. It has been remarked, that the rivers which fall into it are the contributions of a smaller extent of territory than the river-domain of any other inland sea, in proportion to its area; for they are to each other rather less than one and a half to one. Some have contended that there is a current below that setting in from the Atlantic. The only fact offered in proof is stated to have happened in 1712. A Dutch merchantman, laden with wine and brandy, was sunk by a broadside from a French privateer in mid-channel, and a few days afterwards the ship and cargo were cast on shore near Cape Spartel, twelve miles below where the accident happened; but the nature of the cargo probably prevented the complete sinking of the vessel, and she may have drifted within the range of the outgoing current on the African shore. The eastward slope of the bottom of the strait would certainly favour the ingress of the cooler waters of the Atlantic into the Mediterranean, and afford an argument against the existence of this alleged under-current.

There is, however, no need of the hypothesis of a counter-current to explain the preservation of the level of this sea, notwithstanding that it receives several large rivers, and a perpetual supply from the Euxine and the ocean; since Dr Halley has shown, that the amount of evaporation from its extensive surface, in so warm a latitude, is sufficient to preserve its level unchanged.

Tides are but little felt in the Mediterranean. They are only sensible in certain parts of that sea, and seldom rise to six inches above the mean level; but, in the Straits of Messina, the form of the land, and the peculiar set of the currents, give them a more considerable range. These tides, however, are irregular, and are liable to be affected greatly by the direction and force of the winds. The want of considerable tides in the Mediterranean kept the Romans ignorant of the extent of ebbs and floods, and caused them several disasters when they carried their arms to the shores of Western Europe. Even in the time of Tacitus they were imperfectly acquainted with the currents produced by the tides around the northern coasts of Scotland, the difficulty of stemming which the historian ascribes to a "mare pigrum, remigantibus infestissimum."

That large inland sea the *Euxine*, with its branch the Sea of Azof, has somewhat of the characters of the North American lakes in its comparative freshness, which is one cause of the duration of ice on waters that have the same latitude as the finest regions of Italy and France. The surface of the Euxine and the Sea of Azof is estimated as equal to 170,000 square miles; but as they receive some of the largest rivers in Europe, and smaller streams from Asia, the drainage of an extent of country equal to five times their own surface, we see a strong reason why there should be a constant efflux through the Bosporus. This current in the Thracian Bosporus has generally a velocity of from three to five miles an hour, according to the direction and force of the wind. Before this outlet was formed, the Euxine probably united with the Caspian, and constituted an hyperborean sea on the plains of Russia, and the provinces on the Lower Danube; and most probably the floods of Deucalion and Ogyges were connected with *débacles* arising from disruptions of the barrier of this sea.

---

[1] Scoresby's Arctic Regions, and Ross's and Parry's Voyages

ian.

According to Pallas, there are traces of the former union of the *Caspian* with the Euxine, in the saline marshy ground and numerous lakes which intersperse the flat countries of Ulagann-Ternik, Alabuga, and Byeloe. The present Caspian is below the level of the Euxine. From barometrical measurements, Parrot stated its surface to be 300 feet below the level of that sea; but the recent trigonometrical levelling of Fuss, Sabler, and Sawitch, which has been conducted with the utmost care, reduces this depression to 101·2 feet. Its length is about 700 miles, and its breadth about 210, which would give it an area of 147,000 square miles. It has a very unequal bottom. Hanway states, that in some places 450 fathoms of line could not reach the bottom; but in other places it abounds in shallows, which render its navigation perilous, independently of the sudden storms to which it is liable. It is without tides; but its shores are subject to irregular floods, from the size and number of its rivers, and the direction of the winds. It is extremely salt, and abounds with fish; amongst which the most important is the isinglass sturgeon, and the sterlet (*Accipenser huso*, and *A. Ruthenus*). Several species of *Salmo* and *Cyprinus*, and a species of herring, are numerous; and there are extensive fisheries of several kinds of seals. How seals found their way into this inland sea, unless at one time it communicated with the ocean, we cannot easily explain.

A

The *Sea of Aral* seems once to have communicated with the Caspian, from the similarity of their fishes, and the numerous salt lakes and marshes that still crowd the intervening space, especially towards the northern extremity. The Sea of Aral is 200 miles by 100, and therefore has an area of about 20,000 square miles. It is extremely salt, though it receives several very large rivers, particularly the Sihon and Gihon, the ancient Jaxartes and Oxus.

B

The inland sea or lake called *Baikal* differs from those already mentioned in being perfectly fresh. Its length is 360 miles, and its breadth forty; so that its area is about 14,400 square miles, including the islands which it contains. This lake or sea is remarkable for its green tint, and the very great inequalities of its bottom. In some parts its depth is asserted to be more than 3000 feet, but then the water suddenly shoals to 150 feet. Considering the mass of water it receives from the rivers Bargazin, Selinga, Angara, and many less considerable tributaries, and that its only visible outlet is the Lower Angara, which is not capable of discharging above a tenth of the water poured into this sea, it is conceived by some geographers, that evaporation, in a climate where the whole surface is annually frozen for five months, could not carry off the surplus, and that therefore the Baikal must have some secret outlet, by which its superfluous waters may reach the ocean. The same difficulty occurs here as with the Caspian and the Aral. How could the seals which it contains have been introduced? They are extremely numerous in its northern part, and as many as two thousand have been killed in one year. Of the fishes, the *omul*, or *Salmo migratorius*, is the most important in an economical point of view; but it also contains *S. salvelinus*, *S. oxyrhinchus*, the carp, the tench, the sterlet, and the isinglass sturgeon. One fish is peculiar to this sea, *Calyonymus Baikalensis*, which occurs in such quantities as to corrupt the air by its putrefaction on the shores after storms, to which this sea is very liable. There are many appearances of volcanic fire in the vicinity of the Baikal. It is probable that the surface of the waters of this inland sea once stood on a higher level than at present, and that thus the salmon and the seal might have been able to surmount the rapids of the Yenisei, or have found their way into the Baikal by the channel of the Lena.

Red Sea.

The *Red Sea* is the only other Asiatic sea which we shall here notice particularly. It is a long arm of the ocean, extending between Asia and Africa for nearly 1500 miles, whilst its medial breadth is not above 100 miles. Until Lord Valentia's voyage, our charts of this sea were very imperfect, and much still remains to be done; but his lordship has established the important point of the superior depth of the western side, although the general depth is inconsiderable. These peculiarities of its form give it more the character of a river than of an arm of the ocean; a circumstance which, with the position of its strait in the direction of the tidal wave from the Arabian Sea, makes it subject to very considerable tides, especially in its lower part; whilst their rise is not prevented by the influx of any river. The less powerful influence of shape, and the influx of the united streams of the Euphrates and Tigris, tend to diminish the height of the tides in the *Persian Gulf*, another inland sea, about half the length of the Red Sea.

Tchad.

The *Tchad*, an inland sea of fresh water, is one of the most considerable of the kind in the world; and constitutes that *Bahr el Soudan*, so long considered as the common receptacle of the rivers of Central Africa. The discoveries of Denham and Clapperton prove that it is one of the grandest features in the kingdom of Bornou. It seems to be not less than 200 miles in length by 150 in breadth; but in the rainy season it becomes greatly enlarged, and encroaches on its flat shores. It is principally fed by the rivers Shary and Yeou. The former flows from the south into the lake, and is a noble, rapid river, half a mile in width. The latter, once supposed to be the Niger, comes from the west, but is not considerable.

Mexican Gulf.

We have already noticed the general direction of the equinoctial current into the *Gulf of Mexico*, from which it has obtained the name of the *Gulf Stream*. The eddying of this current in the great inland basin, the prevalence of the trade-winds, and the enormous quantity of mud brought down by the Mississippi and the less important tributary streams descending from the Mexican Sierra Madre, are, according to Humboldt, rapidly filling up the gulf. The eastern coast of Mexico, from 18° to 26° north latitude, abounds with bars, over which large vessels cannot pass; and, far inland, that distinguished traveller found banks filled with sea-shells but little changed. Were the Isthmus of Darien annihilated, the equinoctial stream would pass round the globe; and this change would probably, ere long, place the feeble governments of Japan and China at the mercy of some European conqueror.

Hudson's Sea.

Hudson's Sea, improperly called a bay, is during a great part of the year encumbered with ice. This basin is almost three times larger than the Baltic, comprehending an area of about 500,000 square miles. It is inhabited by some kinds of cetacea, especially the Greenland whale and the beluga.

Baffin's Sea.

Baffin's Sea is now found to communicate with the polar sea by several openings. Its extent, if we include Davis's Straits to the latitude of Cape Farewell, is only inferior, as an inland sea, to the Mediterranean. It is locked up for a considerable period of the year in impenetrable ice; but in the summer months the ice is broken up, and partially carried off by a strong current, which is continually setting down through the strait. The centre of that sea, however, is occupied either by a series of rocky islands, or by shoals, on which vast icebergs are perpetually grounded. Its desolate shores have been much frequented by our whale fishers, on account of the multitudes of the *balæna mysticetus* that resort to this inlet.

Buffon has justly termed North America the country of *lakes* or of *fresh-water seas.* Commencing in the north with *Great Bear Lake,* we may trace a connection by means of minor lakes to *Slave Lake,* a vast sea of fresh water, about 200 miles in length and 100 in breadth. This last lake communicates with the Arctic Ocean by Mackenzie's River, and with *Alhabasca Lake* by Slave River. A chain of smaller lakes conducts thence to *Winnipeg,* which is scarcely inferior to Slave Lake in extent of surface. Advancing to the south-east, we arrive at *Lake Superior,* which, with the *Michigan* and the *Huron,* may be considered as forming the great inland sea of Canada. Lake Superior has an extreme length of 380 miles, a breadth of 161, and a circumference of 1525 miles; the coasts are rocky, and its depth, in some points, is 1200 feet, but its mean depth may be about 900 feet; and its surface is 641 feet above the sea. The Huron communicates with the Michigan by a channel four miles in length; it is 250 miles in length, varies from sixty to 180 miles in breadth, and has a circumference of 1100 miles. The Michigan is 262 miles in length by 55 in breadth, and has a circumference of 915 miles. The mean depth of the three lakes is 900 feet, which shows that their bottom is 300 feet below the level of the ocean. Their whole surface is computed at 72,930 square miles. We have already pointed out the danger to the whole valley of the Mississippi, should earthquakes ever burst the rocky barrier at the southern extremity of the Michigan.

Lake Erie is connected with the Huron by a narrow channel, which expands into *Lake St Clair,* and again contracts ere it reaches the lower lake. Erie is 230 miles in length, about sixty in breadth where it is widest, and about thirty-five at the mean. It differs from the upper lakes by its comparative shallowness, the mean depth not exceeding 120 feet. From many observations, it would appear that Lake Erie is rapidly filling up. Long Point, at the Big Creek, is stated to have advanced three miles in three years, in consequence of the *alluvion* carried into the lake by its numerous rivers. The connection of this lake with that of *Ontario* is by the river Niagara. The difference in level between the lakes is 330 feet; and, after the river has passed down twenty-one miles, it suddenly precipitates itself over the celebrated cataracts of Niagara, in a fall with a depth of 160 feet. It then flows for seven miles through a deep rocky chasm to Queenstown, where the country suddenly sinks; and it flows seven miles farther, through a champaign country, to Lake Ontario, another fresh-water sea, 171 miles in length and about sixty in breadth. The lakes above the falls abound with many kinds of fish, as salmon, sturgeons, several species of *cyprinus,* &c. The five last-mentioned seas or lakes are computed to have an area of 70,000 or 80,000 square miles.

Lakes.

3. Lakes.—Several of the large collections of water already mentioned have been considered as *lakes;* but that designation properly belongs to those less considerable bodies of water which we are now to notice. Many lakes are salt; and of such, a considerable number exist in Asia. The most celebrated salt lake in that quarter is the

Dead Sea.

Dead Sea, or Lake Asphaltites. Independently of the account in the sacred Scriptures relating to the destruction of the cities of the plain the site of which is now occupied by this lake, the nature of the surrounding country bears evident traces of the ravages of fire in remote ages. The frowning cliffs on its eastern shore are evidently volcanic, thermal waters occur near them, the country around is often to this day shaken by earthquakes, and asphaltum is yet collected on its shores. Some have supposed it the crater of a volcano. The lake is much more saline than the ocean; and although the waters are limpid, their specific gravity is 1·2110. Mr Gordon attests their great buoyancy, and an analysis of the waters by Dr Marcet shows that they contain one fourth of their weight of salts. An hundred parts of water yielded,

Muriate of lime	3·920
Muriate of magnesia	10·246
Muriate of soda	10·360
Sulphate of lime	0·054
	24·580

This saltness of the Dead Sea is evidently owing to the abundance of salt in its vicinity, which all the streams falling into it perpetually deposit in this lake. Although the waters of the Jordan, the most considerable of these, are nearly tasteless, and do not contain above one three-hundredth of their weight of salts, the latter are of the same kinds as are obtained from the waters of the Dead Sea; and it is easy to imagine how this constant supply of saline matter to a lake of narrow dimensions, without any visible outlet, must produce an accumulation of salt, which cannot pass off by evaporation. On the western shores of this lake are the ruins of considerable edifices, and still more ancient remains are said to be covered by its waters.

Messrs G. Moore and Beek have very lately proved, by the temperature at which water boils, that the surface of the Dead Sea is 500 feet lower than that of the Mediterranean; and the correctness of this estimate they confirmed by the barometrical results of Professor Schubert of Munich, which give 500 feet as the depression of the Lake of Tiberias, and 598 feet as that of the Dead Sea.

Genn a-reth.

The no less celebrated *Lake of Gennesareth,* or *Sea of Tiberias,* is still smaller. According to Ali Bey, it is only seven leagues in length by two in breadth. It is embosomed in lofty mountains of a volcanic character, amongst which Mount Thabor is pre-eminent. Ali Bey considers this lake as the crater of an ancient volcano; and the nature of the rocks around, and the thermal springs of Tiberias, favour the idea of the volcanic nature of the country.

The want of any outlet, and the influx of rivers passing through a very saline soil, are the causes of the saltness of the considerable lakes of *Van* in Armenia, and of *Ourmia* in Persia. The former has a circumference of 168 miles; and its waters, though potable, are brackish. *Ourmia,* or *Ourumea,* is not less than 300 miles in circuit, and is probably the saltest of any known lake. Its waters are stated to contain thirty-two per cent. of salt; and the sinking of the waters, during the dry season of the year, leaves a thick crust of salt on its shores, which at some points extends a considerable distance into the lake. There are many other lakes of considerable size in Central Asia; many of them are salt; but the most singular is that in Thibet, which produces tincal or borax, a substance which is imported in flat prismatic crystals into Europe; where it undergoes purification.

Ame an Lak

Lakes of America.—If North America be the country of lakes, South America is remarkably deficient in them. That of *Titicaca,* in Upper Peru, already noticed, is the only considerable one in the southern division of the new world. It is true, that in the rainy season, the mighty rivers which water the plains of central South America inundate the low country to an immense extent, converting it into seas with a prodigious area, but of small depth; and it appears that inundations of this sort gave rise to the fable of the *Lake of Parima,* or *El Dorado.*

The Mexican lakes are more remarkable for their elevation of 7450 feet above the sea than for their extent. They are essentially saline, being more salt than the Baltic. The specific gravity of the waters of *Tezcuco* is 1·0215, and the impregnation is derived from a soil containing muriate of soda and carbonate of soda. These lakes have diminished since the Spanish conquest, and the capital is no longer in the lake, but connected with it by a canal. The natural decrease of these lakes has been accelerated by the felling of trees, and by a tunnel driven with immense labour through a mountain, to carry off the superfluous water that formerly often flooded part of the city. Between the inland seas of North America and the Icy Ocean there are innumerable lakes; a circumstance in which the northern portion of the new continent resembles the boreal regions of the old. A lake amongst the defiles of the Rocky Mountains, about the fiftieth degree of latitude, we were assured by the late Mr D. Douglas (a botanist, who several times crossed that chain, and was afterwards unfortunately killed by a wild bull in the Sandwich Islands), presents a remarkable peculiarity. From each extremity it discharges a considerable stream, one of which, falling into the Columbia, finds its way to the Pacific, whilst the other forms a branch of the Saskatchewan, and therefore may be said to fall into the Atlantic, through Lake Winnipeg, the inland seas of Canada, and the St Lawrence.

opean s. e of stance.

European Lakes.—Amongst these some of the most celebrated are the *Lakes of Constance* and *Geneva*. The first receives the Rhine, which was fabled to pass through it without mingling with its waters. Like other alpine lakes, it uniformly increases in summer, by the melting of the mountain snows; and its lowest period is in winter, when its sources are locked up in ice. Its length is thirty-five miles, its greatest breadth is eighteen miles, and its mean depth is 600 feet, but in some places it requires a line of 2130 feet to reach the bottom. Its waters thus fill a chasm about 1000 feet below the level of the ocean.

e of eva.

The *Lake of Geneva* has an area less than that of Constance; its extreme length being fifty-four miles, and its greatest width fifteen. Its depth is very variable; in some parts it was found by Deluc to be 960 feet, which shows that its bottom is only 200 feet higher than the level of the Mediterranean. Like the Lake of Constance, it receives a river, the Rhone, at one end, and discharges it at the other extremity, near to which the river precipitates itself into a subterranean channel termed *Perte de Rhone*. The beauty of the banks of this lake, and the prospect of the distant glaciers, have given to it great celebrity. The other Swiss lakes, though eminently beautiful, are not of sufficient importance to be described here.

an

Italian Lakes.—The beautiful scenery on the *Lago di Como* and the *Lago Maggiore* have been the theme of general praise; but some of the smaller Italian lakes, which seem to be the craters of extinct volcanoes, deserve notice. The lakes of *Nemi* and *Averno* are most evidently so; and the poetical representations of the sulphureous exhalations from the latter may possibly have had a real origin in former periods; but now birds rest with impunity on its surface, and fishes inhabit its waters.

sh

British Lakes.—Our lakes are in general of small extent. The lakes of Westmoreland and Cumberland are more remarkable for their picturesque beauty than their size, and appear but as insignificant specks in a map of Europe. A few of the Scottish lakes are on a larger scale. Some of them are remarkable for their depth, and probably on that account *Loch Tay* and *Loch Ness* are never frozen. Loch Ness in some parts is 800 feet deep; so that its bottom is not less than ninety or a hundred feet below the bottom of the deepest part of the German Sea, on the eastern coast of Great Britain. The depth of Loch Tay varies from eighty to 600 feet. *Loch Lomond* is the largest of the Scottish lakes, being thirty miles in length by nine in its widest part, and at its northern extremity it is 600 feet deep. In the terrible earthquake at Lisbon, Loch Lomond repeatedly rose and fell several feet. The same took place in Loch Ness. A huge wave rolled with impetuosity from east to west, and the waters sunk and fell repeatedly in an hour. Loch Tay was remarkably agitated in 1783 and 1784, during the violent earthquakes in Calabria. On 22d September of the latter year, two large waves were observed to rush from each extremity of the lake, and coalesce near its centre, leaving about 100 yards of its banks at the eastern extremity momentarily dry; but the water returned and overflowed its usual boundary. The same appearances were repeated for several successive days with less violence; and the agitations of the loch did not cease till the 15th of October.

The agitation to which some alpine lakes are subject when the air is perfectly calm, in which even whole breakers have been observed, is a very obscure phenomenon. It has been often observed on the lakes in the north-west of England, in the Highlands of Scotland, and in the Lake of Geneva. It may possibly be explained by the compression of air in caverns existing in the adjacent mountains, the roofs of which are on a higher level than the surface, and communicating with the bottom of the lakes. If water much charged with air find its way into such caverns, the air separated may be compressed in their roofs, until its elasticity becoming superior to the pressure of the column of water, forces its way into the lake, and thus gives rise to what in England is termed a *bottom wind*.

Irish lakes.

The Irish lakes of *Killarney* and *Lough Erne* are highly picturesque; but the petrifying qualities of the waters of the more extensive *Lough Neagh*, in Antrim, ought rather to be attributed to the qualities of the soil in its vicinity. We possess specimens from that locality of wood converted into siliceous petrifactions.

Periodic lakes.

Periodic Lakes.—The inundations of rivers may be said to form *periodic lakes*; but there are other instances where the cause is more occult, although the effect be no less conspicuous. The best-known instance of this is the celebrated *Lake of Cirknitz*, in Carolina. It is only about eight miles in length by two in breadth. In the beginning of June its waters disappear through several fissures in its basin, and the peasants immediately begin to cultivate its bottom, or to pasture their herds on the rich herbage which its oozy bed soon produces. The crop is removed, and about the end of September or middle of October the waters return, spouting up through several apertures in the earth with great force. With these waters various species of fish appear; and sometimes is seen amongst them that curious animal, so puzzling to systematic naturalists, the *Anguina Proteus* of Laurenti, the *Syren Anguina* of Shaw. This lake is placed in a valley amongst limestone hills, which are well known to be hollowed out into vast caverns. Of these the most considerable is Mount Javornick. The caves are supposed to be the receptacles of subterranean rivers, which, when augmented by the autumnal rains, overflow into the channel which communicates with the basin of the Cirknitz; and when the sources of these floods fail, the waters retreat to their summer level. Other lakes of a similar kind are said to occur in Dalmatia.

Rivers.

4. Rivers.—The size and course of rivers are chiefly determined by the height and direction of the mountain chains in which they originate. Thus the Rhine, the Danube, and the Rhone, the largest rivers in Europe, take their rise in the Swiss Alps. The great rivers of Asia have their origin in some of its lofty central chains. The northern rivers, the Irtish, Ob, Yenisei, and Lena, may all be traced to the Altai; the Ho-yang-Ho and Yang-tse Kiang of China arise in the mountains forming the eastern abutment of the central table-land of Asia; whilst the southern ramparts of that table-land contain the sources of the great river of Cambodia, the Irawaddy, the Brahmaputra, the Ganges, and the Scind or Indus. In Africa, the Nile has one of its sources in the lofty mountains of Abyssinia, and the other in the more distant central chain; the Niger rises in the western chain, runs eastward, is deflected in the kingdom of Houssa

towards the south and west, and finally pours its waters into the Atlantic in the Gulf of Guinea. In America, the Madalena and Marañon spring directly from the Cordilleras of the Andes, which also contain the principal sources of the Orinoco; whilst the more sluggish streams of the Paraguay and Parana derive their waters from a lower transverse chain, stretching to the coast of Brazil. In North America, the Arkansas, Red River, and Missouri, the great feeders of the Mississippi, spring from the Northern Andes, where also are the sources of the Columbia to the west, and of the Saskatchewan, the principal stream, which, flowing into Lake Winnipeg, becomes thus a part of that vast chain of lakes or seas, the outlet of which is the St Lawrence.

Channels of rivers.

The channels of rivers are partly produced by the action of their own waters; but undoubtedly also by some of the causes which we have indicated as disturbing the original arrangement of the solid materials of the earth. Thus earthquakes have often opened passages for rivers through barriers of rocks and mountain chains. It may be admitted, that the continual action of water will excavate the hardest stone; but the ravines through which rivers flow frequently bear no traces of having been formed by the action of water; and the depth of some channels, compared to the scantiness of the stream, scarcely permits us to ascribe the whole to the excavation produced by the water. Thus, it is impossible to suppose that the small stream of the Lauricocha, in South America, has cut its way through the chain of the Andes, which it traverses in a long mural chasm, only twenty-five fathoms wide, but of astonishing sublimity. In other instances, the bottom of the channel itself is even below the level of the ocean; thus, the bed of the Marañon, above its junction with the Rio Negro, and more than 1000 miles from its embouchure, was found by Condamine to exceed 620 feet; which, by the estimate of Humboldt, is more than 100 feet below the level of the Atlantic. This may be a chasm produced by an earthquake, like that which, in 1752, suddenly opened, and received the whole waters of the Rio del Norte (a river which has a course of 1000 miles), so as to lay dry its channel for a distance of fifty leagues; and it was several weeks before the river assumed its usual level. Sometimes the channel of a river near its mouth is much below that of the adjacent sea. It is so in the Marañon; and the same has also been proved with regard to the Mississippi, which, just above New Orleans, is 153 feet deep, that is, at least fifty feet below the mean depth of that part of the Mexican Gulf. In such circumstances it is obvious, that the lower part of these hollows in river channels must be filled with salt water; which, by its superior gravity, will insinuate itself below the descending current. Indeed this takes place in the mouths of all rivers communicating with the sea by considerable channels of small declivity. Thus the lowest stratum of water at London Bridge, at the highest flood, is salt, though the upper current flowing over this stratum is quite potable. The tides in the Marañon are sensibly felt 600 miles from its mouth; and probably the sea-water forces itself up at least thus far beneath the mighty current of the river.

Rivers occupy the lowest parts of valleys through which they flow, and when they are very large their declivities are generally small. The surface of the Marañon, 3000 miles from the sea, has only an elevation of 1235 English feet, which would give less than five inches per mile for its mean declivity; but, from the point to which the tides of the ocean reach, the declivity is considered as not above 0·2 inch per mile. The Ganges, from Hurdwar, where it issues from the defiles of the Himalaya, has a mean declivity of four inches per mile; that of the Volga is about five inches.

Form on of de a.

The general form of the channels of rivers, however, especially in a champaign country, indicates, that if not wholly formed, they are greatly modified, by the action of their waters. In fact, their beds are usually proportional to the force of the stream. On the banks of many large rivers we can still trace the different heights at which the waters have formerly flowed. Playfair mentions the existence of four or five successive terraces on the Rhine,[1] each of which has evidently been formed in succession by the river; and hence he concludes that the Rhine once flowed 360 feet above its present level. Similar remarks were made on the Upper Rhone by Saussure. The general effect of the action of the water must be the erosion of the channels in the lapse of ages; and even in the rocky beds of rivers this action of water is very perceptible. Thus the waters of the Niagara have apparently worn away the limestone rock of the falls, and formed a deep ravine through the stony bed, six miles in length from Queenstown, where the cliffs terminate abruptly, to the present site of the Falls. The undermining of the cliffs by this stupendous cataract has caused a recession of the Falls equal to about eighteen feet in thirty years; but we cannot thence infer the length of time that this cataract has existed, because we have no certainty of the equability of the disintegration, nor of the other causes which may have aided or facilitated the process. When rivers which have their sources in lofty mountains flow through extensive plains, they are subject to periodical inundations at the rainy season, or when the snows which feed them are melted by the summer heat. Under these circumstances, the swollen river bears along with it mud, sand, and gravel. A portion of these is deposited on the banks of the river, and thus tends to elevate them above the level of the adjacent country; whilst a portion is swept to the sea by the current, and the materials are there collected into sand-banks, or, by the repellent action of the waves, serve to augment the triangular plain often formed at the mouths of rivers, to which the name of *delta* has been applied. This evident and gradual increase of a delta has given rise to the idea of attempting to estimate the antiquity of existing geological arrangements by such a natural chronometer. Thus, if the increase of a delta at the mouth of any river be a certain number of feet in a given time, it has been supposed that we could thence obtain a measure of the age of the whole alluvial land at that point. But for the accuracy of such deductions several data are required. We must ascertain that the supposed delta is really the formation of the river, and that the rate of increase at distant periods is uniform. In every attempt to solve such problems there is danger of mistaking the effects of general for local causes; and there is strong reason to disbelieve the alleged uniformity of the increase of the alluvial soil at the mouths of rivers. The Po, of late years, appears to have gained upon the Adriatic, at the rate of 228 feet per annum, at its two principal embouchures; but had the annual increase always equalled this, the mouth of the Po at the commencement of the Christian era should have been seventy-eight miles from the present shore, or extended beyond Mantua. But towns fifty miles nearer the Adriatic, in the valley of the Po, have existed from before the birth of Christ. The calculations of Volney, on the advance of the delta of the Nile, are founded on very insufficient grounds; and as yet it must be conceded, that we have no determinations of this sort worthy of confidence.

The currents of large rivers may frequently be traced, by their colour, to great distances in the ocean. Thus the Ganges, when in flood, discolours the sea in the Gulf of

---

[1] Works, vol. i.

Bengal to the distance of sixty miles, and its mud covers the bottom at eighty miles from the land. The mud of the Orinoco is carried far into the Atlantic; and on examining water drawn from the sea in latitude 8° 20′ north, that is, in the parallel of the Orinoco, and 200 miles from its embouchure, Traill ascertained that the specific gravity of the water suddenly fell below what it was to the north and to the south of this parallel. The enormous mass of water discharged by the Marañon, according to Sabine, discolours the ocean, and has even considerable rapidity in a direction inclined to that of the equinoctial current, at the distance of 300 miles from the American coast. Fresh water may be obtained from the surface of this current, at a great distance from the shore.

The periodical inundations of rivers depend on great falls of rain in mountainous regions, or on the melting of snows in the neighbourhood of their source. The period depends on the return of these seasons in different places. Within the tropics the rainy season is usually about the time when the sun passes the meridian towards the tropic; and continues until his return to the same place. The floods of the Marañon and La Plata cover a vast extent of unexplored country. The rise of the Orinoco commences in May, its inundation begins in June, and the waters return to their channel in September; from which time they decrease until April of the succeeding year. The inundations of the Lower Mississippi begin in March, are at their height in June, and the river is lowest in October. The waters, at their height, 1000 miles from the sea, attain a rise of fifty feet; at 300 miles, of twenty-five feet; and at 100 miles, of twelve feet. The western bank of the Mississippi forms a vast series of lakes, which are dried up in autumn into arid plains, interspersed with swamps; but the delta below the junction of Red River is a dismal swamp, scarcely elevated above the sea. In the Red River, the Arkansas, and the Lower Mississippi, are found those enormous rafts of drift-wood, formed during the river floods, which sometimes extend for ten or twelve miles in one mass, rise and fall with the stream, yet have a luxuriant vegetation on their summits. The inundations of the Ganges follow a nearly similar course. The waters begin to increase in April, when the rains commence in the mountains in which it has its sources; the rate of its increase is about three inches daily until the month of July, when the rains descend in torrents in the plains. The increase of the river is then more rapid, being about five inches daily; and the country for 100 miles along its banks presents in the end of July the appearance of a vast lake, interspersed with insulated villages and woods. The general height of the inundation-waters in Bengal is about twelve feet, but in some places they have a depth of more than thirty feet. The great river of Ava, the Indus, the Euphrates, and the Tigris, have also their periods of inundation, depending on the circumstances determining the setting in of the rains on the mountains in which they originate.

The inundations of the Nile have long been celebrated. Shortly after the commencement of the rains on the mountains of Abyssinia, in June, the river begins to rise, and attains its greatest height in August. At Cairo the greatest rise is twenty-eight feet; at Rosetta it is no more than four about the middle of August, when the valley of Egypt, with a mean breadth of three or four leagues, and the greatest part of the delta, are covered with one sheet of water. Its increase is irregular; and it decreases gradually until the following May. As soon as the waters are within their usual channel, the soil, moistened and enriched by the sediment deposited from the inundation, is diligently cultivated by the natives.

By such inundations the banks of rivers are usually elevated above the adjacent plains; and when the stream carries down much mud and gravel, the whole bed of the river may become considerably raised above the general level of the country through which it flows. This natural process has been considerably accelerated by art on the Po in Italy. To obviate the evil of sudden overflowings of this river, its channel, and that of the tributary streams, have for many ages been carefully embanked; but the quantity of mud and gravel carried down by its waters is so great, that the bottom of the river is gradually raised, further embankments become necessary, and the repetition of these processes have elevated the whole bed of the river below its junction with the Mincio, until it is now actually thirty feet higher than the general level of the adjacent plains; a circumstance fraught with the utmost danger to the whole country between that point and the sea, should any accident happen to the main embankment.

La colmata.

Where the evil is of less magnitude, the Italian engineers have long followed a remedy, devised, it is said, by Torricelli. When streams bring down much mud, and their channels have been suffered to become elevated above the level of the adjacent plains, the lower ground is subdivided by embanked enclosures; the turbid waters of the river are admitted by flood-gates into the subdivisions, and are there allowed to deposit their sediment. The addition of fertilizing mud thus made, in many situations amounts to four inches in depth by each irrigation, which may be repeated several times in the year. By such means, in five or six years, the soil is raised to a level with the river, and the risk of extensive inundations greatly diminished. The process is termed *la colmata.* It has been very advantageously applied in Tuscany and Lombardy; and if steadily and judiciously directed, under the auspices of a just and vigorous government, might possibly still avert a catastrophe which seems to impend over the districts of the Lower Po.

Rapids and cataracts of Europe;

When river-courses lie amongst mountains, they are subject to sudden breaks, which, according to their depth, give rise either to *rapids* or to *cataracts.* There are many picturesque waterfalls in Scotland, as the Cascade of Fyers and that at Lochleven-head in Inverness-shire, Bruar Cascade in Athole, the Devon Lynn in Clackmannanshire, and the magnificent Falls of the Clyde near Lanark. The most stupendous cascade in Great Britain is the Fall of Glomach, in the district of Applecross, in the parish of Kintail, and county of Ross. At the head of a wild and solitary glen, seven miles from the inn of Shealhouse, the river Girsac is precipitated in one unbroken fall of more than three hundred feet. At the distance of about fifty feet from the bottom, the water impinges on a shelf, whence it falls into a dark pool, amidst naked perpendicular rocks. When the river is in flood, it descends in one unbroken sheet of above 380 feet in height. Wales and Cumberland can boast of many beautiful cascades on a smaller scale, particularly the *Pistil y Cain* and *Pistil y Mouddach,* in Merionethshire. The cataracts of the *Dahl* in Sweden, of the *Staubach* in the Alps, of *Tivoli* and *Terni* in Italy, the less considerable cascades of *Mavraneria,* the far-famed *Styx* of Homer, Hesiod, and Pausanias, in Arcadia, and the Fall of the Rhine at Schauffhausen, are amongst the most celebrated in Europe.

of America;

A cataract may exist in a comparatively flat country, from a sudden sinking in its level. The stupendous cataract of Niagara, in which a large and rapid river, 1650 feet in width, precipitates itself, by two channels, in one vast leap of 160 feet perpendicular, is an instance of such an occurrence. The celebrated cataract of Tequendama, near Bogota, though found by Humboldt to be far less lofty than had been supposed by Bouguer, is still of stupendous height, and one of the most magnificent in the world: a river half the breadth of the Seine at Paris is precipitated into a rocky gulf, at two bounds, to a depth of 540 feet.

of India.

The cataract of the river *Shirawati,* in the Indian province of Canara, exceeds in beauty and sublimity every waterfall which has been hitherto made known in Europe. The country around the village of Haliali, about three miles north-west of the fall, presents the richness of a tropical forest, mingled with cultivation. The traveller comes suddenly on the river. "A few steps more," says Dr Christie, "over huge blocks of granite, bring you to the brink of a fearful chasm, rocky, bare, and black, down into which you look to the depth of a thousand feet." The bed of the river is one fourth of a mile broad, in a direct line; but the edge of the fall is elliptical, with a sweep of about half a mile. This body of water rushes, at first for about three hundred feet, over a slope at an angle of 45°, in a sheet of white foam, and is then precipitated to the depth of eight hundred and fifty feet more, into a black abyss, with a thundering noise. It has therefore a depth of 1150 feet. In the rainy season the river appears to be about thirty feet in depth at the fall; in the dry season it is much lower, and is divided into three cascades of varied beauty and astonishing grandeur; but the smaller streams are almost dissipated in vapour before they reach the bottom. Dr Wilson succeeded in viewing this magnificent cataract from the bed of the river, from which it appears to much advantage.[1]

Number of rivers.

The number of considerable rivers which fall into the sea in different parts of the old continent amounts to 430, and those of the new continent may be estimated at 140, but this seeming disproportion is amply compensated by the vast dimensions of the latter.

Quantity of water they discharge.

Several attempts have been made by philosophers to compute the quantity of water which rivers discharge into the ocean; but it is a problem scarcely admitting of any solution, beyond a probable approximation From the observations of Father Riccioli on the discharge of the river Po, it has been calculated, that the water poured out by all the rivers of the globe is equal to forty-one cubic miles daily, or to 14,965 cubic miles annually. This computation is probably too high. The greatest estimate of the mean annual fall of rain, dew, &c. is not above thirty-four inches for the whole earth; and the superficies of the globe being 196,816,658 square miles, this will afford a mass of water equal to 105,614 cubic miles as the whole that is annually precipitated on the earth. But from this must be deducted all that falls on the ocean, which, if we consider the precipitation in the ratio of their surfaces, will give 38,271 cubic miles as the water that falls on the land. Of this quantity, however, at least two thirds are expended in irrigating the soil or in sustaining vegetable life, and are restored to the atmosphere by the process of evaporation, so that no more than 12,757 cubic miles will become the annual tribute of the rivers of the globe to the ocean. This estimate differs less from that founded on the tables of Cotte than some later speculations on this subject, in which we suspect that the mean annual rain, and the quantity returned by the rivers to the sea, are considerably underrated.

Length of their course.

The length of the course of twenty-two of the principal rivers, and the area of their respective domains or basins, were calculated with much care, and given in a tabular form in the essay on Physical Geography in the last edition of the Encyclopædia Britannica. These elements we here insert, with the addition of a reduction of the proportional lengths into English miles, which has been obtained by multiplying them by 180, the distance between the remotest sources of the Thames and its embouchure at the Nore, that river having been assumed as unity in the first column of the table. The proportion of water discharged by each has been omitted, because the data on which that column was calculated did not seem to be sufficiently established.

Rivers.		Length.	Length in English Miles.	Proportional Magnitude of Basin.	Area of Basin in English Miles.
EUROPE.	Thames	1	180	1	5,500
	Rhine	4½	810	12½	70,000

A diagram exhibiting the lengths of the courses of the principal rivers on the globe will be found in Plate CCCCIX.

Occu-
tion
vers.

We have noticed the usual courses of rivers; but sometimes their streams, after flowing through open channels, are engulfed, and afterwards re-appear at considerable distances from their *occultation.* Limestone districts afford many specimens of this phenomenon. In Derbyshire, the small streams named the Hamps and the Manifold sink into a chasm on a common near Ashburn, and re-appear in Islam grounds, three miles below. The stream which issues from the Cavern of the Peak is believed to be the same which disappears near the road from Chapel-in-Frith to Castleton; and the caves of Weathercote and Yordas in Yorkshire exhibit similar instances. The occultation of the Rhine has great celebrity, and attracts numerous visitors from Geneva. The Guadiana, one of the largest rivers in Spain, disappears near the village of *Castillo de Cervera*, and, after pursuing a subterranean course for twelve or fourteen miles, bursts again into day near the high road to Madrid, between Manzanares and Villaharta, at the spot named *Ojos de Guadiana*, or the Eyes of the Guadiana. No country surpasses Greece in the number of its subterranean streams, the peculiarities of which are often clothed in splendid mythological fictions by her ancient bards. The waters of many valleys in the Peloponnesus have no other outlets than ζερεθρα, or chasms engulfing the streams, which are termed *Katavothra* by the modern Greeks. Such are the outlets of the valleys of Tegea, Mantineia, Asæa, Orchomenus, Alea, Stymphalus, and Peneus. A familiarity with such phenomena, and a poetical temperament, readily led the ancient Greeks to conceive still more distant secret communications; and the imagination which peopled every grove and animated every stream with presiding deities, could easily reconcile itself to the fabled loves of Alpheius and Arethusa, which led the enamoured river-god to pursue his coy nymph, beneath the bed of the ocean, from Greece to the shores of Sicily.

[1] Jameson's Journal, vol. xxiv. for January 1838.

5. Springs.—Springs derive their origin from water raised into the atmosphere by evaporation, falling down in the form of showers or mists on hills, and thence percolating through fissures in rocks, or through porous beds, until they appear at lower points of the earth's surface. Hence springs of any size are rarely found near the summits of mountains. When they occur in such situations, they probably arise from water collected on higher though distant mountains, finding its way, as in the two legs of a siphon, through a fissure open to the air only at its extremities. Springs are most numerous in mountainous districts, because hills readily arrest and condense clouds. The observation of Mr White of Selborne, on the condensation of moisture by a single tree, is a proof of the effect of even small elevations in collecting moisture from the atmosphere. Springs are directed to the surface by the position of the strata or fissures through which they flow. In flat countries, springs sometimes have a long subterranean course, especially when they encounter beds of plastic clay, through which their waters cannot penetrate. Copious perennial springs usually undergo very little alteration in their temperature throughout the year; and therefore very generally indicate the mean temperature of the climate where they occur. But water brought up from considerable depths in the earth, as in those wells which (from having been first introduced in Artois) are termed *Artesian*, has usually a higher degree of heat, which increases with their depth.

A higher temperature than the mean of the latitude is occasionally also observed in large springs, the source of which is perhaps not deep. Professor Traill has stated, that the largest spring in Great Britain, *St Winefrede's Well*, at Holywell, has always a temperature several degrees above the mean heat of our climate, and that at different times he had found it to vary as much as 4° of Fahrenheit. This noble spring may be considered as the bursting out of a subterranean river; for it throws up, it is said, about twenty-one tuns of water per minute, or 30,240 tuns daily. It is worthy of remark, that this spring issues from a hill much disturbed by numerous mineral veins, and probably has its temperature also affected by surface water.

The *Crawley Spring*, from which Edinburgh is supplied with water, though of far inferior size, is yet very remarkable, as it yields 220 cubic feet, or more than a tun, per minute, of the purest water.

The most magnificent spring we have ever beheld is the far-famed *Fountain of Petrarch*, at Vaucluse. It rises within a cavern, at the foot of a vast semicircular precipice of compact limestone terminating a wild valley. In the beginning of autumn, by clambering over a heap of rubbish, the traveller may descend into the cavern, and will find himself on the brink of a gulf of the clearest water, of unfathomable depth, with the deep blue tint of the ocean out of soundings, rising with great force, and an unruffled surface, from the recesses of the mountain. It issues from the cavern through concealed channels, and forms at once the river Sorgue, capable at its very source of moving machinery, and almost immediately navigable for boats. The waters of this extraordinary spring never vary half a degree in temperature. When the melting of snow on the neighbouring Alps increases its sources, the cavern is entirely filled with water, and the stream rushes over the rugged bank at the mouth of the cavern with the tumult of a cascade.

The water of springs always contains air, and some saline ingredients. In good potable water the air usually equals $\frac{1}{24}$th or $\frac{1}{28}$th of its volume; of this one third is atmospheric air, and the rest carbonic acid gas. The saline contents of good spring-water generally vary from $\frac{1}{3000}$th to $\frac{1}{6000}$th of their weight; and such water has a specific gravity of from 1·00016 to 1·00030. Such springs are termed *soft*, and answer well for culinary and other domestic purposes. When the solid ingredients exceed this proportion, the water becomes *hard;* and is less fitted for cooking or dissolving soap, in proportion to the quantity of foreign impregnation it contains. The springs of Upsal, analysed by Bergman, afford a good instance of a very *soft water*. The three purest contained no more than $\frac{1}{3000}$th part of their weight of solid matter, and had a specific gravity of 1·0002. From a *kanne* (about 57,000 grains troy) of the Sandvik spring, he obtained 9·65 of solid contents, in the following proportions:

	Grains.		Grains.
Carbonate of lime	5·5	Muriate of lime	0·5
Muriate of soda	2·25	Sulphate of potassa	0·25
Silica	0·5	Carbonate of soda	0·25

besides four cubic inches of carbonic acid gas, and two cubic inches of oxygen gas.

The same ingredients are found in most potable waters, and many also contain sulphate of lime. The springs which supply Liverpool have a specific gravity of from 1·0026 to 1·0027, and contain $\frac{1}{3840}$ of solid matter. They are rather *hard;* but when the ingredients are in more considerable quantity, the spring becomes a *mineral water*.

Mineral waters.

Mineral springs, besides the substances already indicated, may contain one or more of the following substances: sulphuretted hydrogen, or nitrogen; sulphates of soda, ammonia, magnesia, alumine, iron, copper; nitrates of potassa, lime, and magnesia; muriates of potassa, ammonia, and baryta; more rarely free sulphuric acid, boracic acid, and borate of soda. Muriatic acid uncombined has been detected in the waters of the *Pusambio* in South America, which arise from the volcanic mountains of Purace, and are strongly impregnated with sulphuric and muriatic acids; and in Java sulphuric acid has been discharged by volcanoes in such quantities as to destroy vegetation. Boracic acid is deposited from several of the Tuscan springs, especially from the thermal waters of *Sasso*. The borate of soda is found in some of the lakes of Persia and Thibet. *Mineral waters* may be, 1. acidulous; 2. chalybeate; 3. sulphureous; or, 4. saline. The first generally owe their sparkling appearance and acid qualities to carbonic acid. The second contain either the carbonate or the sulphate of iron. The third owe their fetid smell to sulphuretted hydrogen, or to sulphurets of lime, or of some other alkaline substance. The fourth contain a notable portion of neutral salts, from which they have a disagreeable taste, and are hard waters.

Acidulous and chalybeate:

The acidulous waters almost always contain some alkaline or earthy salt. Such are the waters of Tunbridge, Spa, Pyrmont, Seltzer, and others. The chalybeates generally contain from one to two and a half grains of oxide of iron, or some salts, in each English pint, often combined with other salts. Of this kind are the British springs of Peterhead, Brighton, and the chalybeate sources of Harrowgate and Cheltenham, which last, however, are much mixed with other saline ingredients. These vary from 1·0007 to 1·0010 in specific gravity.

Sulphureous waters:

Our sulphureous waters are potent, and owe their qualities to sulphuretted hydrogen. The principal are, Strathpeffer, near Dingwall; St Bernard's Well, at Edinburgh; Hartwell, near Moffat; Harrowgate, Leamington, and a less known well at Kilburne, near London. Their specific gravity ranges from 1·0042 to 1·0132, especially of those which, like Harrowgate and Leamington, contain much saline matter. Moffat spring contains very little saline impregnation, and its sulphuretted hydrogen amounts to 1·20 cubic inch in each English pint. The old well at Harrowgate contains much saline matter, and 1·75 cubic inch of that gas in the same quantity of water. The thermal waters of Aix-la-Chapelle are very strongly impregnated; containing no less than 5·5 cubic inches of sulphuretted hydrogen.

Saline waters.

Saline mineral waters contain a notable quantity of some of the salts already indicated as found in springs. The most noted in Great Britain are the waters of Dumblane, Pitcaithly, Cheltenham, and Leamington. Their specific gravity varies from 1·0047 to 1·0119. The waters of the two last contain respectively 80·5 and 110·38 grains of salts in each English pint. All these mineral springs are reputed remedies for various diseases, but are evidently unfit for culinary purposes. The source of their peculiar impregnations is the mineral beds through which they flow.

Thermal springs.

Thermal Springs.—The heat of thermal waters has been ascribed, by Hutton, Laplace, and Bischoff, to the agency of a central heat, which is conceived to exist in the bowels of the earth. Some indeed have supposed that their temperature may be derived from the mutual chemical action of local accumulations of certain substances at more moderate depths in the earth. But the long-continued uniformity of their heat has given rise to a modification of this doctrine, which is ably supported by Dr Daubeny. He considers thermal springs as deriving their temperature from the same source as volcanoes, viz. the infiltration of water through the external crust of the earth, to the regions where he conceives the metallic elements of earthy and alkaline bodies to exist. The intense heat extricated during the oxidation of these elements will convert a portion of the water into steam, which, under compression, will attain a high temperature, act on various earthy matters, and communicate its heat to the subterranean waters which issue in thermal springs. The position of such springs in the vicinity of disturbances or upheavings of strata by ignigenous rocks, seems to favour this idea. Whatever may be the cause, we can now no longer doubt that there is within the earth a source of heat, the effect of which is perceived in the increased temperature as we descend in deep mines, and in the distances to which the effects of volcanoes are known to be propagated. The hypothesis of a central heat, unconnected with chemical changes, has been strongly insisted on, from the uniformity of the increments of temperature with the depth of borings for Artesian wells; and the result would lead to the conclusion, that the heat of the earth augments, at an average, one degree of Fahrenheit for every 100 feet of perpendicular depth; so that at the depth of three miles water would be boiling hot. But if we adopt the views of Daubeny, the temperature of particular springs will depend on the variable profundity of the unoxidized materials of the globe, and the supply of water. The temperature of thermal waters seems to be liable to little change in each spring; but in different waters it occurs in every degree, from a temperature very little exceeding the mean of the place, to the boiling point of water.

Table of the Temperature of some Thermal Springs.

Matlock	66°	Vichy, France	113°

Balkan, Turkey	163		

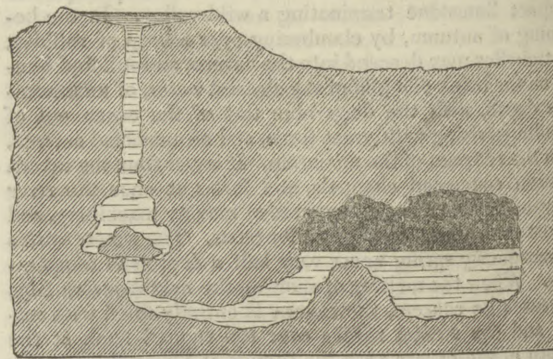
Geysers.

Iceland abounds with boiling springs, some of which are remarkable for their issuing out of a small mass of rock in the midst of a large river, as that figured by Sir George Mackenzie in the *Reikiadalsaa;* others are celebrated for their intermissions and magnificent jets of boiling water, as the *Geysers.* These fountains are well known by the writings of Von Troil, Stanley, Mackenzie, Hooker, Henderson, and by two Danish publications, the first by Olafsen and Povelsen, the latter by Ohlsen. The two principal of these singular fountains are in a valley near Haukadal, about sixteen miles from Skalholt, the bottom of which contains numerous cavities filled with hot water. In the midst of a little mount formed by siliceous deposits from its waters, six or seven feet in height, opens a circular basin fifty-six feet in diameter in one direction, and forty-six in the other. The depth of this basin is three feet; but in its bottom is a round hole about ten feet wide, the termination of a pipe or fissure which sinks into the earth to the depth of seventy-eight feet. By this pipe the water occasionally retires, leaving the basin quite dry, and no steam is then perceived to issue from the pipe. Periodically the water begins to rise in the pipe, and again fills the basin to overflowing; the ground is shaken by hollow subterraneous explosions; suddenly a prodigious column of boiling water is shot into the air with astonishing violence, and clouds of steam obscure the atmosphere. This is followed by successive jets, sometimes to the number of sixteen or eighteen in five minutes, the last of which is generally the most energetic, and attains an altitude of from 90 to 100 feet. On a second visit to the Great Geyser in 1815, Mr Henderson saw it rise to the height of 150 feet; and Lieutenant Ohlsen says that in 1804 he took the altitude of one eruption with a quadrant, and ascertained it to be 212 feet. These efforts are attended with a loud noise, and the ground trembles beneath the feet, whilst the velocity with which the jets and the accompanying steam are hurled into the air is astonishingly sublime. When stones are thrown into the pipe, they remain there until the succeeding jet projects them with great violence into the air, and they may be seen descending amid showers of boiling water. The intermissions of this extraordinary fountain are not absolutely regular; but there are generally four great series of eruptions from its orifice in twenty-four hours.

The jets from the *Strokr*, or *New Geyser* of Stanley, though smaller in diameter, are scarcely less magnificent; and, taking place more frequently, and with surprising violence, afford a high gratification to the traveller.

The mechanism of these Geysers must be simple, to have lasted for many ages. They are mentioned by Saxo in his History of Denmark; and this shows that some of them have existed for about 600 years. It is not easy to imagine an application and removal of a heating cause within the earth in such short intervals; but an arrangement somewhat resembling that represented in No. 13 would be capable of producing a Geyser. A cavity similar to that supposed by Mackenzie or by Lyell, in which water performs the office of a valve, from the form of the lower part of the canal communicating with the surface, might suffice; or its

No. 13.



effect might be increased by a simple valve formed by a mass of stone accidentally getting into the position represented in the figure. Indeed, an experiment of Mr Henderson on the *Strockr* proves the dependence of the force of its jets on some such mechanical obstruction. That gentleman found that the eruptions were accelerated by throwing a quantity of stones into the pipe, and the violence of the succeeding jets seemed to be in proportion to the load so applied; just as loading the valve of a steam-boiler will increase the elasticity of the steam. Henderson asserts that he was thus able to double the effect of the fountain, and to make it project the water to a height of 200 feet. The steam is no doubt produced by the agency of that volcanic fire which everywhere pervades Iceland, and is evidently in great activity under this secluded valley.

If the cavern in the imaginary section, No. 13, be supplied with water from a subterranean source, whilst steam is introduced into it from some more distant volcanic focus, the fountain will remain quiescent until the accumulation of steam, and the pressure of the vertical column of water, aided by the rude valve of rock, will augment its elasticity, until it become sufficient to overcome the resistance, and to project the water remaining in the pipe into the atmosphere.

The Geysers are not confined to the valley near Haukadal; several on a smaller scale exist at Reykum, issuing, at intervals of about an hour and a half, from a bank of hot sulphureous clay.

The waters of the Great Geyser hold a notable proportion of silex in solution, which no doubt is owing to their alkaline impregnation, and their high temperature. According to the analysis of Dr Black, in the Edinburgh Philosophical Transactions, vol. iii., an English gallon contains—

	Gr.		Gr.
Silex	31·58	Argil	2·80
Muriate of soda	14·42	And a little sulphuretted hydrogene.	
Sulphate of soda	8·57		
Caustic soda	5·56		

The silex is deposited in beautiful stalactitic forms in many of the adjacent pools, and the Geysers petrify plants, like other petrifying waters.

In mit- tin rings.

Cold intermitting springs have been well described by the late Mr Gough of Kendal, who divides them into two kinds; *reciprocating*, or such as have a constant but irregular flow; and true *intermitting* springs, in which the issue is entirely suspended for a time, and the water returns at intervals of greater or less regularity.[1] Of the former sort we have a good example in *Giggleswick Well*, in Yorkshire, in which the reciprocations are well marked. In it the water will sometimes rise and fall a foot in ten or fifteen minutes; at other times it will fall as much in four minutes, but usually requires double that time to regain its former height. The water bubbles out with force, so as to carry with it particles of sand. Another reciprocating well occurs near Torbay, called *Lay-well*. It is described, in an early volume of the London Philosophical Transactions, as ebbing and flowing sixteen times in an hour. A similar well, but on a far less scale, is St Anthony's Well on Arthur Seat. The cause seems to be in both instances the confinement and compression of air in tortuous cavities within the subterranean channel of the spring, which, from the position of the aperture, is alternately compressed by the accumulating fluid, until it acquire sufficient elasticity to drive before it the resisting column of water. It is easy to conceive a simple mechanism capable of this alternation, without any species of valve, except that formed by the water itself, which may be represented by the diagram No. 13, without its valve. Of the perfectly *intermitting spring* the most remarkable is the *Bolder-Born*, in Westphalia, near Paderborn. After flowing for twenty-four hours, it entirely ceases for the space of six hours; it then returns with a loud noise, and mixed with air, in a stream sufficiently powerful to turn three mills very near its source. In Lowthorpe's Abridgment of the Philosophical Transactions (vol. ii.), it is said to disappear *twice in twenty-four hours;* and possibly its intermissions are not regular, but may depend upon the quantity of rain which has recently fallen. Dr Boué has described a powerful intermitting spring which occurs at Bihar, in the commune of Maybugyer, in Hungary. It issues, many times a day, from the foot of a mountain, after hollow subterranean noises, in such quantity as in two minutes to fill the channel of a considerable stream. Its returns are most frequent from Christmas to Midsummer, when they take place every quarter of an hour; but they are rarer during the other half of the year.[2]

The most probable manner in which such powerful effects are produced, seems to be the descent of streams of water, much mixed with air, into a cavern, the more direct communication of which with the surface is through a channel so connected with the cavern as to confine the air in its upper part, in the manner of a *water-blast*, until the increasing elasticity, from compression, enables the imprisoned air to dislodge the water accumulated between it and the outlet.

Sect. VII.—*The Atmosphere.*

Atmosphere.

The earth is surrounded by an invisible and highly elastic fluid, termed its *atmosphere*, which accompanies it in all its movements; being retained by the influence of gravitation toward the earth, though, from the repulsion between its own particles, it extends to a considerable distance from the surface. Its density diminishes as it recedes from the earth, and its expansibility is in the inverse ratio of the force by which it is compressed. Its density is farther affected by the influence of heat and cold, by the admixture of watery vapour it contains, by the decreasing force of terrestrial gravitation, and the increasing attraction of the heavenly bodies as its distance from the surface of the earth is augmented. Experiment and calculation have proved that the rate of diminution is such, that the atmosphere at the height of seven miles would only have a density $\frac{1}{4}$th of what it has at the surface; and that if the altitudes be taken in an arithmetical series, the decrease in density will follow a geometrical ratio. Thus, if the density at the surface be assumed as unity, at seven miles it will be $\frac{1}{4}$th, at fourteen miles it will be $\frac{1}{16}$th, at twenty-one miles it will be $\frac{1}{64}$th, and so on. This property of the air would lead to the idea of an indefinite extension of the atmosphere; but there is evidently a limit to this, probably arising from the gravitation of the particles of air; and the nicest observations on the duration of twilight, as well as some other phenomena in astronomy, almost warrant the inference, that the utmost limit of the atmosphere cannot exceed forty-five miles in altitude. See the article Atmosphere.

Its weight.

Air is ponderable; 100 cubic inches of air at the temperature 60° Fahrenheit weigh 30·5 grains troy, at a mean barometrical pressure; and a perpendicular column of the whole atmosphere is just balanced by a mercurial column of about thirty inches in height. Hence the length of such a column is employed to ascertain the weight or pressure of the atmosphere; and the oscillations of the *barometer* have taught us, that this pressure varies in different stations on the earth's surface, and in the same place at different times. See the articles Barometer, Atmosphere, and Meteorology.

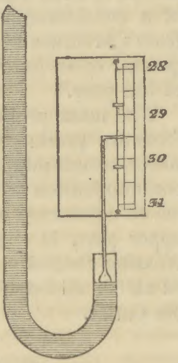
Register barometers.

The height of the barometer forms an important part of a meteorological journal. Observation has made us acquainted, not only with the occasional, but also with the diurnal oscillations of the column; and exhibited the connection of the more considerable variations with changes in the weather. The trouble of continual attention to obtain the mean heights of the barometer at any place, have given rise to several contrivances for registering the maxima and minima during the absence of the observer. A very ingenious instrument for this purpose is described by Mr Keith, in the Philosophical Transactions of Edinburgh (vol. iv.). The open end of the instrument is a larger cylinder than the rest of the tube. The cistern is placed horizontally at the upper part, and an ivory float, supporting a *kneed wire*, is placed on the surface of the fluid, as in No. 14. The scale is above the opening of the tube, and the kneed wire moves two light indices, sliding on a fine wire, with sufficient friction to retain them in the position which they receive from the movements of the ivory float. The same gentleman caused the instrument, by a slight modification, to record the whole course of its observations through a given period. A perpendicular cylinder, divided into thirty-one compartments, is moved round its axis once a month by clock-work; a pencil attached to the float wire records the whole course of the oscillations; and a proper scale, marked on the cylinder, gives the value of the irregular curves thus traced. Once a month the cylinder is covered with a fresh paper, ruled into thirty-one columns, for another monthly series.

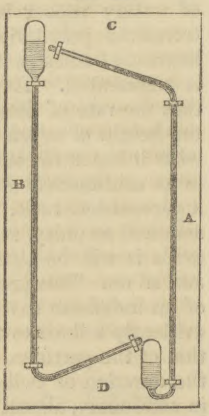
No. 14.



Professor Traill has given a simple and cheap form of a register barometer for maxima and minima.

A diagonal barometer registers the maximum height of the column. Before the tube is bent, a piece of iron wire is introduced into the closed end of the tube, which is then filled in the usual way. The wire being lighter than the mercury, will rise to the top of the column, is pushed before it on the rise of the barometer, and, on the fall, remains, by its own weight, at the point it had attained. A slight modification of Cassini's rectangular barometer marks the minima, by means of a piece of iron wire introduced at the open end of the tube, as in No. 15. To make the indications of both instruments as nearly equal as the construction will allow, the lower part of this tube is bent to less than a right angle.

No. 15.

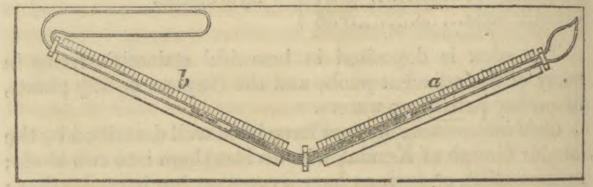


It is obvious that the barometer affords the means of ascertaining the weight of the whole atmosphere. The pressure of the atmosphere varies from twenty-eight to thirty-one inches of the barometric column. A column of pure mercury, whose base is a square inch, and its height the mean between twenty-eight and thirty-one, or 29·5 inches, is found to weigh 14·5 pounds avoirdupois; therefore the pressure of the whole atmosphere will be 14·5 pounds on each square inch of the earth's surface. And as the superficies of our globe is equal to 790,116,426,647,756,800 square inches, if we multiply this number by 14·5, we obtain, as the absolute weight of the whole atmosphere, 11,456,688,186,392,473,600 pounds; or, if we adopt the more common estimate of the mean barometric height at 30 inches, and the weight of that column at 15 pounds on the square inch, this will give 11,851,746,399,716,352,000 pounds, or 5,290,958,214,159,085·7 tons, as the mass of our atmosphere.

The variations of atmospherical temperature are ascertained by the thermometer. (See the articles Meteorology and Thermometer). The instrument, for this purpose, should be placed in the shade, protected against reflected heat, and also against that transmitted through walls, or other bodies to which it is attached. It is by no means easy, in a town, to obtain an eligible position for a measure of atmospheric temperature, on account of the many causes which affect the instrument. It ought to be protected by a glass case against rain; yet the air should circulate freely around it, and it ought to radiate its heat freely to the sky. The importance of obtaining accurate information on changes of the temperature of the atmosphere has given rise to numerous observations on the annual, monthly, daily, and hourly variations of the thermometer.

The labour and minute attention required in such investigations have induced ingenious men to devise methods of ascertaining mean temperatures from a few observations. It has been found that the mean of the thermometer during the month of April will, in our climate, nearly indicate the mean annual temperature; and that the mean of observations made about half past 8 A. M., at 2 P. M., at 9 P. M., and an hour before sunrise, will give the mean temperature of each day. To abridge such fatiguing observations, *register thermometers* have been devised. The best known of these are the thermometers of Six and of Rutherford. (See the article Meteorology, Plate CCCLIV. fig. 6 and 7.) A modification of Six's thermometer, rendering springs to the indices unnecessary, has been constructed by Professor Traill, in which the indices slide in slightly inclined tubes, as will be easily understood from No. 16.

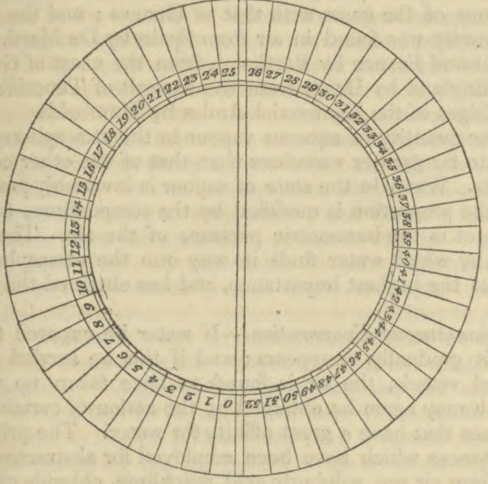
No. 16.



As in Six's thermometer, the expansions of alkohol are the measure of the temperature; the indices, of iron wire, enclosed in glass tubes, are moved by a short column of mercury; and they are adjusted for a fresh observation by bringing them to the extremities of the mercurial column with a magnet.

The atmosphere itself is invisible; but the column of air interposed between the eye and distant objects invests them with an azure hue. This tint depends upon the greater refrangibility of the blue rays of light than of those towards the other end of the spectrum. When a ray of white or undecomposed light enters our atmosphere, the red and yellow rays pass with little deviation from a rectilineal course; but the blue rays are dispersed in the air, and affect the colour of objects beheld through a long column of the atmosphere. As we ascend lofty mountains, the refractive power of the air diminishes with its density, and hence the blue tint is lost in the blackness produced by the want of refraction; until a traveller, on the ridges of the Alps, the Andes, or the Himalaya, will perceive the sky to assume a hue approaching to deep blue or black. Saussure has described this phenomenon, and invented the *Cyanometer*, an instrument for measuring the intensity of the colour of the sky. (See the article Cyanometer.) The form will be best understood from No. 17.

No. 17.



With this instrument Saussure found a numerical value for the colour of the sky at different places. Thus it was at Geneva = 17°, at Chamouni = 19°, on Col du Géant = 31, and on Mont Blanc, at the height of 15,750 feet, it was = 39°. It also showed that the intensity of the colour varied at the same place at different times. The intensity of the colour is greatest at the zenith. It increases towards mid-day, more rapidly on mountains than on plains; and the difference between morning and mid-day is then also greatest; but the whole difference is most considerable in plains.

The following comparative tables of observations on Col du Géant, and at Geneva, illustrate these points. The first column shows the degrees above the horizon, the second the degree of the cyanometer.

Geneva.		Col du Géant.	
1°	4°	5°	16°
10	9	10	18
20	13	20	20·5
30	15	30	29
40	17·5	40	32
50	19	60	34
60	20	60 to zenith	34
60 to zenith	20		

At midnight, on the Col du Géant, the cyanometer indicated 51°.

Some years ago we endeavoured to give greater permanence to the tints by employing thin films of blue glass in constructing a cyanometer. The first degree was formed of a single film enclosed between plates of thin crown glass, and each succeeding degree consisted of an additional film.

To the refractive power of the atmosphere we owe the splendours of sunrise and sunset. When the sun is on the horizon his beams reach the eye through a long column of dense air; the more refrangible rays are dispersed, and the eye receives the red and orange rays undiluted, especially through the serene air of a summer evening. As the brilliant hues of sunset melt away, the blue tone which the atmosphere had acquired by the dispersion of the most refrangible rays, but which was lost in the splendour of sunset, gradually reappears. and, mingling with the ruddy gleam, sheds the purple light of evening on the softened landscape. As the sun descends more below the horizon the purple colour fades away, and gradually gives place to the "faint erroneous ray," that "flings half an image on the strained eye."

Composition of the atmosphere.

Atmospherical air was long considered as a simple substance, one of the elements of other matter; but the discoveries of Black, Cavendish, Priestley, Scheele, and Lavoisier, have proved it to be a compound, of which the principal constituents are oxygene and nitrogene gases, usually estimated at twenty-one volumes of the former to seventy-nine of the latter. Dr Black discovered that the atmosphere always contained carbonic acid, which was found to exist in slightly variable proportions; and it holds water suspended in the state of vapour, in proportions which are still more fluctuating. If we average the two last ingredients, the composition of the atmosphere may be stated as follows:

	Volume.	Weight.
Nitrogene	= 77·50	= 75·55
Oxygene	= 21·00	= 23·32
Carbonic acid	= 0·08	= 0·10
Aqueous vapour	= 1·42	= 1·03

The manner in which these different ingredients are united has given rise to some controversy. The opinion once generally entertained was, that they were united by an affinity between their particles, like that which forms chemical compounds. The celebrated Dr Dalton first suggested the theory, that of the various elastic fluids constituting the atmosphere, the particles of one are neither retractive nor repellent of the particles of another; but that the pressure upon any one particle of such a mixture is entirely derived from particles of the same kind of matter. Each fluid, on this view, is considered as occupying the same space as it would in a vacuum; and each constituent of the atmosphere, under a mean barometrical pressure of thirty inches, as exerting its own separate pressure in the following proportions, depending on its own quantity and specific gravity. Thus, the

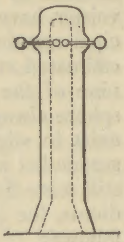
	Inches of Mercury.
Nitrogene would exert a pressure	= 23·36
Oxygene	= 6·18
Carbonic acid	= 0·02
Aqueous vapour	= 0·44
	30·00[1]

Eudiometers.

Soon after the composition of the atmosphere was detected, and the qualities of oxygene in supporting combustion and respiration were understood, it was conceived that important modifications of disease might depend on or originate in the varying proportions of this essential ingredient in the air; and various methods were devised for analysing atmospheric air, and ascertaining the quantity of oxygene it contained. 1. Dr Priestley devised a method of doing this by the *eudiometer*, or measure of the purity of the air. His method consisted in adding, in a graduated tube, fifty-five volumes of nitric gas to a hundred of atmospheric air. The property of this gas is to abstract oxygene from the air, and to form nitrous acid, which is absorbed by water; and the amount of the diminution marked the quantity of oxygene in the air. 2. Gay-Lussac improved Priestley's eudiometer. Instead of adding the nitric gas in the graduated tube, he mixed a hundred volumes of the gas with as much of the air to be analysed, in a wide jar, and transferred this mixture to the graduated tube to ascertain the diminution; on dividing the residual air by four, he obtained the amount of the oxygene present in the air. 3. Scheele employed the sulphuret of potassa for the same purpose. 4. Seguin used the rapid combustion of phosphorus; and, 5. Volta exploded a mixture of hydrogene and air by means of an electrical spark. This is one of the most elegant and accurate of the eudiometers. He recommends a mixture of 200 volumes of hydrogene with 300 of air. On passing an electric spark through the wires in the top of the jar, the hydrogene is fired, instantly forms water with the oxygene of the included air, and, in ordinary cases, the diminution of volume of the mixture amounts to 195, of which one third is oxygene, or sixty-five parts of oxygene have been lost by 300 of air, or about twenty-one per cent.

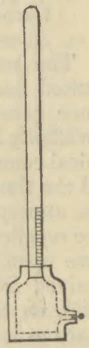
---

[1] Manchester Memoirs, vol. v. See the article ATMOSPHERE.



No. 18.

6. Dr Hope's eudiometer consists of a graduated tube exactly ground to a small tubulated phial. The bottle may be filled, either with hydrosulphuret of potassa, or with a liquid proposed by Davy (which is formed by saturating sulphate of iron in solution with nitric gas.) The air is in the tube, which is inserted in the neck of the phial; the instrument is inverted; the air, now in the phial, is agitated with the liquid for a few minutes, and on opening the tubulature of the phial, below the surface of the liquid, the amount of the oxygene absorbed will be indicated on the graduated tube. This very neat instrument has been modified by Dr Henry, who substituted a bottle of caoutchouc for the phial. Any of these instruments, especially 18 or 19, will show the quantity of oxygene in any given air; but it has been found that the quantity of oxygene of the air is little subject to variation, and that gas is equally present on mountains and in plains, in the town or in the country, except in confined situations, where fuel is burning, or many animals respiring. Air which is very deleterious to man has no sensible difference in the proportion of the oxygene from the purest atmosphere; and we must probably look to other causes than this for the unwholesomeness of the atmosphere.



No. 19.

Carbonic acid in the air.

The quantity of carbonic acid in the atmosphere is subject to slight variation, except in confined apartments. Dr Dalton found it only varying from $\frac{1}{1400}$th to $\frac{1}{1000}$th of the whole air, an uniformity which is surprising, considering how much carbonic acid is constantly formed during respiration and combustion. Perhaps this may be partly owing to our imperfect modes of ascertaining very minute changes in its quantity. If we are to give credit to the experiments of the younger Saussure, the quantity in the atmosphere is greater in summer than in winter, by 2·3 volumes in 10,000; but his experiments are not generally considered as satisfactory, in a case where the difference appears so great, and the point so difficult of determination. Even the experiments of Dalton are not considered as decisive; for lime-water does not appear to be capable of abstracting all the carbonic acid from air, as was remarked by Cavendish; and philosophers have generally considered the quantity as ranging from $\frac{1}{800}$th to $\frac{1}{1000}$th of the whole atmosphere. In confined apartments, however, the quantity of carbonic acid is sometimes much increased, while the oxygene is consumed in the process of combustion and respiration; and this double vitiation of the air may give rise to fatal consequences, as was too well illustrated in the catastrophe of our unfortunate countrymen in the dungeon of the *Black Hole* in Calcutta in 1756, and in one which happened to persons confined in St Martin's Roundhouse in London in 1742. In the celebrated *Grotta del Cane*, the carbonic acid which issues from crevices in the floor fills the bottom of the cave to the level of the entrance, and then flows out by its superior gravity, so that the upper part is free of the noxious impregnations. A man enters with impunity, because his head is above the stratum of carbonic acid; but the air of the cave is speedily fatal to a dog, because the prone position of his air-passages brings his respiratory organs into contact with the gas. It is remarkable that these gases do not appear to vary considerably in their relative proportions in any part of the accessible atmosphere. Air collected on the summit of Mont Blanc was analysed by the younger Saussure, and agreed in the proportions of the gases with that of Geneva; and the same uniformity was found in air from Spain by De Marti, from Egypt and France by Bertholet, from the coast of Guinea and England by Davy, from the summit of Teneriffe and the ridges of the Equinoxial Andes by Humboldt.

Aque vapou the ai

The quantity of aqueous vapour in the atmosphere is liable to far greater variations than that of the other constituents. Water in the state of vapour is invariably present; but the proportion is modified by the temperature, and by changes in the barometric pressure of the air. The process by which water finds its way into the atmosphere is one of the highest importance, and has obtained the name of

Evapo tion.

Spontaneous Evaporation.—If water be exposed to the air, it gradually disappears; and if this be carried on in closed vessels, the air is found to have taken up water, which may again be obtained by the action of certain substances that have a great affinity for water. The principal substances which have been employed for abstracting water from air are, sulphuric acid, quicklime, chloride of lime, and carbonate of potassa. If given proportions of any of these be enclosed in a vessel containing air, they absorb the moisture of that air; and the weight they thus acquire has been taken as the measure of the quantity of its water. The same is estimated by the quantity of water which is absorbed by a given volume of air thus artificially dried. Some very careful experiments on this subject were made by Saussure, who inferred that a cubic foot of air, at temperature 65° Fahrenheit, when fully saturated with moisture, holds eleven grains of water dissolved. Notwithstanding the acknowledged accuracy and patience of this philosopher, we are inclined to prefer the method of Dr Dalton (founded on the suggestion of Le Roy of Montpellier), of observing the temperature at which moisture begins to be separated from the air. This is termed the *Dew-point* of that atmosphere, and forms an important element in several interesting problems in meteorology. Dalton had shown, that the water existing in the atmosphere has precisely the same elasticity as it would assume in a vacuum at the same temperature; hence it is obvious that it exists in the air, not as water, but as elastic vapour. But the elasticity of vapour is demonstrated to depend on temperature; and, therefore, if we could measure the elasticity, we could determine the quantity of water in the atmosphere. This elasticity is measured by the *Manometer*, a barometer the cistern of which is enclosed in the vessel containing the air, and therefore only affected by the variations of elasticity of the included air. Deductions from these experiments have been given in a tabular form in the Manchester Society's Transactions.

In the article HYGROMETRY there is another table of great value, showing the elasticity, weight, and rate of expansion of aqueous vapour, in air saturated with moisture, at each degree of Fahrenheit's thermometer, from 0° to 100°, which was intended by the author of that treatise to facilitate hygrometrical investigations. In this table the elasticity of the vapour is calculated on a formula deduced by Biot from Dalton's experiments.

The quantity of water suspended in the air is liable to great variation, from several natural causes; and it is chiefly liable to be deposited or separated, on a diminution of the capacity of the air for moisture, by a reduction of its temperature. Warm air is capable of taking up, in the state of invisible vapour, more water than cold air. Thus a cubic foot of saturated air, at 32°, contains of watery vapour 2·350 grains; at 60°, 5·825 grains; at 70°, 7·941 grains. When the temperature of the air is diminished, as, for instance, by mingling with colder currents in the atmosphere, a quantity of water is separated; and, according to the suddenness of the change, will be suspended in the form of visible clouds, or precipitated in fogs or rain.

Changes in the density of the air also affect its capacity for retaining moisture. Evaporation is quicker, everything else remaining unchanged, in rare than in dense air. Saussure found, that water evaporated quicker on the Col du Géant, which is 11,275 feet above the sea, than at Geneva, which is but 1324 feet above that level, in the proportion of eighty-four to thirty-seven. Light air then speedily becomes charged with moisture, which slight changes in temperature are ready to precipitate; and hence a falling barometer is often the immediate precursor of rain.

When atmospheric air approaches its point of saturation with moisture, evaporation goes on slowly, at length ceases, and a slight diminution of temperature is sufficient to precipitate a portion of water on contiguous bodies; we then term the air *damp* or *moist*. This change is not always to be immediately recognised by our sensations; and as the change is important to the success of some processes in the arts, and also to health, philosophers have invented instruments for indicating the approaches of the air to saturation, which have been named

Hygrometers, or measures of moisture. The change in bulk which some vegetable and animal substances undergo, in moist air, has been employed for this purpose. The most common are the twisting and untwisting of a cord of flax or hemp by moisture and dryness; the movements of the natural twist in the beard of the wild oat, *avena fatua;* in the Indian grass, *andropogon contortum*, proposed by Captain Kater; or the arista of the seed of *stipa pennata* (a common inmate of our gardens, and often found in our fields), proposed by Dr Cumming of Denbigh. Unfortunately these substances, though indicating minute changes in the air, are incapable of forming *comparable* hygrometers, and gradually become less and less sensible to the influence of humidity. The same may be said of the animal substances which have been employed in the construction of such instruments. The most simple of the animal hygrometers is Wilson's, formed of a rat's bladder fixed to a glass tube, and filled with mercury to a certain point on the tube when the bladder is moist. As it dries, the contraction of the bladder raises the mercury in the tube. Still more delicate hygrometers were formed by Saussure and De Luc, on nearly the same construction. (See the article HYGROMETRY.) Saussure employed a fine human hair, freed from unctuous matter by boiling in a weak alkaline solution; and De Luc used a slip of whalebone, scraped extremely thin. These animal bodies lengthen by moisture; and, in both instruments, one end of the hygrometric substance was fixed to the frame, while the other was attached to a fine flat wire lapped round an index made to move along a graduated arc by the varying length of the hygrometric substance. In Saussure's instrument, the index was brought back by a small weight as a counterpoise; and the same was effected in De Luc's by a spiral gold-wire spring. Both instruments were graduated by placing them in a jar filled with air saturated with moisture, and then in air dried by quicklime, or some similar body; and the space between these extreme points was divided into 100°, or any given number of degrees.

The imperfection of these instruments, when made by the hands of the inventors with every care, rendered it difficult to have two that gave the same indications under similar circumstances; and the still more fatal objection, that they become altered by time in mobility and delicacy of indication. Although both Gay-Lussac and Biot have endeavoured to show the relation between the indications of the hair hygrometer and the quantity of moisture in the air, we cannot consider the instrument as entitled to confidence.

A very elegant hygrometer was invented by Daniel, founded on the determination of the temperature at which dew begins to be deposited; but for the description of it we must refer to the article HYGROMETRY, as well as for an ingenious substitute devised by Mr Adie of Edinburgh, and another by M. Pouillet. All these depend on the dew-point; and all are liable to the objection, that it is difficult to determine the precise degree at which dew begins to be formed, especially at low temperatures. The original idea of obtaining a measure of the hygrometric state of the air from comparing the indications of a thermometer with its bulb moist and dry, is certainly due to Dr James Hutton, the celebrated geologist. This eminent philosopher made use of a single thermometer, which he carried enclosed in a glass case. This form of hygrometer, neglected for thirty years, has at length become an object of philosophic interest in this country and Germany; and two thermometers are now mounted on the same scale, and the indications of the wet and dry bulbs seen at the same time. This instrument has been termed a *psychrometer*. The most elegant form of an instrument on this principle is the hygrometer of Sir John Leslie, or double air-thermometer; one of the balls is covered with tissue paper, defended by a thin covering of blue silk, while the other is naked; but in order to obviate the effect of light, the dry ball is formed of pale-blue glass. This instrument is described in his original paper, and fully in the article METEOROLOGY of this work. When the covered ball is moistened with water, the evaporation produces a degree of cold in proportion to the dryness of the ambient air; and the air within that ball contracting, the elasticity of the air in the other ball pushes the coloured fluid in the stem towards the covered ball. This transference is marked on a scale, each degree of which is equivalent to $\frac{1}{10}$th of a centigrade thermometrical degree. This hygrometer does not indicate the absolute *dryness* of the atmosphere, but only the degree of dryness it has after being reduced to the temperature of the humid ball. In the article to which we have just referred, there are tables given for correcting the indications of Leslie's hygrometer, and showing the point of saturation at different centesimal degrees, and the corresponding degrees of the hygrometer.

The instrument gives excellent comparative results; and two or three minutes are sufficient to bring the fluid to equilibrium, which marks the full effect of the evaporation; and no farther sinking of the hygrometer is produced by keeping the ball bedewed with moisture. In winter, in our climate, it ranges from 5° to 25°; in our summer from 15° to 55°. It has occasionally been observed as high as 80° or even 90°, and in thick fogs it falls to the beginning of the scale: it rises when the weather clears up after rain, and in long tracts of clear warm weather it remains high. It always falls before rain, and remains low during wet weather. When as low as 15°, the air feels damp; when it is between 30° and 40°, we should term the weather *dry;* from 50° to 60°, *very dry;* and from 70° upwards, it would be called *intensely dry*. In a warm inhabited apartment the hygrometer would not be below 50°; but when below 30°, that room would be felt to be uncomfortably damp.

Annual evaporation.

The mean annual evaporation is an interesting subject, for an approximation to which we are mainly indebted to the experiments of Dr Dalton and Mr Hoyle, at Manchester, in 1796, 1797, and 1798. A cylindrical vessel of tinned iron, three feet deep and ten inches in diameter, was filled with soil; it was provided with one pipe near the bottom, and another one inch from the top. This was left in this state for a year, until it became covered with grass. Bottles were now applied to the end of each pipe, so as to collect both the surplus water which soaked through the earth, and that which ran off at the upper pipe. The soil was soaked with water on commencing the experiment; a rain gage of similar dimensions was placed near the cylinder of tin; and the evaporation was estimated by subtracting the quantity which passed into the bottles from the whole rain.

	1796.	1797.	1798.
Rain	30·629 in.	38·791 in.	31·259 in.
Evaporation	23·725 ...	27·857 ...	23·862 ...

The mean evaporation for each month, deduced from the three years, was

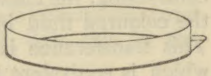
	Inches.		Inches.
January	1·008	July	4·095
February	0·528	August	3·386
March	0·623	September	2·954
April	1·485	October	2·672
May	2·684	November	2·055
June	2·184	December	1·484

giving 25·158 inches for the annual evaporation at Manchester. Dr Dalton considers that we ought to add five inches to this for the annual dew, which will raise the evaporation to about thirty inches.

Evaporator.

From the nature of our climate, the mean annual evaporation over the globe cannot be estimated at less than thirty-four; and this would make the whole mass of water raised from the surface of the earth equal to 105,614·72 cubic miles, or equal to all the rain that falls upon the globe. The evaporation of any place may be ascertained by exposing freely to the air a given quantity of water in a shallow circular dish, accurately turned, so as to have 100 inches of superficies. It should be so placed as not to receive any rain: on measuring the remainder once a week or once a month, we shall obtain the evaporation.

No. 20.



There is reason to believe that the evaporation from the foliage of trees and from herbage is somewhat greater than from an equal area of water, and that the quantity from the surface of new-ploughed land is almost equal to what arises from water; but we have got no good comparative experiments on this subject.

Having considered the conversion of water into an elastic fluid, let us turn our attention to the mode by which it is re-converted into moisture.

Clouds.

1. *Clouds.*—Some have accounted for the suspension of so dense a fluid as water in air, on the supposition that the vapour in clouds existed in the shape of hollow spherules, filled with a lighter fluid than the atmosphere; but this suggestion would seem to be devised rather to meet the difficulty than to be supported by observation; and it is possible to explain the considerable durability of clouds without recourse to any such gratuitous assumption.

The experiments of Volta and Cavallo have shown, that when water is converted into vapour, not only is caloric absorbed, but electricity is also developed. The vapour acquires positive electricity, and the remaining fluid possesses the opposite electric state. By the process of evaporation much electric fluid must be carried into the atmosphere; and when the capacity of the vapour for electricity is diminished by its partial condensation by cold in the upper regions of the air, it may be conceived that the spherules of vapour may become surrounded with atmospheres of electric fluid, the mutual repulsions of which may prevent the coalescing of the particles of vapour into drops so heavy as to descend by their gravity on the earth, especially as a stratum of air charged with moisture is specifically lighter than dry air at the same temperature. The form of clouds, and their different degrees of aggregation, may depend on the electric tension of the atmospheres surrounding the particles of which they are composed; or on a balance between the electric repulsions and the gravitation of the particles for each other. This view is favoured by the generally positively electrified state of the atmosphere when clouds are forming, the heavy falls of rain which accompany electric explosions when the discharge of the accumulated electricity allows the coalescing of the moisture into heavy drops, as well as by the peculiar odour of some kinds of fog, and the highly electric state such fog often exhibits. Beccaria, Romayne, Bennet, and Volta have remarked, that the atmosphere exhibits signs of electricity on the appearance of clouds and fogs. Beccaria always found the electricity of the air *positive;* and Romayne states, that mere diminution of volume in any substance is constantly attended with increased electrical tension. The various forms of clouds, their aggregation in deep masses piled on each other, or their dispersion in long radiated filaments, may be more easily explained on an electric theory than on any other supposition; and the accidental manner in which solar light is reflected from them to the eye of the spectator gives an infinite diversity to their appearance.

For of clou

The vulgar have long remarked the association of certain forms of clouds with the state of the weather; and meteorologists have begun to appreciate the value of a descriptive language for indicating their varied appearances. No system of nomenclature has yet been applied to clouds superior to that proposed by Mr Luke Howard. He divides them into seven species. (See Plate CCCCXI.)

1. *Cirrus.*—A cloud resembling a lock of hair or a feather, composed of parallel, flexuous, or diverging fibres, unlimited in the direction of their increase.

2. *Cumulus.*—A cloud which increases from above, in dense, convex, or conical heaps.

3. *Stratus.*—An extended, continuous, level sheet of cloud, increasing from beneath.

4. *Cirro-Cumulus.*—A connected system of small roundish clouds, placed in close order or contact.

5. *Cirro-Stratus.*—An horizontal or slightly inclined sheet, attenuated at its circumference, concave downwards, or undulated. Groups having these characters.

6. *Cumulo-Stratus.*—A cloud in which the cumulus is mixed with cirro-stratus or cirro-cumulus; the cumulus flattened at top, and overhanging its base.

7. *Nimbus.*—A dense cloud, spreading out into a crown of cirrus, and passing beneath into a shower.[1]

The cirrus is generally formed of white radiated streaks, pencilled on an azure sky. It is the most elevated species of cloud. Its motions are slow. It generally indicates a breeze, and often precedes a storm. Horizontal sheets of cirrus, with streamers pointing upwards, often indicate rain; while the depending fringes are the precursors of fine weather.

The cumulus is generally a dense cloud, moving near the surface of the earth. When large, this species often exhibits large intervening spaces of clear sky. It begins in the morning, and obtains its maximum about two P. M., and usually decreases before sunset, breaking up and disappearing before nightfall. It is the prognostic of settled weather.

The stratus is the lowest modification of cloud, often creeping along the ground, in calm evenings, from lakes and rivers, and rising toward the higher grounds. It often, at night, travels over plains, invests the summits of moderate elevations, but usually melts away before the morning sun. Few days are more serene than those ushered in by stratus.

---

[1] Philosophical Magazine; Rees' Cyclopædia; Nicholson's Journal, xxx.

Cirro-cumulus consists of dense rounded masses, in close position. It often forms beds at different altitudes in the air. It is transient in winter, and occurs in the intervals of summer showers. A frequent repetition of it is amongst the best prognostics of fine weather.

The cirro-stratus is narrow in proportion to its horizontal length. It seldom retains long the same form. It is often seen very high in the air, especially that variety which is composed of grouped masses, and is chiefly seen in summer evenings. When seen overhead, it has an uniform hazy appearance; but viewed on the horizon, it often seems very dense, from being viewed edgewise. It indicates rain or storms of snow when it is stationary. It often forms the seat of rainbows and halos when descending from the zenith. It often shrouds mountain summits, and in cold weather often descends into plains as soaking dense mist. The cumulo-stratus usually appears in an overcast sky, and may be regarded as a prognostic of rain. It appears to be formed by the successive blending of cumuli, inlaced by streaks of dark stratus. The thunder-cloud is one modification of this species. It often assumes a portentous size, and is contorted into singular forms. Its indications are not uniform. When it appears in the morning, the day is often dry, though overcast; but when much mixed with stratus, it indicates approaching rain, after some interval.

The nimbus is a shower seen in profile as it approaches the spectator from the horizon. The thunder-cloud, on the discharge of its electricity, generally passes into the nimbus.

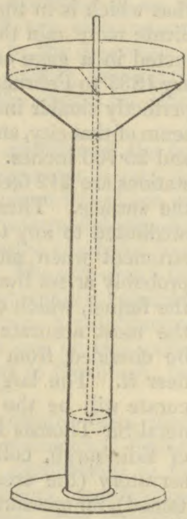
Mists or *Fogs* are but the condensation of invisible vapour into minute drops of water. They are generally more stationary on the sea than on the land. They are less frequent in the day than the night, in hot than in cold climates; and they are frequent in approaching the poles. One of the most remarkable stationary fogs is on that part of the Atlantic called the *Banks of Newfoundland.* The warm waters of the gulf-stream, after sweeping along the shores of the United States, and warming the superincumbent air, are encountered at Newfoundland by the polar currents, and the colder air over them. The consequence of this intermixture of the aerial currents at different temperatures, is the diminished capacity of the mixture for moisture, and the consequent deposition of a portion of its vapour in the form of mist. When the cold producing condensation of atmospheric moisture is intense, instead of mist, a deposition of minute particles of ice may take place, and will cover with delicate crystallizations the hair and clothes of the traveller, or the twigs and branches of trees. When the air is saturated with moisture, sudden condensation assumes the form of

Rain.—Amongst the numerous speculations on the production of rain, one of the most ingenious is that proposed by Dr James Hutton. He evidently considered the water as *dissolved* by the air; but if we merely consider the term "complete saturation with moisture" as meaning the dew-point, and the quantity suspended by air as indicating the quantity of vapour existing in the atmosphere at a given temperature by its own elasticity, this phraseology will produce no error. Hutton ascribed rain to the intermingling of air saturated with moisture at different temperatures. His views were communicated to the Royal Society of Edinburgh in 1787; but, from his contenting himself with a mere enunciation of his theory, it has been scarcely noticed by meteorologists, until illustrated in the articles METEOROLOGY and HYGROMETRY. Sir John Leslie has shown, that the mere commixture of air at different temperatures would produce but a small part of the effect perceived. It is proved by experiment that the capacity of air for moisture, or the quantity of vapour in a given space, increases in a much higher ratio than the temperature; and hence, if the space occupied by the mixture of masses of moist air, at different temperatures, have the mean temperature of the mixture, or one below it, a deposition of moisture or of rain will follow; but the whole effect would be smaller than what is often observed to take place, unless we suppose that two currents of air are moving, with considerable velocity, in opposite directions.

The objection to this simple view of the question is, that there are often heavy falls of rain when the clouds emitting it are evidently in very slow movement; and we have long believed, that without calling in the aid of electricity, as already stated when treating of the formation of clouds, no theory of rain will be satisfactory.

The hygrometric water in the air seems to owe its suspension to the repulsions among the electric atmospheres of its particles: when that electricity is withdrawn by any cause, the particles of water, no longer kept asunder by their electricity, coalesce, and descend by their gravity with a force proportional to their quantity and the reduction of their electric tension. If the electric fluid be slowly withdrawn, there is neither lightning nor any explosion; but if the accumulation has been great, and the abstraction sudden, we have the phenomena of thunder and lightning. On this view, evaporation is to be considered as the grand mode by which the atmosphere acquires electricity, and the accumulation seems in general in proportion to the intensity and duration of the evaporation. Hence lightning is most common and vivid in warm latitudes; and there is seldom any considerable electric discharge from the atmosphere, without a concomitant fall of rain, which is usually proportional to the violence of the thunder-storm.

No. 21.

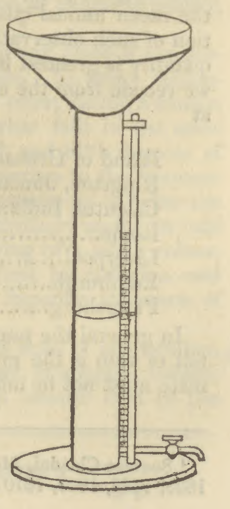


Rain falls in drops of a size varying from $\frac{1}{25}$th to $\frac{1}{3}$d of an inch in diameter; and it has been calculated that their ultimate velocity is in the duplicate ratio of their diameters. When formed high in the atmosphere, or passing through very cold strata of air, they congeal into hail or into snow.

Ombrometers.

To ascertain the quantity of rain which falls in any place in a given time, various species of *ombrometers* or *rain-gages* have been employed. The most usual form of the gage is that represented in No. 21. It consists of a cylindrical vessel of copper, usually 3·75 of an inch in diameter. Upon its upper part, a funnel of the same metal, with an upright brim exactly one foot in diameter, is fitted; a hollow vessel of metal, or a piece of cork, serves as a float, to support a rod of boxwood graduated in tenths of an inch. The water which falls into the funnel finds its way into the cylinder, and raises the float. The quantity is read off the rod at a stay placed across the funnel, and from the relative proportion of the cylinder and funnel, each $\frac{1}{10}$th of an inch is equivalent to $\frac{1}{100}$th of an inch of water entering the mouth of the funnel.

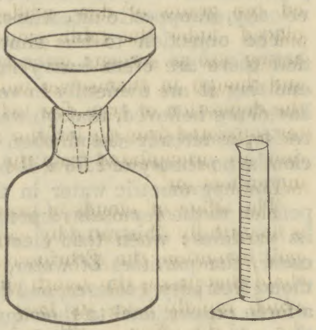
No. 22.



Another very convenient form is represented in No. 22., where the height of the column of water in the cylinder is seen in a glass tube connected with the cylinder below. A scale is applied, as in the figure; and when the observation is made, the water is let off by the stop-cock.

Mr Luke Howard's rain-gage is seen in No. 23. The funnel is fitted on the neck of a glass bottle, by means of an exterior tube, which is soldered to the funnel, and prevents the entrance of water into the vessel, except through the mouth of the funnel. The quantity of rain is ascertained by a graduated glass measure, the divisions of which correspond to 100ths of an inch, falling on the mouth of the funnel. This same measure will serve to ascertain the quantity evaporated in a given time, provided the mouth of the vessel, No. 20, is exactly equal to the mouth of the rain-gage.

No. 23.



Their position.

There are considerable practical difficulties in the proper position of a rain-gage. It is found, that if one be placed on the ground, and another on the top of a building, that which is in the lowest position will almost always indicate more rain than the upper. Thus, the quantity collected in a gage on the top of York Minster, from February 1833 to February 1834, only equals 14·963 inches, while perfectly similar instruments placed on the top of the museum of that city, and on the ground, gave relatively 19·852, and 25·706 inches. The elevations of the first and second stations are 212 feet 10½ inches and 43 feet 8 inches above the surface. These differences are too considerable to be attributed to any thing but some imperfection in the instrument when much exposed to gales of wind; and it probably arises from eddies being formed round the rim of the funnel, which divert part of the water. On the whole, the most accurate estimate of the quantity of rain will be obtained from instruments placed on the ground, or near it. The larger the recipient surface, the more accurate will be the indications; and on this principle, General Sir Thomas Brisbane, president of the Royal Society of Edinburgh, collects the rain from the roof of his observatory (the area of which has been accurately ascertained), for measuring the quantity of rain which falls in his vicinity.

Quantity of Rain.

When the quantity of rain which falls at any place has been regularly kept for several years, it is easy to obtain the mean annual quantity at that place. The multiplication of such observations has proved, that the mean annual quantity is greatest in tropical climates, and diminishes as we recede from the equator. Thus, the mean annual rain at

		Inches.
Island of Granada,	lat. 12°	=126
Kingston, Jamaica,	lat. 18°	= 83
Calcutta, India	lat. 22° 23′	= 81
Rome	lat. 41° 54′	= 39
Liverpool	lat. 53° 22′	= 33
Edinburgh	lat. 55° 57′	= 24
Petersburg	lat. 59° 56′	= 16

In general the number of rainy days is least where the fall of rain is the greatest, and the dampness of any climate must not be inferred from the annual quantity of rain. A country may be involved in almost perpetual fogs, or have many days of drizzling rain, in which the number of inches of rain throughout the year may be very small.

The quantity of rain, however, depends upon other circumstances than the latitude. It is much influenced by the vicinity of mountains in every climate. Thus,

	Inches.
At Kingston, on the shores of Jamaica, it	= 83
In Caraib country, among the mountains there	= 97
In Demerary, in the swamps of Guyana	= 73
In the lofty island of Granada	=126

Yet in Demerary as much as six inches of rain have been observed to fall in twelve hours. Similar observations occur in our own country.

	Inches.
At Carlisle the annual rain	=34
At Whitehaven	=52
At Kendal	=56
At Langside, near Glasgow	=37
At Carbailly, in Stirlingshire	=46
At Ardincaple	=50
At Lochlomond	=52
At Castle Toward, Argyleshire	=56

In Great Britain, it is generally found that much more rain falls on the western than on the eastern coasts. Thus,

	Inches.
At Edinburgh the rain	=24
At Elgin	=24
At Garnet Hill, near Glasgow	=32
At Greenock	=39

The latter town lies in a sheltered nook, or perhaps its annual quantity would have been higher; for,

	Inches.
At Catrine House, in Ayrshire, it	=45
And at Lanfine House, ditto	=52

It is scarcely necessary here to dwell on various extraordinary substances which have sometimes fallen from the air. *Showers of sulphur* have been mentioned by different observers. Wormius records such a shower as occurring at Copenhagen in May 1646; but the same phenomenon occurred in May 1804; and the philosophers of our own age, on analyzing this deposit, recognised it to consist of a vegetable pollen, resembling the powder of *lycopodium.* This substance fell in the night time, and, being phosphorescent when observed, gave considerable alarm. At Bordeaux, in 1761, a shower of a yellow powder was observed, which, however, was recognised as the pollen of the pine forests in the neighbouring *landes,* carried up into the air by a violent gale. Of a similar nature, in all probability, was the *yellow rain* which covered the Lake of Zurich in 1677.

The supposed *showers of blood* which have been recorded in some ancient chronicles are now ascribed to the same source as the red snow of Greenland and the Alps, that is, to the red globules or seeds of the *uredo nivalis;* or to minute red insects, which are sometimes carried down in great quantity with rain. The appearance of drops of blood falling from the air has occasionally been produced by the red excrement of insects. That small frogs and fishes have occasionally descended with rain has been admitted, as such animals, and even much more ponderous matter, have been elevated into the atmosphere by whirlwinds.

The showers of stones which have been noticed by several ancient writers as happening in Italy, Greece, and Asia Minor, are now believed to belong to the class of facts described under the article METEOROLITE.[1] These are mineral bodies, which, however they find their way into the atmosphere, have undoubtedly fallen upon the earth; and, however remote the places in which they descend, they are all distinguished by one remarkable similarity, viz. their containing an alloy of iron and nickel, generally with twenty-five of the former to six or eight of the latter.

Dew.—The phenomena and cause of this deposition have engaged the attention of philosophers from the time of Aristotle; but their speculations present little that is satisfactory until the experimental investigations of Dr Wells. One of the most remarkable circumstances attending the deposition of dew is, that the bodies on which it is found have invariably a lower temperature than the ambient air, as was first pointed out by Dr Patrick Wilson of Glasgow, who ascribed the coldness to the deposition of dew; but Dr Wells has proved that the cooling of these bodies below the temperature of the air always *precedes the formation of the dew*, and is, in fact, the cause of this aqueous meteor. His theory is founded on Leslie's view of the heat which is sent off from the earth toward a clear sky; and on this simple principle Wells has been enabled to give a satisfactory explanation of the phenomena of dew.

The essential requisites for the deposition of dew are five in number, viz.

1. An atmosphere replete with moisture. As dew is a deposition of water from the air, it obviously must be in excess ere it is deposited. In Egypt, the south winds, blowing over extensive tracts of sandy desert, deposit no dew; but when the *Etesian* or north wind blows, loaded with moisture from the Mediterranean, the deposition of dew in lower Egypt is sufficient to soak through the garments of the inhabitants; and in the arid plains of New Castille the dews are far less copious than on the coasts of Andalusia.

2. There must be a considerable difference between the temperature of the earth in the night and the day. Other things being the same, the deposition is greatest when a cool evening succeeds a sultry day. In our climate, the dews are most abundant in spring and autumn, when the difference of temperature is greatest; but as the ratio of the increase of moisture in the air is greater than the increase of heat, hot climates have more copious dews than Great Britain, even though the difference between diurnal and nocturnal temperature be less in the former. Thus we have found the dews in the south of Spain, and in Marocco, far more copious than here; a short exposure about sunset in those countries completely soaking one through the clothes.

3. But the most essential requisite for the deposition of dew is, that the bodies upon which it forms should have their temperature considerably lower than that of the ambient air. In repeating Wilson's experiments, Dr Wells found that all bodies on which dew formed were colder than the air by 10° or 15°. Thus, in clear weather, he observed that a thermometer laid on grass was 12° lower than one laid on mould, and sixteen and a half below one on a gravel walk. He always found that the coldness of the body preceded the deposition of dew; and this is illustrated by the deposition of moisture which immediately takes place on pouring into a glass cylinder, placed in a warm, moist room, very cold water.

4. A serene and cloudless sky is also very favourable to the formation of dew. Wells found, that although the atmosphere be in other respects favourable to the deposition, yet little or none is formed if the sky be veiled in clouds; and, in such cases, the temperature of objects on the surface was near that of the air. He points out how clouds act as a screen to intercept the emanations between the earth and the upper regions of the air, which are well known to be the abodes of perpetual congelation. The same effect was produced by interposing screens of an opake material between the sky and the surface of the earth. Thus a thermometer, laid on a table, indicated a lower temperature than one placed on the ground under the table; and a lock of wool laid on the table collected ten grains of dew, whilst an equal weight of wool placed under the table gained only two grains. Fogs, acting also as screens, intercept the influence of the sky; and though in themselves moist, they are unfavourable to the deposition of true dew, which may be regarded as water separated from the inferior stratum of air; but fogs, like rain, are precipitated from the general mass of the superincumbent air.

The effect of clouds in preventing the radiation of heat is beautifully illustrated by carrying Professor Leslie's elegant invention, the Æthrioscope, into the open air. Every cloud that passes the zenith affects this delicate instrument, which rapidly loses its heat when exposed to the clear sky; or the effect is still more conspicuous if the operator hold a parasol, and alternately extend the æthrioscope beyond the shade and withdraw it under the parasol.

5. Serene and calm weather is favourable to the formation of dew; a fact which had been noticed by Aristotle. The influence of wind seems to depend on the rapid succession of aerial particles preventing the full influence of the cooling medium on the general temperature of an inferior stratum of the atmosphere. Every circumstance which favours radiation is favourable to the deposition of dew, such as a rough surface, and dark colour; proving the dependence of dew on the cooling of the objects on which it is deposited.[1]

Honey and jelly dew.

Dew often partakes of the sensible qualities of the bodies upon which it is found; hence dew-water is very apt to putrefy. Some substances found on plants have been erroneously confounded with dew. What is termed *honey-dew* generally owes its qualities to the saccharine exudation from the bodies of the insects called *Aphides*. The *jelly-dew* is believed to be the original form of a cryptogamian vegetable production, the *Tremella nostoc* of Linnæus; a membranous, pellucid, greenish-yellow matter, about one or two inches in width, which is at first moist and soft to the touch, but dries into a blackish membrane.

Snow.

Snow.—When the congelation of moisture takes place slowly, the flakes of snow assume very symmetrical figures, the varieties of which have been well represented in the work of Scoresby. They usually present modifications or combinations of the hexangular prisms, often consisting of a star of six rays, formed of prisms united at angles of 60°; and from these other prisms shoot, at similar angles,[2] giving the whole a plumose appearance, of exquisite beauty, and often of surprising regularity.

The quantity of snow which falls in any place is not proportional to the height of its latitude. In many temperate countries, the successive falls of snow, during a winter, may often greatly exceed in depth what falls in the same period in countries between the 65th and 80th degrees of latitude. In fact, it bears some proportion to the evaporation in countries where the winter temperature is below the freezing point of water. Snow is extremely useful, in cold climates, as a loose and spongy covering of a white colour, in preventing the loss of terrestrial heat by radiation, and in defending the surface from the frigorific influence of very cold winds.

Hail.

Hail differs from snow chiefly in its state of aggregation, and its far less regular crystalline form. It appears, indeed, to be the production of sudden and intense cold in the higher regions of the atmosphere, and therefore often occurs in warm climates, where snow is utterly unknown. A hail shower is often ushered in by a rattling noise, heard over head, before almost any hailstones have reached the ground. The ordinary size of hailstones with us varies from $\frac{1}{10}$th to $\frac{1}{3}$d of an inch in diameter. Occasionally they are much larger; as in the remarkable hail-storm described by Dr Neill, which occurred during a thunder-storm in the Orkneys on the 24th of July 1818.[1] Mingled with ordinary hail were enormous masses of ice, some as large as the egg of a goose; by which animals were killed, and individuals wounded. An enormous hailstone is recorded to have fallen, amongst many very large masses, at Handsworth House, near Birmingham, during a thunder-storm, on the 8th of June 1811. It consisted of a cuboidal mass $6\frac{1}{2}$ inches in diameter; and, from the engraved sketch, it resembled a congeries of frozen balls about the size of walnuts. On the Continent of Europe, the large hail of summer is frequently exceedingly destructive to vineyards; and in some districts of France, where the damage has often been great from thunder-storms, accompanied by large hailstones, the ingenious device of the *Paratonnerre* has been employed to prevent the accumulation of electricity over these valleys. The contrivance consists in the erection of pointed electric conductors on the surrounding hills, by which the lightning is silently and gradually abstracted from the air, and dangerous accumulations over the included districts generally prevented. In hot climates, the descent of large masses of frozen water is still more common than in Europe, especially within the *Calms* off the western coast of Africa.

[2] Scoresby's Arctic Regions, vol. i.

Winds.

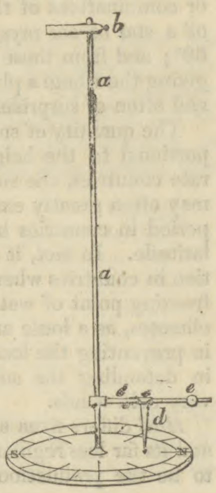
Winds.—The influence of mechanical causes in producing those aerial currents termed winds has been generally admitted, from the ages when they were poetically imagined as viewless forms, imprisoned or let loose from the caverns of Æolus, to the present day, when they are considered as the consequences of partial changes in the density of the atmosphere, arising from the unequal distribution of heat over the surface of the globe, or from alterations on its hygrometric and electric states. But the manner in which their force and direction are affected by these circumstances, in those sudden and local storms which frequently agitate the air, is difficult of explanation, although the general phenomena may admit of a very probable solution.

Register anemoscopes.

The dependence of the weather on the direction and force of the winds has given rise to many inventions for indicating their variations. The direction is shown by the well-known vane, or simple *anemoscope*, the movements of which are referred to the cardinal points by a fixed index, or by a plate marked with the rhumbs of the mariner's compass. To save the trouble of frequent daily observations, the labour of the meteorologist may be materially abridged by the following methods of obtaining *maxima* and *minima* of the direction of the winds.

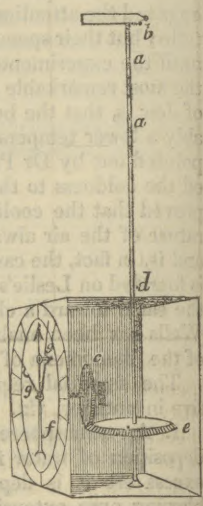
In the first, No. 24, the vane *b*, fixed to the axis *a*, causes the latter to revolve in a socket, in the centre of a writing slate marked with the rhumbs of the compass. The arm *c*, jointed to it, carries a pencil *d*, which records the progress of the vane on the slate. The pressure of the pencil may be regulated by sliding the ball *e* on the arm; and, to diminish friction, the socket consists of a flint, with a smooth hollow cavity, and the axis is kept perpendicular by moving between friction rollers.

No. 24.



In the second, No. 25, the same effect is shown on a vertical dial, by converting the horizontal motion of the vane into a vertical movement of the index. This is produced by one bevelled wheel *e* on the axis of the vane, and a similar one *c* on the axis of the index *f*. The *maxima* and *minima* are shown by two moveable arms *gg*, concentric with the index, but pushed to either side by a stud on the lower surface of the index. These instruments, devised long ago by Traill, and published in Professor Jameson's Journal for 1837, sufficiently answer the object for which they were intended.

No. 25.

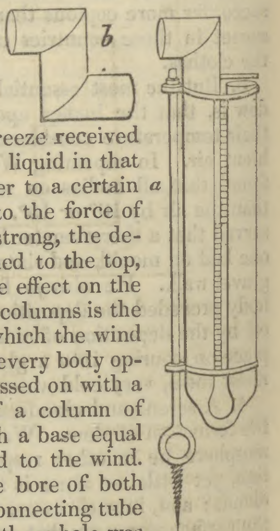


Anemometer.

The varying force of the wind is ascertained by the *anemometer*. The principle of several such instruments is the direct pressure of the wind on a given surface, kept by a vane perpendicular to the direction of the breeze. Sometimes this pressure is measured by raising a weight; in some instruments by the degree of compression of a spiral spring; or, as in the ingenious anemometer of Mr Waddel of Leith, by the compression of a slender cylindrical bag filled with quicksilver, and connected with a vertical tube one foot in length, with a bore of $\frac{1}{20}$th of an inch. The force of the wind is estimated by the height of the column of mercury. A practical difficulty arises from the quickness of the oscillations, which renders it not easy to read off the indications of the instrument during a smart gale.

The same objection in some measure applies to the elegant pocket anemometer of Dr Lind. It consists of two equal glass tubes, united below by a narrow connecting piece, as in No. 26, and having between them a scale of equal parts. The tubes are filled to the middle with water; and as the instrument is made to revolve freely round the iron spindle *a*, its body acts as a vane, to keep the orifice of the kneed brass tube always directed to the wind. The breeze received at that aperture depresses the liquid in that limb, and raises it in the other to a certain point on the scale, according to the force of the breeze. When it is very strong, the detached piece of brass *b* is joined to the top, and an allowance made for the effect on the column. The sum of the two columns is the height of a column of water which the wind is capable of sustaining; and every body opposed to that wind will be pressed on with a force equal to the weight of a column of water of that height, and with a base equal to that of the surface exposed to the wind. In the original instrument the bore of both legs = $\frac{4}{10}$ths of an inch, the connecting tube was $\frac{2}{10}$ths, and the length of the whole was six inches. Lind gave the following table as its indications.

No. 26.



---

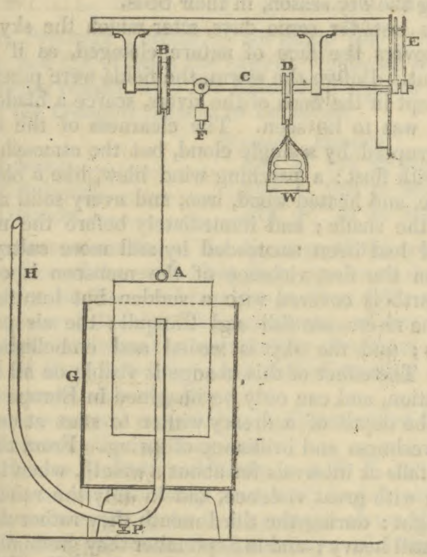
[1] Edinburgh Philosophical Transactions, vol. ix.

Height of Water in the Gage.	Force of the Wind on One Foot Square, in lbs. avoirdupois.	Common Designations.
12 inches.	62·500	
11	57·293	
10	52·083	Most violent hurricane.
9	46·875	
8	41·667	Very great hurricane.
7	36·548	Great hurricane.
6	31·750	Hurricane.
5	26·041	Very great storm.
4	20·833	Great storm.
3	15·625	Storm.
2	10·416	Very high wind.
1	5·208	High wind.
0·5	2·604	Brisk gale.
0·10	0·521	Fresh breeze.
0·05	0·260	Pleasant wind.
0·025	0·030	Gentle wind.

This instrument is, upon the whole, the most convenient anemometer we possess, and has the advantage of portability. The oscillations of the liquid might be farther checked by twisting spirally the tube of communication, as in the marine barometer.

A very ingenious anemometer has been constructed by Mr Richard Adie, late of Edinburgh, now of Liverpool. An index E is moved by the rising and falling of a cylinder A, closed at one end, and inverted in a larger cylinder G, containing water, on the principle of a gasometer for chemical experiments. The inverted vessel is suspended by a cord passing over a pulley B fixed on the axis C of the index. The counterpoise is a weight W, the cord of which, wound on a fusee or snail D, equalizes the counterpoise in the different positions of the internal cylinder. The influence of the wind on the instrument is produced through a tube, as in the figure. One end terminates in the interior cylinder, and the other in a kneed tube moving freely round by means of the attached vane. A very gentle breeze is sufficient to elevate the cylinder, and the revolution of the index marks the comparative force of different winds. This anemometer has been found to act well, and has been put up at several of the northern lighthouses.

No. 27.



The last anemometer we shall notice is that invented by Professor Whewell, who exhibited it to the British Association. It consists of a small *wind-wheel* of eight vanes, directed to the wind by an attached vane. By a train of toothed wheels and endless screws, the rapid revolutions of the wheel are converted into a slow vertical motion, by which a pencil is made to trace a downward line on the surface of a vertical cylinder having the same axis as the vane. The length of this line records the whole amount of the aerial current that passes over the place of observation, and the part of the circumference of the cylinder on which the trace appears indicates the direction of the winds. Three of these instruments are, by direction of the Association, on trial in different places, and the results will be communicated in the present year (1838).

Force of the wind.

In Smeaton's valuable paper upon the moving power of wind and water (Philosophical Transactions, vol. li.) there is the following table of the force of the wind, calculated by his friend Mr Rouse; which the celebrated engineer considers as entitled to confidence, especially in velocities below fifty miles per hour.

Velocity of the Wind.		Perpendicular Force on an area of One Foot, in lbs. avoird.	Common Designations of the Winds.
Miles per Hour.	Feet per Second.		
1	1·47	0·005	Hardly perceptible.
2	2·93	0·020	Just perceptible.
3	4·40	0·044	
4	5·87	0·079	Gentle breezes.
5	7·33	0·123	
10	14·67	0·492	Pleasant brisk gales.
15	22·00	1·107	
20	29·34	1·968	Very brisk gales.
25	36·67	3·075	
30	44·01	4·429	High winds.
35	51·34	6·027	
40	58·68	7·873	Very high winds.
45	66·01	9·963	
50	73·35	12·300	A storm or tempest.
60	88·02	17·715	A great storm.
80	117·36	31·490	A hurricane.
100	146·70	49·200	A great hurricane.

The third column is calculated according to the squares of the velocities of the wind, which Smeaton considers as generally correct.

Trade-winds.

Trade-winds.—In those portions of the Atlantic and the Pacific Oceans between the tropics, the wind has, throughout the year, a direction from the *east.* The following explanation agrees pretty well with the facts. The dense cool air of the polar and temperate regions naturally tends to displace the lighter warm air over intertropical regions, which, heated by the sun, produce vertical movements in the superincumbent atmosphere. Hence the ascending current of warm air between the tropics has its place supplied by the denser air from either side; and thus two currents are set in motion, from the poles towards the tropical regions. The velocity of every point on the earth's surface increases from the poles to the equator. But as the particles of these currents cannot at once acquire a velocity equal to the continually accelerating velocity of the parts of the earth's surface over which they arrive in this transit, the northern and southern currents will gradually seem to acquire a motion in an opposite direction to that of the rotation of the earth, that is, both will gradually decline to the west, assuming in the northern hemisphere the character of a N. E., and on the south side of the line of a S. E. wind; whilst both will become more *easterly* as they approach the equator. This effect of the augmenting velocity of the earth's surface, in approaching the equinoxial line, is increased by the continual movement of the point over which the sun is vertical, and consequently his heat the greatest, to the west; and the effect of the gravitation of the sun and moon on the atmosphere, as was shown by D'Alembert, must directly tend to increase the force of the easterly wind. The influence of these luminaries on our atmosphere is corroborated by the observations of Bacon, Halley, and Gassendi, on the frequency of storms about the equinoxes, or at full and new moon, and the general occurrence, in calm weather, of light airs of wind at the time of high water. When these causes are not counteracted by the superior rarefaction of air over land heated by the sun's rays, the easterly winds blow with much regularity, as in the great oceans; and, from their important influence on navigation, they have obtained the denomination of *trade-winds.* They extend to about 30° on each side of the equator; but, from the less density of the atmosphere in the northern hemisphere, arising from the greater quantity of land to be acted on by the sun's rays in that half of the globe, the line which marks the blending of the S. E. and N. E. trade-winds is between two and three degrees north of the equator.

If the surface of the globe had been one expanse of water, the trade-winds would have blown all round the equator, and the only other winds known would have probably been N. and S. winds near the poles, gradually bending from E. to W. as they approached the tropics. But the air over the land being much more heated by the sun's rays than that over the sea, the vicinity of large islands or of continents causes interruptions to the regularity of the trade-winds. Thus, on the coasts of Africa, within the regular limits of the trade-winds, *westerly* gales are not unknown; and a *southerly* wind prevails along the western shores of that continent, from Cape Palmas to the Cape of Good Hope; a consequence of the form and climate of Northern Africa, which continues the southern polar current far beyond its limits in the free ocean.

A similar cause appears to give rise to the *Calms* on that coast, from 10° to 4° N., a tract avoided by seamen, on account of these calms, and sudden alternations, with tremendous storms of thunder and lightning, to which it is subject. The general direction of the trade-winds is affected by their approach to the shores of America; they are expanded, chiefly owing to the resistance they meet with from the land, and also by the additional rarefaction of the air re-acting upon that continent. Precisely similar disturbances from the position of land produce

Monsoons.

The *Monsoons* of the Indian Ocean. The eastern trade-wind blows regularly in that sea between the parallels of 10° and 30° S.; but from these parallels northwards, or on the sea between Sumatra and Eastern Africa, the course of the trade-winds is reversed for half the year, from April to October, during which period there is a constant wind from the S. W. During the other six months the regular trade-wind, from the N. E., resumes its course. These winds are termed the S. W. and N. E. *monsoons*, from a Malayan word signifying *seasons.* The latter is produced by the same causes as the general trade-wind. The other appears to be occasioned by the great rarefaction of the atmosphere over the extensive regions of Eastern Asia when the sun is north of the equator, and the dense air of the Indian Ocean rushes in to occupy the place of the ascending current.

This disturbance of the trade-wind is attended with very remarkable effects on the climate of the country where it prevails. It is the harbinger of the rainy season in India, which is ushered in by violent thunder-storms. A most striking picture of this change of monsoon is given by Mr Elphinstone in his Account of Caubul. "The most remarkable rainy season is that called in India the S. W. monsoon. It extends from Africa to the Malayan peninsula, and deluges all the intermediate countries, within certain lines of latitude, for four months in the year. In the south of India this monsoon commences about the beginning of June, but it gets later as we advance towards the north. Its approach is announced by vast masses of clouds, that rise from the Indian Ocean, and advance towards the N. E., gathering and thickening as they approach the land. After some threatening days, the sky assumes a troubled appearance in the evenings, and the monsoon in general sets in during the night. It is attended by such a thunder-storm as can hardly be imagined by those who have only seen that phenomenon in a temperate climate. It generally begins with violent blasts of wind, which are succeeded by floods of rain. For some hours lightning is seen almost without intermission; sometimes it only illumines the sky, and shows the clouds near the horizon; at other times it discovers the distant hills, and again leaves all in darkness; when, in an instant, it re-appears in vivid and successive flashes, and exhibits the nearest objects in the brightness of day. During all this time the distant thunder never ceases to roll, and is only silenced by some nearer peal, which bursts on the ear with such a sudden and tremendous crash as can scarcely fail to strike the most insensible heart with awe. (Malabar is the province most distinguished for the violence of the monsoon.) At length the thunder ceases, and nothing is heard but the continued pouring of the rain, and the rushing of rising streams. The next day presents a gloomy spectacle; the rain still descends in torrents, and scarcely allows a view of the blackened fields: the rivers are swollen and discoloured, and sweep down along with them the hedges, the huts, and the remains of the cultivation which was carried on during the dry season, in their beds.

"This lasts for some days, after which the sky clears, and discovers the face of nature changed, as if by enchantment. Before the storm, the fields were parched up, and, except in the beds of the rivers, scarce a blade of vegetation was to be seen. The clearness of the sky was not interrupted by a single cloud, but the atmosphere was loaded with dust: a parching wind blew, like a blast from a furnace, and heated wood, iron, and every solid material, even in the shade; and immediately before the monsoon this wind had been succeeded by still more sultry calms. But when the first violence of the monsoon is over, the whole earth is covered with a sudden but luxuriant verdure: the rivers are full and tranquil; the air pure and delicious; and the sky is varied and embellished with clouds. The effect of this change is visible on all the animal creation, and can only be imagined in Europe by supposing the depth of a dreary winter to start at once into all the freshness and brilliancy of spring. From that time the rain falls at intervals for about a month, when it comes on again with great violence, and in July the rains are at their height: during the third month they rather diminish, but are still heavy; and in September they gradually abate, and are often suspended till near the end of the month, when they depart amid thunders and tempests, as they came."[1]

Sea ar land b zes.

Sea and land breezes are occasioned by the same causes which produce the S. W. monsoon, and are chiefly experienced on tropical sea-coasts.

The sea-breeze commences about 10 A. M., and continues throughout the day, till towards 6 P. M., when it gradually dies away, and about eight in the evening is succeeded by a much fainter breeze from the land, especially in those islands which have considerable mountains. It is well known in Jamaica, but less so in the smaller Antilles, and scarcely at all on the flat coasts of America. It continues during the night, and usually dies away before six or seven in the morning; but it is much less regular in its periods than the sea-breeze. The latter, too, occurs in places where the land-breeze is quite unknown. An admirable description of these is contained in the voyages of Dampier, and given at length in the article METEOROLOGY. The sea-breeze is more or less felt on the coasts of all warm countries. We have had occasion to observe with what regularity the sea-breeze sets in from the S. W. during the summer at Gibraltar, and it blows with considerable force throughout the greatest part of the day.

---

[1] Account of Caubul, p. 126.

The explanation of the sea-breeze is the rarefaction of the air by the heat of the land, and the rushing in of denser air from the sea to supply its place; and as the influence of the sun decreases, this breeze dies away. The land-breeze is chiefly produced by the descent of air from mountainous regions, flowing, by its gravity, towards the sea, over which the atmosphere is less liable to suffer extreme rarefaction and condensation than the air over the land.

In temperate climates the winds are far less regular than in tropical countries. The general causes which produce them act with less force and constancy; and the disturbing causes, such as the vicinity of land, alteration in density from moisture and dryness, act with more uncontrolled energy. The most prevalent winds in Great Britain are from the S. W., especially on the western side of our island. The Royal Society registers give the following average for the winds throughout the year at London.

S. W.	112 days.	S. E.	32 days.
N. E.	58	E.	26
W.	53	S.	18
N. W.	50	N.	16

Or, with Professor Playfair, if we group the S. with the westerly, and the N. with the easterly winds, we shall have the following results, from the Edinburgh register of Playfair, and the Glasgow register of Dr Meek.

	Westerly.		Easterly.	
London	233	+	132	= 365
Edinburgh	242	+	123	= 365
Glasgow	314	+	51	= 365

These determinations of the direction of the winds refer to the surface of the earth; but there can be no doubt that the direction of the aerial currents is often different in the upper regions of the air. The permanence of very elevated clouds, their occasional movements in directions opposite to those of the winds below, and the information obtained from aeronauts, all prove this point.

There are several remarkable modifications of the wind, which deserve notice in this place.

The *Sirocco* of Italy and Sicily is a S. E. or S. wind, which, heated on the sandy wastes of Arabia and Libya, becomes occasionally moist in its passage across the Mediterranean, and oppresses the inhabitants of Italy, Malta, and Sicily with excessive languor, and a sinking of their mental energies. When it sets in, it causes a very sudden and powerful rise of the thermometer, and is accompanied by a haze which obscures the pure sky of those southern countries; the sun appearing dimmed and shorn of his beams.

The *Solano* of Spain is only a modification of the Sirocco. We have experienced it as most oppressive on the eastern shores of Spain; and it is greatly detested by the natives, who gravely remark, that "no animals except a pig and an Englishman are insensible to the Solano." The Italian condemnation of a stupid work, "era scritto in tempo del Sirocco," is not more pointed than the Spanish adage, "no rogar alguna gracia en tiempo de Solano," not to ask any favour during the Solano; and both proverbs sufficiently indicate the belief of the people of southern Europe in the disagreeable qualities of the S. E. wind. We have observed fine dust deposited from the Solano or *Levanter* at Gibraltar, and to this we partly attribute the haze with which it is accompanied. If this dust be brought with the Solano from Africa, it is less surprising than the following instance of dust carried by the easterly wind into the Atlantic. On the morning of the 19th January 1826, when the Clyde East Indiaman was on her voyage to London, in latitude 10. 40. N., longitude 27. 41. W., her rigging was observed to be covered with an impalpable powder of a brownish colour, and on unfurling the sails at two P. M. to catch the breeze, they emitted clouds of dust, which had lodged in them during a strong gale from the E. and N. E. In this case the nearest land in that direction was about seven hundred miles distant.

Khamsin or Simûn.

The *Khamsin* of Syria, the *Samiel* of the Turks, and the *Simûn* of the Arabs, is well described by Volney. It is a wind in no degree poisonous, except in as far as it is dangerous from its extreme heat and aridity; qualities it derives from blowing over sandy deserts intensely heated by the sun. Denon states, that it is loaded with impalpable sand, which penetrates into the closest packages. These winds derive their Syrian name from their prevalence during the fifty days about the equinoxes. They produce difficult respiration, a shrivelled skin, and a distressing sense of heat. Volney compares the effect of them to the sensation produced by the hot air from a baker's oven. They sometimes blow in squalls, and in Egypt usually continue for about three days at a time. In that period vegetation is withered, the inhabitants shut themselves up in their houses or their tents; and the Simûn is dangerous to persons of a full habit, from the sudden entrance of this heated and parched air into the lungs. In the sandy deserts it is greatly dreaded; but fortunately its extent is not considerable, and it seldom lasts long. It has been well described by Chardin, Sir John Malcolm, and Badhia.

Harmattan.

The *Harmattan* of the west coast of Africa is of the same kind, and produced by the same causes. The extreme dryness of this wind has been mentioned by all observers. It usually blows from the Great Sahara towards the coast, from the N. E., and, like the Solano, Sirocco, and Simûn, is loaded with dust. The dust which fell on the vessel just mentioned was from a violent Harmattan. The only difference between the Sirocco and these other winds appears to be, that the Sirocco obtains some moisture in crossing the Mediterranean; but they all seem to be mere modifications of aerial currents produced by the same causes.[1]

Tornado, &c.

The *Tornadoes*, *Typhons* of the Chinese Seas, the *Ox-eye* of the Cape, and the *Hurricanes* of the West Indies, are violent and extraordinary agitations of the air, generally accompanied by thunder-storms, and usually of short duration. The destructive violence of the three first has been well described by several navigators; and of the hurricane which desolated Barbadoes in the year 1780 we have a short but good account by Sir B. Blane.[2]

Whirlwind.

The name of *Whirlwind* has been given to eddying currents, seemingly depending on electricity, which sometimes rage with surprising fury in particular spots, tearing up trees by the roots, and overthrowing buildings. The extent of the whirlwind is usually confined; and as it passes through a forest it has been observed to form a lane or long track of inconsiderable breadth. The singular columns of moving sand, described by Bruce as occurring in Africa, appear to have been the effect of whirlwinds, or probably analogous to the meteor termed a *Waterspout,* which seems to be decidedly an electrical phenomenon.

---

[1] For an account of the Harmattan, see Norris in Philosophical Transactions, lxxi.; and Lind on Hot Climates.

[2] Edinburgh Philosophical Transactions, vol. i.

A curious account of waterspouts is contained in Michaud's *Mémoire* in the Transactions of the Academy of Turin, which has been translated in Nicholson's Journal (vol. i. 4to series). The conical pillar would appear to consist of condensed vapour, which often has the deep indigo-blue tint of the cloud from which it proceeds. As this column descends to the sea, the spot below it becomes agitated, and, according to some observers, the waters are bodily drawn up towards the cloud. But this opinion seems to be doubtful; for it is stated that the water discharged on the bursting of a waterspout is always fresh, and therefore any water derived from the sea must have passed into the air in the form of vapour. Besides, they generally dissolve merely into mist on touching the land.

Iris.

On the luminous meteors which appear in the air our space will not permit us to expatiate. The *Iris* is well known to be produced by the refraction of white light by the spherules of water in a cloud, as has been beautifully and satisfactorily demonstrated by Newton. The explanation of the single and the double iris will be found in every treatise on natural philosophy.

Aurora.

The *Aurora Borealis,* and the similar luminous *Southern Meteor,* are still objects of doubtful origin. The brilliancy of the colours is subject to periodical increments and intervals of decline; and, after a considerable period of obscuration, it has, within the last few years, again begun to blaze forth with increasing splendour. We have seen all the prismatic colours present in an aurora; and many years ago, in the Orkney Islands, we were enabled at midnight to distinguish letters of a large print by its light. From the distance to which the same aurora has been seen, the meteor must often be very high above the earth, perhaps in the utmost limits of our atmosphere; but at other times it appears to be nearer to the earth, and we have persuaded ourselves that we have heard a noise accompanying the sudden coruscations of a brilliant aurora.

Halo and parhelion.

The *Halo,* the *Parhelion,* and *Paraselene,* are optical phenomena produced by refraction of light by vapour, or minute spicula of ice floating in the air. Parhelia have been described by Scheiner, Gassendi, Delahire, Cassini, Halley, Muschenbroeck, and Epinus.[1]

Lightning has been considered, with other electrical phenomena, under ELECTRICITY. The identity of lightning with common electricity, as excited by the *machine,* was so completely established by the celebrated Franklin, that no doubt has since existed on the subject; and the recent discoveries of Oërsted and Seebeck have indicated a close affinity between the phenomena of electricity, heat, and magnetism. As the electrical state of the atmosphere is an important subject of inquiry, we beg leave to recommend to the philosophical traveller some instrument for ascertaining this quality of the atmosphere; and perhaps no better portable electroscope has yet been devised than the pocket instrument of Cavallo.

Bolis, St Elmo's fire.

The *Bolis, St Elmo's Fire, Castor and Pollux* of the ancients, appear to be electric meteors. The former we have twice seen. The last time was on the 18th of September 1835, at eleven P. M., when at sea. The head appeared an elliptical ball of the most intense, brilliant, bluish-white light; the train had a tint of azure mixed with reddish, which sufficiently distinguished it on the clear sky; and sparks proceeded from its tail. Its motion was nearly horizontal, from S. W. to N. E., at a considerable height. It was visible for five or six seconds, and disappeared in a dense cloud. It was observed by four gentlemen standing together on the deck, and we thought that it emitted a crackling noise as it proceeded, with a majestic uniform movement.

No. 28.

Shoo star.

The more common meteor, the *Shooting Star,* as it is vulgarly termed, seems to be an electrical ball of fire, at a considerable height in the atmosphere. Its general course is from the zenith towards the horizon, which it seldom appears to reach.

Ignis fatu

The *Ignis Fatuus,* or *Will o' the Wisp,* is a meteor which apparently is connected with decaying animal or vegetable matter; and probably is produced by the disengagement of phosphuretted hydrogene. It is frequently seen in boggy grounds, as a flickering, unsteady light, in irregular motion. It sometimes plays over dunghills; and has occasionally, to the extreme terror of the ignorant, appeared as a lambent flame in church-yards. Dr Derham saw it once playing about a dead thistle. The most extraordinary meteor of this kind is that described by Signor Beccari, in the Philosophical Transactions (vol. xxxvi.). In the low grounds to the north and east of Bologna, *ignes fatui* of remarkable splendour were at that time seen almost every dark night. That in the fields of Bagnara, to the east of the city, was especially brilliant. It appeared and disappeared suddenly; it rose and fell, and often hovered about six feet from the ground; it sometimes contracted its volume, then expanded or divided into two; would again unite, and assume the form of a wave of flame; often it dropped bright scintillations, and occasionally threw as much light upon the road as a large torch.

The curious meteor described by Dr Shaw[2] as running along the ground, and playing on the ears and mane of his horse, has its counterpart, on a smaller scale, in other countries, and has often been witnessed in Britain. It seems in some instances to be an electrical meteor; but possibly it may also arise from the disengagement of phosphuretted hydrogene from living animals, or of a luminous and unctuous matter, like that of the glow-worm, or of phosphorescent marine animals.

A lambent flame has occasionally been observed to play around the heads of children, which has probably a similar origin; it has been finely described by Virgil, in his account of the glory that surrounded the head of the young Ascanius.

> Ecce levis summo de vertice visus Iuli
> Fundere lumen apex, tractuque innoxia molli
> Lambere flamma comas, et circa tempora pasci.
> *Æn.* ii. 682.

SECT. VIII.—*Climate.*

Climat

The temperature of the atmosphere is derived from the heating of that portion of it in contact with the ground, which has received and absorbed the incident solar rays. Whilst the earth revolves on its axis, successive portions of its surface are illuminated and heated by the sun; but the excessive accumulation of heat in any particular place is prevented by the abstracting power of the air, and by the radiation from the earth's surface which takes place during the night. These causes alone, however, could not have secured the diffusion of warmth over a large portion of the earth. Had the axis of the earth been perpendicular to the plane of its orbit, the same places would have had the sun always vertical; the equatorial regions would thus have been parched with intolerable heat; and much of what is now the fairest portions of the globe, the seats of literature and the arts, would have been doomed to sterility and desolation. The simple yet stupendous contrivance of the inclination of the axis to the plane of the orbit, by bringing successive portions of the northern and southern hemispheres alternately under the vivifying solar influence, has rendered the largest portion of the globe the abodes of animated beings; the fervour of a tropical climate is thus rendered less oppressive, and the limits of the temperate regions are greatly extended. The division into five *Zones*, and their denominations, give us a general idea of the temperature in each; but these are very inadequate to express the diversities of atmospherical temperature. Ancient geographers distributed the earth's surface into twenty-six parallel bands or *Climates*, which were supposed to indicate, with sufficient exactness, the differences of the heat of each region, until the invention of the thermometer gave more precise information.

---

[1] See Priestley on Vision, and Muschenbroeck's Philosophy.

[2] Travels in Palestine and the East.

We have already stated how multiplied and careful observations may point out the mean temperature of any place, and the contrivances which have been resorted to for abridging the labour of the meteorologist; and philosophers have endeavoured to supply by calculation what is wanting in observation. The most ingenious of these speculators was Mayer of Göttingen. From an examination of such registers of temperature as he could obtain, he concluded "that the mean temperatures decrease from the equator to the poles, as the squares of the sines of latitude;" and therefore, if the mean temperature at the level of the sea under the equator were ascertained, this formula would enable us to calculate the mean temperature of any given latitude. Mayer applied his formula to the equatorial temperature as determined by Bouguer, = to 24° of Reaumur; but this has been found by Humboldt to be too high. It should have been only 22° of that scale, which is equivalent to 27°·5 of the centigrade, and to 81°·5 of Fahrenheit. With these corrections, Mayer's formulæ for the three thermometers, T signifying the temperature sought, will be

$T = 22^{\circ}\ {}^{2}\text{cos. lat.}$ for Reaumur.
$T = 27^{\circ}\cdot 5\ {}^{2}\text{cos. lat.}$ for Centigrade.
$T = 81^{\circ}\cdot 5\ {}^{2}\text{cos. lat.}$ for Fahrenheit.

Unfortunately, however, later observations have shown that Mayer's formula is worse than useless in high latitudes, and indeed is only found tolerably consistent with observation in latitudes between 40° and 60° N. The thermometrical registers of Scoresby, Parry, Franklin, and Ross, have proved that the mean temperature of the parallel between 70° and 75° is very far below what Mayer's formula would assign, and is even far below what that empirical rule would give to the pole. In low latitudes, too, it is not to be depended on; and it is totally at variance with the recent but well-established fact of *meridians of greatest cold.* No attempt of this kind has yet been found reconcileable with observation. In the mean time, the celebrated Humboldt has performed an acceptable service to science, by a more critical examination of the accumulated observations of his predecessors and contemporaries. The results he has given in his essay *on the Distribution of Heat over the Globe;* and the representation of them upon a chart of *Isothermal Lines* is peculiarly valuable, as deductions from actual observation. An inspection of such a chart shows, that these lines are neither parallel to the equator nor to each other. They are higher in Europe than at 100° to the E. or W. Thus the isothermal line of temperature 54°·5, in France passes through lat. 45° 46′; in China (long. 116° E.) it is in lat. 39° 54′; and in America, on the western coast (in long. 104° W.), it is in 44° 40′.

The isothermal lines descend lower in America than in Europe. Thus the line of 32°, or the freezing point, in Europe, lies in Lapland between 66° and 68°, but in America it passes on the coast of Labrador in lat. 54°; and this difference, which is small near the tropic, increases much with the latitude. Thus,

Lat.	Mean Temperature.		Difference.
	Old.	New.	
30°	70°·52 F.	66°·92 F.	3°·60
40	63 ·14	54 ·50	8 ·64
50	50 ·99	37 ·94	12 ·96
60	40 ·64	23 ·74	16 ·92

In both continents, the most rapid decrease of temperature takes place between lat. 40° and 45°. This circumstance has justly been considered by Humboldt as producing a happy influence upon the civilization and industry of the nations inhabiting these parallels; because there slight changes in latitude produce considerable diversity in the vegetable productions, which may become objects of rural economy; and when contiguous countries differ much in their products, it stimulates the industry of each, and gives vigour to commercial intercourse; circumstances highly favourable to civilization. The range of the thermometer is not the same under the same isothermal lines, as representing the mean temperature of the year. It is greater in the New than in the Old Continent. Thus, Cincinnati in America, and St Malo in France, are both on the isothermal line of 54°; yet the difference between the mean heat of summer and winter is 40° at the former, and but 32° at the latter. Even though the difference between the mean temperature of the seasons increase with the latitude, under the same meridians, yet the difference at Philadelphia in America, in lat. 40°, is much greater than at Copenhagen in Europe, in lat. 56°.

	Lat.	Mean of Summer.	Mean of Winter.	Difference.
Philadelphia. ...	40°	73°·94	32°·18	41°·76
Copenhagen.....	56	60 ·60	30 ·74	29 ·86

Effect of longitude.

The remarkable fact of the influence of *longitude* on temperature leads to the conclusion, that on each side of the equator there are two meridians, under which the mean temperature is lowest. These have been termed by Sir David Brewster the *cold meridians*, and their extremities are the *poles of greatest cold.* The position of these in the northern hemisphere may be approximated from recent investigations; and perhaps we shall not greatly err if we assign the longitude of 95° W. for the American, and of 100° E. for the Asiatic cold meridians. The apparent coincidence of the cold meridians with the general direction of Hansteen's lines of no variation is perhaps more than accidental, when we reflect that there seem to have been, in former ages, migrations of the cold meridians eastward and westward, coincident, as far as we can judge from recorded changes of climate in northern countries, with similar migrations of the magnetic needle.[1]

Effect of elevation above the sea.

Elevation above the sea is one of the most important circumstances by which climate is modified. As we ascend in the atmosphere the temperature diminishes, and under every latitude the summits of very lofty mountains penetrate into the abodes of perpetual congelation: such summits are covered with perpetual snows. The altitude at which this takes place varies with the latitude, diminishing from the equator to the poles. In climates where there is a great difference between the heat of summer and of winter, this point will fluctuate between two limits, one of which is the *upper*, the other the *lower limit of congelation.* The distance between them is least at the equator, and increases as we recede from it. This circumstance is important; for it influences the formation of those stupendous glaciers, that excite the astonishment of the traveller, on the elevated regions of the temperate zone, and on the declivities of the arctic circle.

---

[1] Traill in *Mémoires de la Société de Physique et d'Histoire Naturelle de Génève*, tom. iv.

Sir John Leslie concluded, from some experimental investigations, that in moderate elevations we might estimate this decrease of temperature as we ascend, at 1° of Fahrenheit for every 300 feet of elevation; and he has given a formula for computing the point of congelation for every latitude; which, however, does not agree with observation in high parallels. The same remark applies to Kirwan's formula,[1] which presupposes a gradual depression of the point of congelation in receding from the equator. The requisite data for his calculations are the mean temperature at the level of the sea at the equator and at the given place, and the height of the equatorial point of congelation. Thus, if we take the point of perpetual congelation at Humboldt's estimate of 15,744 feet, and the mean temperature at the level of the sea there at 81°·5, the difference between that mean temperature and 32° will bear the same ratio to the equatorial point of congelation, as the excess of the mean temperature at the given place above the freezing point, to the point of congelation at the latter. Thus, if we wish to find the point of congelation in this latitude, 56°, we turn to a table of mean temperatures, and find it = 49° Fahrenheit.

Perpetual congelation.

$$81{\cdot}5 - 32 = 49{\cdot}5, \text{ and } 49 - 32 = 17, \text{ and}$$
$$49{\cdot}5 : 15744 :: 17 : 5407.$$

On this formula, then, 5407 feet would be the point of perpetual congelation in our climate; and had we any mountain exceeding that elevation, its summit would be covered with perennial snow.

We apprehend, however, that no formula will apply to all latitudes; and we know that Kirwan's does not agree with observation in high latitudes.

Effect of vicinity of the sea.

Even when the latitude and elevation of two places do not differ greatly, they may suffer very different extremes of temperature. The chief agent in effecting this is the ocean. It has been found that the proximity of the sea, in all climates, affects the extremes of temperature. When cold air sweeps over the surface of the ocean, the caloric of the upper particles is diminished, their density is increased, and they sink, while their place is supplied by fresh particles from below, which becoming cooled in their turn, give rise to internal motions in the ocean. As the law of *expansion* during cooling from 39° to 32°, which forms so singular an exception in the case of fresh water, does not take place in sea-water, there is nothing to arrest these internal motions in the ocean:[2] and from its enormous mass, it is obvious that no partial application of cold, in this way, can sensibly reduce its mean temperature. Hence we find that the temperature of islands is not in winter so low as that of continents in the same parallels. Thus the severity of winter in Britain bears no proportion to that of continental regions under the same parallel. The Orkney Islands are in the same latitude as St Petersburg; yet, in the former, a frost of a week's duration is a comparatively rare occurrence, whilst at the latter, the wide, deep, and rapid Neva is for several months annually frozen over.

On the other hand, the ocean exerts a great influence in mitigating the excessive heat of tropical climates. It is true, that when the upper particles of its waters become heated, the internal motions cease; but the rarefaction produced sets a current in motion to the west (as becomes apparent in the Gulf Stream), the place of which is supplied by the influx of cooler waters from either pole. This is not all. The increased temperature is mightily diminished by increased evaporation; a process by which as much caloric is absorbed as would be capable of heating an equal weight of water 942° Fahrenheit. Hence tropical islands are less oppressively hot than continents in the same latitude. The summer temperature of the smaller Antilles, for instance, is lower than that of the same parallels in America, Africa, or Arabia. The intersection of continents by arms of the sea, or by vast collections of water, tends to mitigate the fervour of summer. The extended form of the old continent toward the east renders inequalities of temperature much greater in Eastern Asia than under the same parallels in Europe. Thus, at Pekin, in latitude 40° N., longitude 116° 20′ E., the mean temperature of summer is 78°·8, and of winter 23°—a difference of not less than 55°·8, which gives rise to a frost of several months' duration in that part of China; yet Pekin is under the same parallel as the southern extremity of Naples, where frost is unknown, and of the central provinces of Spain, in which, though at an elevation of 2000 feet above the sea, ice is an extremely rare occurrence.

The face of a country, though less important than the circumstances already noticed, affects its climate. A region shrouded in primeval forests, or covered with swamps and marshes, will have a different temperature when cleared and drained. Marshes, by evaporation, rob the surface of much of its heat; and forests, by intercepting the sun's rays, the source of terrestrial warmth, and by the increased exhalent surfaces exposed to the air, undoubtedly have some effect on mean temperature. In hot climates forests tend to cool the air, and in frigid regions to prevent the loss of the earth's heat by chilling blasts. The clearing of forests may thus affect the temperature, and the draining of marshes increase the salubrity of particular regions; but the mere effect of cultivation can never be very considerable in changing a climate.

A combination of several of the causes already noticed as affecting climate have conspired to render the North American continent colder than the same parallels in Europe. Thus Nova Scotia and Canada, in latitude 47°, are in the same parallel as the central provinces of France and Upper Italy. In the former, the cold of winter has been observed as low as —40° Fahrenheit, or 52° below the freezing point of water; and the lakes and rivers of that part of America are bound up in impenetrable ice during four or five months of the year; while in the latter, in ordinary seasons, the severity of winter is scarcely felt. Labrador and England, each in latitude 53°, differ widely in mean temperature.

	Mean Temperature.		
	Summer.	Winter.	General.
Labrador...........	51°·8	3°·2	= 27°·5
England...........	62 ·6	37 ·4	= 50

The climate of America, however, should not be compared with that of Europe, but with the eastern side of the old continent. The eastern sides of both, from causes which perhaps are not easily explained, are certainly colder than the western; and when observations are multiplied on the western shores of America, it will probably be found that both continents approximate more nearly in mean temperature than the above comparisons would seem to indicate. In fact, the whole of Europe, as Humboldt has remarked, has an *insular climate* compared with the eastern parts of Asia and America; "and upon the same isothermal line the summers become warmer, and the winters colder, in proportion as we advance from the meridian of Mont Blanc to the east or to the west."[1] The eastern parts of China, and the Atlantic portions of the United States, have great differences between their summer and winter temperatures, or they are what Humboldt terms *excessive climates;* whilst all that we yet know of California, and of the country between it and the mouth of the Columbia, shows that the mean temperature of their winters and summers differs much less, and that they approach more nearly to the climate of Europe.

---

[1] Essay on Climate.

[2] Dr Hope, Transactions of the Royal Society of Edinburgh.

The distribution of the land in high latitudes is not unimportant as regards climate. Land is more easily heated than water by the sun's rays; and where the icy barriers are in contact with land, there is a greater probability of their being melted by the heat of summer, than where the ice extends over a large surface of uninterrupted ocean. This seems to be one cause of the greater extent of the southern than of the northern polar ices.

Had the globe been uniformly covered by water, the progression of climate would probably have been very regular. Indeed it might be shown, that the effect of the polar currents produced by equatorial rarefaction, supposing them to move with a velocity of two miles per hour, or to make three annual transfers from the pole to the equator, would be sufficient to produce the variations of temperature which are experienced at the level of the ocean.

On the whole, the peculiarities of climate are chiefly attributable to latitude, elevation, the distribution of land and water, proximity to the cold meridians, the humidity or dryness of the air; to which we may add, though less important, the prevalence of particular winds, the transparency or cloudiness of the sky, and the state of the general surface of any country.

SECT. IX.—*Geographical Distribution of Plants.*

Whoever considers the vast accessions made to our list of vegetable species within the last twenty years, and the immense tracts of the earth still unexplored by scientific men, will readily conceive that we are yet in no condition to pronounce even as to the probable amount of the existing plants. In Professor Lindley's Introduction to Botany, the following is an approximation to known species.

	Phænogamous.	Cryptogamous.
Number of described species, according to Sprengel, in 1827...	31,000	6,000
Add for errors and suppression of real species	6,000	1,000
Add for India and the rest of Asia	10,000	2,000
Add for America	20,000	
Add for Africa	10,000	
	77,000	9,000

But if this afford a just estimate of the known species, it cannot give us any idea of the plants existing on the globe. Europe, with a surface $\frac{1}{9}$th that of Asia and Africa, and in some respects less favourable to a varied vegetation, has a flora more numerous than either, and, till within a few years, superior to both united. This can only be attributed to the greater diligence with which the botanic riches of Europe have been explored, and may lead us to suspect that we are yet far from a knowledge of all existing species.

While botanists considered plants only as belonging to artificial systems, the progress of geographical phytology was inconsiderable. Tournefort, in ascending Mount Ararat, had observed at its foot the plants of Western Asia; but a little way up he recognised the vegetable forms of Italy; at a still higher level, those of Central France; next those of Sweden; and beyond them the flora of Lapland and the Alps.

Similar remarks were occasionally made by other botanists in other regions. They had determined with considerable accuracy the northern boundaries of some plants, especially those useful to man; but whilst the method of grouping plants was merely artificial, the physical laws which regulate their distribution were not perceived, and the circumstances which limit certain vegetable forms to particular situations were not comprehended. Humboldt's essay on the geography of plants appeared at Paris in 1807, and contained some generalizations on the succession of vegetable forms in Equinoxial America; but it is admitted on all hands, that the disquisitions of Dr Robert Brown, in the Supplement to Flinders' Voyage, published in 1814, led the way to still more extensive generalizations on the geographical distribution of plants, and first indicated the proportions that subsist in different places between the three great divisions of the vegetable kingdom. Since that period, the progress of vegetable geography has been rapid, chiefly through the labours of Von Humboldt, Brown, Wahlenberg, Decandolle, Von Buch, Parrot, Hornemann, and Schouw; and this improvement is ascribed, by the illustrious philosopher first named, to the adoption of the natural method of Jussieu. To none of these writers are we more indebted than to Von Humboldt. The ideas developed in his *Essai sur la Géographie des Plantes*, and in his *Tableaux de la Nature*, were expanded in the *Prolegomena de Distributione Geographica Plantarum.* His invaluable *Mémoire* on isothermal lines (*Mém. d'Arcueil*, and Edin. Phil. Journ. iii. iv. and v.), and, last of all, his New Enquiries into the Laws which regulate the distribution of Vegetable Forms (same Journal, vi.), contain an admirable summary of almost all we know on vegetable geography.

The primary divisions of the natural arrangement are into *acotyledones*, which include the ferns, fungi, lichens, mosses, sea-weeds, &c.; *monocotyledones*, including palms, rushes, sedges, grasses, liliaceous plants, &c.; *dicotyledones*, which comprehend all plants not contained in the other groups. The circumstances on which the geographical distribution of these different vegetable forms depend, may all be comprehended in climate and soil. The causes chiefly modifying climate are, latitude, elevation above the sea, longitude, moisture, and insolation; particularly the first two. We shall endeavour to point out very generally how vegetation is modified by these circumstances; and, first, of the effect of latitude.

Effects of latitude on plants.

In proceeding from the equator towards either pole, the temperature diminishes; but we have seen that the isothermal lines are not parallel to the equator, and the vegetable forms which characterize them descend lower in the new than in the old continent. In equatorial regions the vegetation consists of dense evergreen forests, characterized by palms and arborescent ferns, mixed with Epidendra and rigid grasses; and the lower tribes of vegetable life, such as Fungi, Confervæ, and Musci, are very rare; but Musaceæ, Melastomaceæ, Scitaminiæ, Myrtaceæ, Piperaceæ, and the larger Compositæ, are very frequent. On receding from the equator these tropical forms give place to Rosaceæ, Coniferæ, and Amentaceæ; verdant meadows of soft grasses intersperse the landscape, the epiphytal Orchidiæ disappear, and are succeeded by plants whose fleshy roots draw their sustenance from the soil; the trunks of aged trees are clothed with mosses, parasitic Fungi invest decaying vegetables, and the waters abound with Confervæ. On entering the frigid regions trees disappear; dicotyledonous plants become more and more rare; and Gramineæ, Mosses, and Lichens are the last retreats of vegetable life. The northern hemisphere, with which we are best acquainted, is by Humboldt divided into six isothermal bands.

---

[1] Edinburgh Philosophical Journal, vol. iii.

1st band has a mean temperature above 77° F., and may be considered the natural region of Palms, of the Banana, and the Coffee-tree. It extends northwards in the old continent to lat. 32°, in the new to 23° 30′.

2d band, with a mean temperature ranging between 77° and 68°, is the proper region of the Citron and its varieties. In the old continent it reaches to 37° or 38°, in the new to 29°.

3d band, with a mean temperature from 68° to 59°, is the true region of the Olive and the Vine. In the old continent it extends to 43° 30′; in the new, and in Eastern Asia, to 32° or 33°.

4th band, with a mean temperature from 59° to 50°, produces the Vine, and in perfection Wheat, and the Oak. In Europe it extends to 52° 25′, in America to 42° 25′, in China to 40°.

5th band, with a mean temperature from 50° to 41°, is the region of various Cerealia, and of forests of Quercus Robur. In Europe it extends to lat. 60°, in America probably to 50°.

6th band, with a mean temperature from 41° to 32°, is the native region of the Pine, the Birch, and the Willow, in its lowest parallels; and in its higher, of alpine plants, Lichens, and Byssi. It reaches to the limits of perpetual congelation. In Europe it extends to lat. 71°, in Asia to the arctic circle, but in Eastern America only to 57° 8′.

Effect of elevation.

But the effect of elevation above the sea is no less striking, and is capable of counterbalancing or of subverting the influence of a low latitude. Wherever lofty mountains occur in the torrid zone, their summits are veiled in perpetual snows; and the ascent presents the flora of a vast variety of climates. This is beautifully illustrated in Humboldt's *Géographie des Plantes Equinoxiales*, the chart of which forms Plate CCCCXII. in this volume. He divides Equinoxial America into eight regions.

1. The region of Palms, Scitaminiæ, and Liliaceæ. This is the habitat of true Palms, of the Musa, Theophrasta, Mussænda, Pumeria, Cæsalpinia, Hymenæa, Cecropia, and Cusparia. It extends from the level of the sea, under the equator, to the elevation of 5700 feet. One species of tree found in this region extends to the height of 6800 feet.

2. The region of arborescent Ferns, and the true Cinchona. Gigantic Ferns first appear at the height of 1200 feet, and disappear at an elevation of 4900 feet. The medicinal Cinchonæ attain the height of 8800 feet.

3. The region of Oaks commences at 5200 feet, and reaches to

4. The region of Shrubs. Trees disappear entirely at a height of 10,800 feet, and are succeeded by shrubby plants.

5. The region of plants corresponding to the alpine plants of Europe. These are first found at 6100 feet above the sea, and continue to the great height of 12,600 feet. Amongst these the most conspicuous are the genera Gentiana, Lobelia, Ranunculus, &c.

6. The region of Grasses. Here the Gramineæ are the sole vegetable produce; and the principal genera are Avena, Agrostis, Dactylis, Panicum, Stipa, Javara. In this region snow regularly falls, and the plants enumerated continue to the vast elevation of 14,200 feet.

7. The region of the Hyperoxylon, Byssi, Hepaticæ, and Lichenes. These lowly and hardy forms of vegetable life continue to the very verge of uninterrupted winter, which in the

8. Region covers the Equinoxial Andes, from the height of 15,700 feet, to their towering summits.

In the temperate climate of Europe, the changes produced by elevation, though less striking, are not less important on vegetation. M. Ramond, in examining the Pyrenees, found vegetable forms distributed into very regular zones.

1. The region of Oaks lies at the foot of the chain, and is chiefly characterized by Quercus Robur, which continues to the elevation of 4800 feet above the sea.

2. The zone of Beeches, characterized by the Fagus Sylvatica, commences at 1800 feet above the sea, and extends to 1400 feet beyond the oaks, rising to 5200 feet, or to a mile, in height.

3. The region of the Silver Fir, or Pinus Picea, and Yew. It commences at 4200 feet, and extends to the height of 6000 feet, or 600 beyond the region of Beeches.

4. The region of the Pinus Sylvestris and Pinus Pumilio, commencing at 6000 feet, and extending to an elevation of 6200 feet; and this is the extreme limit of trees.

5. Region of dry-leaved shrubs and creeping plants, such as Rhododendron, Daphne, Passerina, Globularia Repens, and two diminutive species of willow, Salix Herbacea and S. Reticulata. The limit of this last is uncertain, but it rises much beyond this region.

6. The region of alpine plants with perennial roots and naked stems; as Gentiana, Primula, Saxifraga, Ranunculus. The extreme limit of phænogamous plants is marked by Ranunculus Glacialis, Saxifraga Cespitosa, S. Oppositifolia, S. Androsacea, and S. Groenlandica. These elegant but hardy individuals, intermixed with Byssi and Lichens, reach to

7. The region of perennial snow.

As a further illustration, we may give the progress of vegetation within the arctic circle from the masterly sketch of Wahlenberg. In ascending the Lapland Alps, from the head of the Gulf of Bothnia, he found eight well-marked zones.

1. The region of the Spruce Fir had almost ceased before reaching the mountains. It had become a slender pole, with short, drooping branches. The Rubus Arcticus had ceased to ripen its fruit, and the pools were no longer ornamented with Arundo Phragmitis, Galium Boreale, and Carex Globularia. The upper limit of the Spruce Fir is 3200 feet below the line of perpetual snow. This is the true region of Tussilago Nivea; it has a mean temperature of 37°·5 of Fahrenheit.

2. Pinus Sylvestris, or Scotch Fir, is still found; but its stem is low, and its branches widely spread. In this region is the last appearance of Ledum Palustre, Salix Pentandra, and Veronica Serpyllifolia. Near the upper limit of the Scotch Fir the Phaca Alpina is found, and the berries of Vaccinium Myrtillus do not ripen well. The upper limit of this zone is 2800 feet below the line of snow; its mean temperature 36°·5 Fahrenheit. A little below this boundary barley ceases to ripen; but grazing farms, with turnips and potatoes, are cultivated, even 400 feet higher.

3. The zone of the Birch with short, thick stems and knotty branches; its lively green leaves are refreshing to the eye, but the tree is diminished, so as to be commanded from every eminence. The upper boundary of the Birch is 200 feet below the line of snow. The Alnus Incana, Prunus Padus, and Populus Tremula, had long before this disappeared; and Sorbus Aucuparia, Rubus Arcticus, and Erica Vulgaris, disappear near the upper limit of this region; but the drier spots produce Lichen Rangiferinus, Tussilago Frigida, and Pedicularis Sceptrum Carolinum, to the upper boundary of the Birch.

4. The lower skirts of this region are covered with the

dark foliage of Betula Nana; Salix Glauca fringes the streams; every hill is covered with Arbutus Alpina, and variegated with Andromeda Cærulea and Trientalis Europæa; while the bogs are ornamented with Andromeda Polifolia and Pedicularis Lapponica. This zone reaches to within 1400 feet of perpetual snow.

5. Brush-wood has disappeared; Salix Lanata is two feet high; Betula Nana creeps along the ground; the hills abound with Azalea Procumbens and A. Lapponica. No berries ripen here, except those of Empetrum Nigrum. This zone rises to within 800 feet of the line of snow; its mean temperature is 34° Fahrenheit.

6. Region where patches of snow remain all the year. Bare places still produce a few shrubby plants, as Empetrum Nigrum, Andromeda Tetragona, and A. Hypnoides, Gentiana Nivalis, G. Tenella, Draba Alpina, and Dryas Octopetala. This zone reaches to within 200 feet of perennial snow, which forms

7. Zone in which, wherever a patch of soil is visible, various Saxifrages and Ranunculi appear. The upper limit of this region is 4200 feet above the sea; but on the higher mountains we have an

8. Region of pure snow. Yet even here, if a southern aspect chance to thaw for a few days any cleft in a rock, a few hardy specimens of Ranunculus Glacialis venture to bloom. The plant has been gathered even 500 feet above the last zone; and Umbilicated Lichens have been seen 2000 feet above the line of perennial snow. The mean temperature of the eighth region is 30° Fahrenheit.

In these instances, then, the effect of elevation is equivalent to latitude; but it must be recollected, that plants will not thrive equally in places with the same mean temperature. Some require a strong ephemeral heat. Hence, in judging of the aptitude of any place for rearing particular plants, we must compare the mean temperature of the summer, as well as of the whole year, before we decide. Thus we are enabled to explain why the Pistacio-nut ripens in Pekin, but will not ripen in France, where the isothermal line for the whole year is the same; but though the Chinese winter be more severe than that of France, the summer heat is far greater. Innumerable other instances might be adduced of the same fact. The moisture of a climate has much influence upon its vegetation. Water is the vehicle of the food of plants, and perhaps yields a great proportion of it. If moisture be deficient, plants die; but they require water in very different proportions. Those with soft, broad, smooth leaves, that grow rapidly, and have many cortical pores, require much water to maintain their vitality; on the other hand, plants with few cortical pores, with oily or resinous juices, and small roots, will generally thrive best in dry situations.

Insolation, or exposure to light, is necessary for most plants. The green colour of plants is only formed in light, as is shown by etiolation; and light appears to be the cause of certain movements which are remarked in the flowers of most plants, and in other parts of some delicately organized individuals, which open and close their leaves according to the degree of light. This last property is chiefly seen in tropical plants. Light appears to be necessary to the decomposition of carbonic acid, and the fixation of carbon in their tissues; and it is indispensable to the right performance of the function of reproduction.

The influence of soil on vegetables is seen in the preference which many plants have for a calcareous soil; some affect siliceous sands, others clay retentive of water; some plants thrive best in the clefts of slaty rocks; some delight to dwell amid granitic rocks, and others on a saliferous soil. Earthy matters enter largely into the composition of some vegetables; and, in the epidermis of the Gramineæ, silica is invariably found. The presence of animal matter in soils is necessary to many plants, and is generally nutritive to all. Iron and copper are found in small quantities in some plants. The *stations* of particular plants have often been determined by these peculiarities of soil; and where a soil and climate are equally suitable for many *social plants*, we find them growing together, until the strongest obtains the mastery, and chokes the others. Thus Erica Vulgaris appears to have usurped in Europe a space once occupied by other genera, if we may judge by what generally happens on exterminating heath; for then other plants very speedily make their appearance, the seeds of which seem to have long preserved their vitality in the earth, and only to have wanted room to spring into visible existence.

A combination of these causes no doubt influences the distribution of particular species. Thus, in the old world, Ericeæ and the Proteaceæ of Southern Africa are peculiar, and are replaced in Australia by Epacrideæ and new genera of Proteaceæ. The Banksia, the Yucca, the Goodenia, and the leafless Acacia, are peculiar to the latter country. The Cinnamon, Nutmeg, and Clove are confined to the Indian islands; the Thea and Camellia are indigenous to China. America does not contain a single species of Erica, from one extremity to the other; nor has a Pæonia ever been found in it, except a solitary one observed by Douglas to the west of the Rocky Mountains. That mountain barrier divides two vegetations, almost as peculiar as those of two continents. On its eastern side the forests of North America are distinguished by the variety of their Oaks and Juglandes, the magnificent inflorescence of the Rhododendron, the Magnolia, the Azalea, and the humbler beauties of the Actea and Vaccinium; all of which are utterly unknown on the western side of that ridge. America is the real habitat of the Cinchonaceæ and the Cacti, of the Fuschia, the Calathea, the Mustisia, and all the Bromeliaceæ.

Numerical relations between different varieties of plants.

One grand question in vegetable geography, first considered by Brown, has yet to be noticed, viz. the numerical relations that subsist between different vegetable forms. We may ask, which natural families of plants abound most over the world? and give in succession the comparative numbers that are known to exist. This interesting comparison has been attempted in Decandolle's grand work. But this information is less important and satisfactory than the investigation of the relation which the numbers of each family bear to soil and climate. The question thus becomes far more complex; and we are under the necessity of comparing the ascertained number in each division with the whole mass of phænogamous plants.

It is to this last mode of studying vegetable forms that the admirable inquiries of Humboldt are directed. We strongly recommend the whole of that paper to the perusal of our readers. Our limits will only permit us to give his table of the numerical results of his investigations of the distribution of certain extensive families which exert a marked character on the vegetable physiognomy of the countries where they occur.[1]

In the following table the sign ↗ indicates that the denominator of the fraction diminishes from the equator towards the pole; ⟶ that it diminishes towards the equator; ⟵ that it diminishes from the north pole and the equator to the temperate zone; ⟶ ⟵ that it diminishes towards the equator and the north pole.

---

[1] The *Agamæ* of Humboldt correspond to the *Acotyledones* of other botanists; his *Glumaceæ* include the families of *Monocotyledones* indicated in the table.

Groups founded on analogy of Form.	Proportion to the whole mass of Phænogamous Plants.			Signs indicating the direction of the Increase.
	Equatorial Zone. Lat. 0° to 10°.	Temperate Zone. Lat. 45° to 52°.	Frigid Zone. Lat. 67° to 70°.	
Agamæ (*ferns, lichens, mosses, fungi*)	Plains, $\frac{1}{15}$ Mountains, $\frac{1}{5}$	$\frac{1}{2}$	$\frac{1}{1}$	↗
Ferns alone	Countries nearly flat, $\frac{1}{20}$ Very mountainous, $\frac{1}{3}$ to $\frac{1}{8}$	$\frac{1}{70}$	$\frac{1}{25}$	←→
Monocotyledones	Old Continent, $\frac{1}{5}$ New Continent, $\frac{1}{6}$	$\frac{1}{4}$	$\frac{1}{3}$	↗
Glumaceæ (junceæ, cyperaceæ, gramineæ)	$\frac{1}{11}$	$\frac{1}{8}$	$\frac{1}{4}$	↗
Junceæ alone	$\frac{1}{400}$	$\frac{1}{90}$	$\frac{1}{25}$	↗
Cyperaceæ alone	Old Continent, $\frac{1}{22}$ New Continent, $\frac{1}{50}$	$\frac{1}{20}$	$\frac{1}{9}$	↗
Gramineæ alone	$\frac{1}{14}$	$\frac{1}{12}$	$\frac{1}{13}$	↗
Compositæ	Old Continent, $\frac{1}{18}$ New Continent, $\frac{1}{12}$	Old Cont. $\frac{1}{8}$ New Cont. $\frac{1}{6}$	$\frac{1}{13}$	→ ←
Leguminosæ	$\frac{1}{10}$	$\frac{1}{18}$	$\frac{1}{35}$	↘
Rubiaceæ	Old Continent, $\frac{1}{14}$ New Continent, $\frac{1}{25}$	$\frac{1}{60}$	$\frac{1}{80}$	↘
Euphorbiaceæ	$\frac{1}{32}$	$\frac{1}{80}$	$\frac{1}{500}$	↘
Labiatæ	$\frac{1}{40}$	America, $\frac{1}{40}$ Europe, $\frac{1}{25}$	$\frac{1}{70}$	→ ←
Malvaceæ	$\frac{1}{35}$	$\frac{1}{200}$	0	↘
Ericeæ and Rhododendra	$\frac{1}{130}$	Europe, $\frac{1}{100}$ America, $\frac{1}{36}$	$\frac{1}{36}$	↗
Amentaceæ	$\frac{1}{800}$	Europe, $\frac{1}{45}$ America, $\frac{1}{25}$	$\frac{1}{20}$	↗
Umbelliferæ	$\frac{1}{500}$	$\frac{1}{40}$	$\frac{1}{60}$	→ ←
Cruciferæ	$\frac{1}{800}$	Europe, $\frac{1}{18}$ America, $\frac{1}{60}$	$\frac{1}{24}$	→ ←

"On comparing the two continents, we find in general in the new world, under the equatorial zone, fewer Cyperaceæ and Rubiaceæ, but more Compositæ; under the temperate zone, fewer Labiatæ and Cruciferæ, and more Compositæ, Ericeæ, and Amentaceæ, than in the corresponding zones in the old world. The families that increase from the equator to the pole, according to the method of fractional indications, are Glumaceæ, Ericeæ, and Amentaceæ. The families which decrease from the pole to the equator are Leguminosæ, Rubiaceæ, Euphorbiaceæ, and Malvaceæ: the families that appear to attain their maximum in the temperate zone are Compositæ, Labiatæ, Umbelliferæ, and Cruciferæ."

Botanical regions.

Botanists have attempted to divide the globe into botanical regions. The first successful attempt of this kind was made by Decandolle, who divides it into twenty regions, the designations of which are drawn from particular portions of the earth, marked by the peculiarity of their vegetable productions. But the most able and luminous exposition of this sort is the *Phyto-Géographie* of Professor Schouw. The designations of each kingdom or region are usually derived from some of its most characteristic vegetable productions; but where we are not sufficiently acquainted with the botany of certain districts, he uses a geographical designation. Schouw divides the earth into twenty-two botanical regions, of which our limits will only allow a very imperfect sketch.

1. *Region of Saxifragæ and Musci*, or of the alpine arctic flora.—This includes all countries within the arctic circle.

2. *Region of Umbelliferæ and Cruciferæ.*—This includes the whole of Europe north of the Pyrenees not included in the last region, most of Siberia, and the Caucasus.

3. *Region of Labiatæ and Caryophylleæ*, or Mediterranean flora.—It includes the south of Europe, north of Africa, the Canaries and Azores, as well as Western Asia.

4. *Japanese Region* includes Eastern Asia and Northern China.

5. *Region of Asteriæ and Solidagines.*—The north-eastern part of the United States. It is marked by the varieties of its Oaks and Pines.

6. *Region of Magnoliæ.*—This comprehends the southern portion of the United States.

7. *Region of Cacti, Melastomaceæ, and Piperaceæ.*—This includes Lower Mexico, the West Indies, and the northern coast of South America.

8. *Region of Cinchonaceæ.*—This includes Bolivia and Columbia to a certain elevation, or Peru and New Granada.

9. *Region of Escalloniæ, Calceolariæ, Winteriæ, and Vaccinia.*—It includes the highest parts of South America.

10. *Chilian Region.*—It is formed into a district region, because not above one half of its plants occur in the lower regions of South America.

11. *Region of Arborescent Compositæ.*—This includes Buenos Ayres, and the eastern division of temperate South America.

12. *Antarctic Region.*—This includes the southern part of the American Continent, the Magellanic region of Decandolle.

13. *New Zealand Region.*—It has many plants in common with New Holland, as Epacris, Melaleuca, and Myoporum; some common to South America, as Wintera, Ancestrum, and Weinmannia; some common to South Africa, as Gnaphalium, Xeranthema, and Mesembryanthema; some which seem peculiar, as Phormium, Areca Sapida, Dracæna Indivisa.

14. *Region of Epacrides and Eucalypti.*—This embraces the southern parts of Australia and Van Diemen's Land. The families of Tremandreæ, Stackhouseæ, Protaceæ, Eucalypti, Cassuarineæ, Diosmeæ, Stylideæ, &c. characterize it.

15. *Region of Mesembryanthemum and Stapeliæ.*—This comprehends the south of Africa. Besides these plants, it is distinguished for the number and beauty of its Ericæ. It possesses several plants mentioned under 13, which are only found in it and Australia. It abounds in compositæ.

16. *Region of Western Africa.*—Its characteristic is Adansonia, the largest of known trees. Many of its Cyperaceæ are peculiar. It wants, or has very sparingly, the American Cacti, Palms, Peppers, and Passion-flowers.

17. *Region of Eastern Africa.*—Two thirds of its known

plants belong also to India. This region includes Madagascar.

18. *Region of Scitamineæ.*—This includes the flora of the Indian peninsula. It contains Carcuniæ, Zedoariæ, Cardamona, &c.; and its Scitamineæ are more numerous than the same family in America.

19. *Himalayan Region.*—Tropical forms here disappear. It bears a strong resemblance in its vegetation to some parts of Europe. Orchideæ and Filices are numerous. It presents the Cerealia and Fruits of Europe.

20. *Southern Chinese and Cochin-Chinese Region.*—The flora of this region is little known, but appears peculiar.

21. *Region of the Cassia and Mimosa.*—This includes Persia and Arabia. The peculiar plants are Senna, Balsamadendron, Cadia, Caucanthus, Stræenia, Coffæa Arabica. Ferula Assafœtida belongs to it.

22. *Polynesian Region.*—Most of the genera are common to this region and India, or to America.

SECT. X.—*Geographical Distribution of Animals.*

The slightest acquaintance with zoology is sufficient to show that animals do not indiscriminately spread themselves over every part of the habitable earth. One species is found to be peculiar to a certain region, and sometimes is represented in another region by an analogous yet different animal. Difference of climate, and the greater or less facility of procuring subsistence, are often the probable causes of such limitations, when animals have the power of emigration; but in numerous instances we can trace the operation to no secondary cause. Why, for instance, should animals, incapable of crossing arms of the sea, be found in certain insular situations, and denied to other lands, seemingly as well fitted for their propagation and their maintenance?—why should the forms of organization which we find to prevail in one portion of the globe be represented in another by other forms, and by a very different though not less admirable structure? In this species of inquiry, one thing is demonstrable, that if, in every class of animals, we compare their organization with the intended residence and mode of life of each creature, with its necessities and the nature of its aliment, the most admirable adaptation of means to the end is everywhere perceptible; whether we consider the instinct which impels the ant and the hamster to lay up stores of food for the season of scarcity, or the bee at once to solve a delicate problem in practical geometry; whether we regard the structure of the proboscis of the gnat or of the elephant as suited to their wants; or whether we contemplate the form and position of the levers that move the limbs of animals, or the exquisite mechanism of the visual organ; all proclaim the handiwork of a wise and beneficent Creator.

ogical ions.

To us it appears evident that nature has only distinguished animated beings into *species*, the limits of which are fixed by the capability of procreating fertile progeny; and that all our divisions into *genera*, *orders*, and *classes* are more or less artificial, though of high value in assisting the memory to recollect individuals, or to arrange newly-discovered species, and often as leading to interesting inferences respecting their habits and geographical distribution. When several species resemble each other in structure and habits, we agree to consider them as of one genus; when their resemblances are somewhat less numerous, we consider them as belonging to the same order; and when their similarity is confined to a few points, they are grouped in the same class. All these divisions are but artificial helps to our memory, whether we follow the system of the illustrious Swede; or, with Cuvier, found distinctions more on the anatomical structure of the animals; or, with our sagacious countryman Macleay, attempt to reduce all recognized animals to *quinary circular groups;* or, with Swainson, resolve these circles into *ternary* associations; or, with Kirby, expand these groups into the magic number *seven*. Some arrangement is absolutely necessary in pursuing the subject of animal geography, when we consider the multitude of species; and perhaps no system is so convenient as that of Cuvier, from its very general reception, and its sufficiently according with the geographical distribution of species.

Number of species.

It is not easy to give any accurate idea of the real number even of known species of animals, from the difficulties thrown in the way of animal statistics, by the multiplication of species, and from confounding the effects of sex and age on some animals, and overlooking specific differences in others. Naturalists have differed widely on this subject. The estimate of Keferstein, as exhibiting the number of extinct as well as of living species, is interesting.[1]

	Living.	Extinct.
Mammifera	883	270
Aves	4,099	20
Reptilia	1,270	104
Pisces	3,586	386
Insecta		247
Arachnida		211
Mollusca	3,816	6,056
Annelida	102	214
Radiata	187	411
Polypi	816	907
	14,759	8,826

But this table contains no account whatever of living insects and arachnides. Mr Swainson[2] gives the following as the numbers known at a later period.

Mammifera	1,000
Aves	6,000
Pisces	6,000
Insecta	120,000
Mollusca	5,100
Radiata	1,000
Polypi	1,500

In the same work Swainson has given a conjectural estimate of the number of probably existing species.

Vertebrata	17,500	Mammifera	1,200	Sp.
		Aves	6,800	...
		Reptilia and Amphibia	1,500	...
		Pisces	8,000	...
Annulosa	552,500	Insecta	550,000	...
		Vermes, &c.	2,500	...
Mollusca	7,600	Radiata, star-fish	1,000	...
		Polypi, corals	1,500	...
		Mollusca, nuda	600	...
		Testacea	4,500	..
	577,600		577,600	

Besides these, there exist innumerable hosts of *Infusoria*, in which the researches of Ehrenberg have detected remarkable peculiarities of structure; proving that, though minute, they possess a very complex organization, not less wonderful than the anatomy of the higher animals.

To these statements we may add, that M. Temminck has lately given the number of well-ascertained *mammifera* as =930, besides 140 species which he considers as doubtful; that the birds of our recent catalogues exceed 6000; and that Cuvier had enumerated 6000 species of fishes. With regard to insects, some naturalists have stated, that at least two species of insects feed on every species of plant; and therefore, that as the ascertained vegetable species amount to 86,000, there must be 172,000 species of insects.

---

[2] ZOOLOGY, vol. ii. of the Cabinet Cyclopædia.

Geographical distribution of animals,

The evident tendency of animals to be congregated in groups peculiar to certain divisions of the earth's surface, had long been familiar to zoologists; but it does not appear that any attempt was made to define the limits of those zoological divisions until the appearance of the essay of Mr Swainson, in the Cabinet Cyclopædia. The ingenious author has there shown the claims of Europe to be considered as one of the grand zoological divisions of the globe, from the number of the types of natural families which it possesses. Swainson contends that the *birds* of any district afford a fairer criterion of the limits of a geographical distribution than any other class of animals. Quadrupeds he believes to be too much under the dominion of man, and liable to have their geographic limits disturbed by human interference; and the other classes of animals are either too numerous or too few to afford the means of determining the limits of such divisions; whilst birds, though seemingly fitted by nature to become wanderers, are surprisingly steady in their localities, and even in the limits of their annual migrations. These migrations are evidently caused by scarcity of food. Thus our swallows leave us when their insect food begins to fail, and they naturally pursue that route which is shortest, and affords subsistence by the way. The distance from the shores of the Baltic to Northern Africa is not half so great as that between England and America; and during the migration over land, the winged travellers find food and resting-places as they proceed to more genial climates.

The distribution of mammifera may probably be less characteristic than that of birds in Europe, where the long progress of civilization, and the spirit of commercial enterprise, have blended the races of the larger animals; so that it would be difficult, in most cases, to trace the native country of their original stock: but in most other parts of the world peculiar quadrupeds might be found sufficiently characteristic of each division.

The natural associations of animals have suggested another division of the earth into zoological *kingdoms;* and, did our limits permit, it would not be difficult to subdivide these into zoological *provinces*, each distinguished by some less considerable peculiarities of its animal productions. It is at once apparent, that these divisions will not correspond to the zones of the geographer, which do not coincide with marked differences in climate, nor with the supply of food, nor with the configuration of the dry land; circumstances most materially influencing the distribution of animals. The earth may be divided into fourteen *zoological kingdoms;* the first eight belong to the old, the six last to the new world.

OLD WORLD.

in the old world;

1. *Palæonarctic Kingdom.*—This division includes all Europe and Asia within the 60th degree of N. lat. Many of its mammifera and birds are common to it and the northern regions of America, and its peculiar animals of this class are but few. The Polar Bear it has in common with North America, but the Rein-Deer of Northern Europe now appears to be at least a variety differing from the Rein-Deer of North America; and certainly the Elk of the former should not be considered as the same species with the Moose-Deer of the latter. The Glutton, *Gulo Borealis,* seems to be confined to this region; as are the common Lemming and the Hamster. The great Sea-Otter, *Lutra Marina* of Steller, is found on both sides of the Northern Pacific, as low as 50° or perhaps 45° N. lat. The Cetacea, as might be expected, are common to the arctic seas of both worlds, and some of these occasionally wander southwards; but the true Greenland Whale, and the Narwal, are confined to the arctic seas. The birds that constantly reside in the arctic regions are very few; but this region is penetrated by numerous birds well known in other parts of Europe and Asia, which resort to it as their breeding-places during its transient summer. These birds chiefly belong to the order of *Natatores.* A single Woodpecker, *Tridactylia Hirsuta,* is peculiar to the palæonarctic kingdoms; as are the Great Wood-Grouse, and several other species of the genus *Tetrao.* The Snowy Owl and Jer-Falcon belong to this region, though occasionally they are found in the north of Scotland, and occur also in North America. Yet these regions, seemingly so inhospitable, are not without numerous tenants. No part of creation is an absolute waste, destitute of animation. It is well known that the enormous number of ducks and other water-birds which frequent the streams and lakes of arctic countries, are attracted by the infinite swarms of insect food which abound in them during their short summer. Scoresby found numerous butterflies and other insects on the bleak shores of East Greenland; and he states that the Greenland seas teem with myriads of minute animalcules, which are the food of the *Balæna Mysticetus,* and which, in sea-water examined by him, existed to the number of 110,592 in each cubic foot, or 23,887,872 in every cubic fathom of that water.

2. *Occidento-Caucasian Kingdom.*—This division is equivalent to the *European province* of Swainson; but that designation appears to be not very appropriate to a region embracing also a part of Western Asia and of Northern Africa. The zoology of this division has been more completely explored than that of any other portion of the globe, and it presents to the naturalist *types* or characteristic species of a great number of genera in all classes of zoology. It contains many imported species, some of which are domesticated, or rendered subservient to the wants of man; so that it is difficult to trace its larger mammifera to their parent stock. Its most characteristic quadruped is the *Auerocks,* or Bos Urus. It is the animal next in size to the Rhinoceros, but is not the original stock, as has been alleged, of our domestic cattle. It formerly was abundant in Europe, but has fled from human persecution into the pathless forests of Lithuania, and the wilds of the Carpathians and the Caucasus. The Brown Bear, *Ursus Arctos,* appears strictly to be a denizen of this region, though it is also found in the palæonarctic kingdom. The Ibex, the Stag, and the Roe, are also among its characteristic animals; and though the Fallow Deer is said also to be found in Eastern Asia, it appears to be chiefly an inhabitant of the Occidento-Caucasian kingdom. The Horse and Ox, though both imported, nowhere attain to greater perfection in their most valuable qualities, though the former requires the occasional transfusion of Arabian blood to preserve its energies unimpaired. Its more considerable characteristic birds are, the noble *Gypaete* or Bearded Vulture of the Alps; the Imperial and Royal Eagles of Temminck, F. *imperialis* and *chrysætos;* and several species of Falcons. The Red Grouse is found in no part of the world except the British islands. The Great and the Little Bustards are peculiar also to this division, which is particularly rich in many other genera of birds. It contains about 470 species of aves, of which 310 are inhabitants of Britain; in this list are seventeen *Raptores,* 117 *Insessores,* seventeen *Rasores,* sixty-six *Grallatores,* ninety-three *Natatores,* besides thirteen occasional visitors to our shores.

3. *Oriento-Caucasian Kingdom.*—In this division there is included all Asia between the Altaian and Himalayan chains. It should most probably be subdivided into two provinces.

a. The Mongolian province, of which the characteristic Mammalia are the *Yak, Bos Gruniens;* the Argali, *Ovis Ammon,* the Onager or Wild Ass; the Wild Horse, or *Æquus Hemionus* of Pallas. The *Felis Onea* also belongs to this region; as does the *Ursus Thibetianus,* the Thibetian Musk, which is pretty widely diffused in this division; and the lively Jerboa. Its birds are little known to the naturalist, except the few which have been brought from Dauria.

b. Septentrio-Sinican Province.—The little we know of the zoology of China enables us only to state, that this division abounds with beautiful *Phasianidæ*, particularly with the Golden and Silver Pheasants, which were originally brought from China. The *Argus Polyplectron* is said to be found in the colder regions of Thibet and China; and the *Impeyan Lophophorus*, which we have received from the Himalayan Mountains, may probably also inhabit the mountainous districts of China.

4. The *Austro-Asiatic Kingdom* may be considered as bounded by the 30th degree of N. lat. and the equator. It includes Southern China, Cambogia, Siam, the Birman empire, Hindustan, and Ceylon. It may be characterized as the native region of the Tiger, the Panther, of the Asiatic Elephant, and of the Long-armed Apes; of the Peacock, the Giant Argus, and the Hornbills; of the Gangetic Crocodile, the Python, and Cobra de Capello. Its other remarkable animals include the One-horned Rhinoceros, the Hunting Leopard, the Malayan Bear, the Ursine Sloth; that curious animal described by Sir William Jones, the Slow Lemur, or *Stenops* of Illiger; the Short-tailed Pangolin or Scaly Manis, the Brahmins' Bull, the Urneh or Wild Buffaloe, and the less-known wild ox of India, named the Gour, as well as the *Antelope Picta* or Nilghau, *A. Tragocamelus*, and several other antelopes; the beautiful Spotted Axis, and several other deer; the Pigmy and Indian Musks. Among its characteristic birds, besides those already mentioned, we should not omit the Jungle Fowl, and the Bankiva Cock, which many naturalists suppose to be the stock of our domestic poultry. The genus *Buceros* is the representative of the Toucans of America, and has the nerves of its nose distributed in its upper mandible and bony casque; the *Ciconia Argala*, or gigantic Adjutant-bird, is the most remarkable of its waders.

5. *Polynesian Kingdom.*—In this division we include the Philippines, Borneo, the Moluccas, Celebes, Java, and Sumatra. It may be considered as the native country of the great Orang-Outan, and numerous Monkeys, among which the Proboscis Monkey and Cochin-China Monkey are the most remarkable; of enormous Bats, of the Galeopithecus or Flying Lemur, of the Indian Tapir, and of a species of Musk. It is also characterized by its very magnificent birds: among these we may notice the genera *Iöra*, *Calyptomena*, *Eurylaimus*, *Irena*, *Gracula*, *Lamprotornis*, and its very splendid *Lories*. It is distinguished by the beauty and splendour of the genus *Cinnyris*, formerly included among the Creepers; and the elegance of its *Columbidæ*. It also contains the Argus Pheasant or Polyplectron, the Gigantic Argus, and the *Lophyrus Cuvierii*. Its seas abound in most beautiful and valuable shells, though it is comparatively poor in fluviatile Testacea.

6. *Chaldæo-Arabian Kingdom.*—The natural boundaries of this province are well marked by seas, the river Tigris, and by the cultivated part of Syria. It may be distinguished as the region in which the most valuable qualities of the Horse are developed, and where the Camel, and its variety the Dromedary, with the *Gazelle* or Antilope Dorcas, are the most conspicuous mammifera. Its ornithology is but little investigated; but the deserts are traversed by the Ostrich; its mountainous regions breed Pheasants and Doves; and one bird that frequents Arabia, and is greatly respected by the people, is a thrush, *Turdus Seleucus* of Forskal, which follows and destroys the innumerable swarms of locusts. The rarest and most beautiful shells are found in the adjacent seas; and the pearl-fisheries of the Persian Gulf have been long celebrated.

7. *Australian Kingdom.*—If we are permitted to include in this division New Holland, Papua, Van Diemen's Land, and New Zealand, it has one of the richest and most peculiar fauna of any on the globe. It may be characterized as the native region of the *Kangaroo*, the *Ornithorhynchus*, and *Echidna*, of the entire superb family of Birds of Paradise, of the Honey-suckers, of innumerable Parrots, of the Emeu, and *Menura Superba*. The absence of all the larger and pachydermatous quadrupeds was common to Australia, with the islands in the great Southern Ocean, at the time of their discovery, and is one reason for grouping those islands in this zoological kingdom. We have, besides the quadrupeds above mentioned, whole genera peculiar to this kingdom, particularly the *Perameles*, *Phalanger*, *Petaurista*, *Phascolomys*, and *Hypsiprymnus*. The following genera of birds are peculiar to that region: *Sericulus*, *Podargus*, *Malurus*, *Ptilonorhynchus*, *Glaucopis*, *Pardalotus*, *Mellisuga*, *Menura*, *Dacelo*, *Megapodius*, *Scythrops*, *Dromiceius*, *Ceriopsis*, &c.

8. The *African Kingdom* includes that continent south of Atlas, with the islands of Madagascar and the Seychelles. It is the region of the Camelopard, the Hippopotamus, and the Two-horned Rhinoceros, of the African Lion, the Leopard, and African Elephant, of the Zebra and Quagga, of the Pongo or Black Orang, and of the larger Baboons. It abounds in a great variety of Antelopes. These animals, with few exceptions, are found over a large extent of Africa; but the Hyrax of the Cape, and the Tenrec of Madagascar, are more limited in their range. Of the variety and beauty of its birds, some idea may be formed by consulting the splendid works of Le Vaillant. The Occipital Vulture of Burchill, and numerous Eagles, are found in its southern regions. The genera *Pogonius*, *Musophaga*, *Numida*, *Struthio*, *Anastomus*, *Touraco*, *Indicator*, *Pomerops*, *Centropus*, contain its most remarkable birds; but the brilliancy of the *Cinnyridæ* and *Lamprotornidæ* is well known. Most of the African birds brought to Europe have rich plumage. The extinct species of bird, the *Dodo*, belonged to this division of the earth, as our early voyagers found it in the Mauritius and Isle of France. The Crocodile and Cayman appear to be diffused throughout this continent. The number of poisonous Serpents is considerable, and highly dangerous in its hotter regions; yet in Africa, as in other parts of the earth, by far the greater number of snakes are harmless. Africa is peculiarly rich in land Testacea, among which is the *Achatina Zebra*, the largest of land shells. Amongst its insects, we may notice the number of its locusts, and the prevalence of the *Termes Bellicosus*, an insect allied to the ant, which constructs a mansion of clay, equalling in size, and surpassing in solidity, the simple habitations of most of the natives of Africa to the south of the desert of Sahara.

NEW WORLD.

In the new world.

The zoology of North America has been so admirably treated by Dr Richardson in his memoirs in the Sixth Report of the British Association, that it ought to be studied by all interested in such researches, who will not fail to consult the splendid *Fauna* of North America, lately published by him and Mr Swainson. In most parts of America we meet with many new genera in every class of animals, and find few species that are not peculiar to the new world, with the exception of marine animals. The *Quadrumana*, which range in America between 29° on each side of the equator, have the peculiarity of either wanting the thumb on the fore extremity, or having it so placed, or imperfectly developed, as not to be a real opponent to the fingers; while the prehensile tails of many, and the hairy buttocks of all, showing that none of them sit erect, distinguish them from the individuals most resembling them in the old world. The *Carnivora* of America are almost all peculiar to it; indeed, with the exception of some of the marine carnivora, and a very few terrestrial species, all are specifically distinct from those found in other parts of the earth. The whole order of *Marsupiata* are either American or Australian; and the species of one zoological kingdom are unknown in the other. America exceeds every other country in the number of its *Rodentia;* and there is reason to doubt whether almost any of this order are common to the two worlds. The *Edentata* occur chiefly in South America, but all are peculiar to the new world. Though America appears at one period to have been rich in the number of its *Pachydermata,* as their fossil remains testify, yet at its discovery by Europeans there were not above four or five species of this order found in that continent, all peculiar to America, and only one, *Dicotyles Torquatus,* or *Peccari,* common to its northern and southern divisions. Among *Ruminantia* we consider the American Rein-Deer and the Elk as peculiar species; and the identity of the *Ovis Montana* of the Rocky Mountains and the *Argali* of Siberia as very doubtful. The order of *Cetacea* is probably common to both worlds, with the exception of the *Manatus Americanus* of Cuvier, which occurs on the coast of Florida, and seems also to occur in that of South America. Dr Richardson reckons, that out of 207 species of Mammifera found in North America, 169 are peculiar to that country; and if we take Temminck's estimate of this class to be correct, North America contains $\frac{1}{5}$th of all known Mammalia. The same author gives the number of North American birds at 696 species, of which 54 are *Raptores*, 400 *Insessores*, 33 *Rasores*, 87 *Grallatores*, and 122 *Natatores.* Except in the last two orders, the species common to the new and old worlds are few, and a great many genera are wholly American.

The Alligator, the Boa Constrictor, and the Rattlesnake, are all peculiar to America. The former and the latter are widely diffused over the American continent; and the Rattlesnake is found even as far north as Canada.

In the new world we begin with the

9. *Neonartic Kingdom.*—This includes all America between lat. 50° N. and the pole, with Greenland and the intervening islands. The characteristic Mammifera are the Musk Ox, the Black American Bear, the Occidental Wolf, the Wolverine, and, as we have already stated, the Rein-Deer and the Moose-Deer, with several species of Marmot, Squirrel, Lemming, and other animals allied to the genus *Mus.* The animal discovered by Scoresby in Greenland, the *Mus Groenlandicus,* has since been discovered in Novaia Zembia. The Arctic Fox, Arctic Hare, and the Beaver, are common to both continents. The *Mustela Erminea* and *Ursus Maritimus* seem identical in both.

The Raptorial birds peculiar to this region are, several kinds of hawks and owls; of the genus *Tetrao, T. Canadensis, T. Franklinii, T. Obscurus,* and *T. Leucurus.* Most of the *Natatores* are also found in the first zoological kingdom. The *Cycnus Buccinator* is peculiar to this region; and among the duck tribe we may notice as American species *Anas Valisneria, A. Canadensis,* and *A. Hutchinsónii.*

10. *Septentro-American Kingdom.*—In this region, on account of the considerable similarity of species, we would include all the British possessions south of lat. 50°, New Albion, and the other country west of the Rocky Mountains, between Queen Charlotte's Sound and New Mexico, and all the territories of the United States, as far as lat. 30° N. It may zoologically be characterized as the region of the Griesly Bear, the Bison, the Wapeti, the giant of the deer tribe, and of the *Antelope Furcifer.* It possesses one marsupial animal, *Didelphis Virginica,* a species which ranges from the lakes of Canada to the intertropical regions of America. But its most distinguishing characteristic is the number of its *Rodentia,* amounting to not less than fifty-three well-ascertained species, and only one of which, the Beaver, is found in the old continent.

Its birds are numerous, and among these the Wild Turkey is the most conspicuous and characteristic. Of the *Raptores* it has many falcons and hawks, and, among the rest, Washington's Eagle, a magnificent bird, which is found in Kentucky. Of its numerous *Insessores,* the greatest number are peculiar to North America. The *Trochilidæ* first appear in this region. A considerable number of species are found in it, but only three range to the north of latitude 33°. They resemble in structure the *Honey-eaters* of the Australian kingdom; but we doubt the propriety of denominating the Humming-Birds *suctorial;* for, having dissected a considerable number of them, we invariably found their stomachs crammed with minute insects. To capture these is probably the object of their fluttering about flowers, the nectar of which they were supposed to sip. Their structure, too, assimilates them to insectivorous birds. The *Rasores* of this kingdom are all, except a single species of *Tetrao,* peculiar to America. Of this genus the most remarkable are *Tetrao Cupido, T. Umbellus, T. Franklinii, T. Urophasianus, Oxtyx Douglasii, O. Picta.* Of the numerous *Grallatores* found in this region a considerable number occur also in Europe, and still more of the *Natatores;* but of the former order, the *Ardea Herodias, Platalea Aiaia, Ciconia Maguari,* are peculiar to America; as are of the latter order *Pelicanus Americanus,* and *Rynchops Nigra.* The *Alligator Lucius* abounds in the valley of the Mississippi. Two very peculiar reptiles are there found, the *Syren Lacertina* of Carolina, and *Meopoma Gigantea.* These have no animal at all resembling them in the old world, except the *Proteus Anguinus* of the subterranean lakes of Carniola. Among the numerous tortoises there may here be noticed *T. Serpentina, T. Ferox,* and *T. Clausa.* The serpents are numerous; the most remarkable are the Rattlesnakes, four, if not five, distinct species of which are to be found in this kingdom.

11. *Equinoxial American Kingdom.*—Using this term in an extended sense, we would include under it the regions between the parallels of 30° N. and S. of the equator, but exclusive of the elevated valleys and table-lands of Mexico and Bolivia, which, from the peculiarities of their climates, are entitled to be considered as separate zoological kingdoms.

The division under consideration is distinguished by the number of its *Quadrumana,* all of which are furnished with tails, and many of them have that organ *prehensile,* or so formed as to constitute a sort of fifth hand. It is the region of the Jaguar, a beast of prey of vast strength and courage, so very unlike the account of its habits in the pages of Buffon, that it is now generally supposed that the French naturalist confounded it with another South American *Felis,* the Ocelot.[1] In this region, too, the Puma abounds, an animal that has far less claim to the name of *lion of America* than the Jaguar has to be termed the *tiger* of that continent. The Puma has a considerably larger range than its congeners now mentioned, being found in the woods of America from Brazil to Canada. We once possessed the large skin of a black Jaguar, killed in Brazil, which is now deposited in the museum of the Royal Institution in Liverpool. It is of a beautiful deep blackish-brown ground, on which, in certain lights, the still deeper ocellated marks of the Jaguar are visible. It also abounds with the Tapir, the Capybara, and the Agouti. The Orinoco and other rivers of Equinoxial America swarm with the Manati, *Trichechus Amazonius,* which wanders far from the sea, as does a species of Porpesse not yet ascertained. It is also distinguished by the splendour of the plumage of its birds, of which numerous genera are either wholly peculiar to Tropical America, or are almost unrepresented in other regions. Its Raptorial birds are often distinguished by their size. To this region belong the magnificent King Vulture, and a very numerous species of the same family as large as a turkey, the *Vultur Uruba;* the Destructor and Harpy Eagles, the giants of their tribe, are the tyrants of the lower provinces. The *Insessores* of Tropical America are very numerous. Among them the American genera *Trogon, Galbula, Ampelis, Rupicola, Procnias, Nectarinia,* and *Trochilus,* are remarkable for the magnificence of their plumage. The bell-bird, *Casmarhynchus Carunculatus,* is celebrated for the deep intonation of its simple note, which simulates the distant bell of a convent; the Troupiales are distinguished by the abrupt yet pleasing contrast of their colours. The enormous Goatsuckers, especially that of the cave of Caripe, and the *Momots* or *Prionites,* are peculiar to this region. The Toucans and Aracaris are conspicuous for the size and structure of their bills, in which the organs of smell are conspicuously developed. Tropical America also abounds with beautiful Psittacidæ, among which the Ultramarine Parrot, the Scarlet and Blue, and the Blue and Yellow Macaws, are the most conspicuous.

---

[1] See Humboldt's Personal Narrative.

The beautiful family of *Crax* or *Pauxi,* of *Penelope,* the singular *Rhea,* and *Serpent-eater,* are among its *Gallinaceæ;* the Boat-Bill, *Cancroma,* and the remarkable species *Mycteria Americana,* and *Palamedea Cornuta,* the Scarlet Ibis, the Trumpeter or *Psophia Crepitans,* the Jacana, are among its waders.

This region abounds with snakes. Some, like the *Boa Constrictor* and *Boa Cenchris,* are remarkable for their enormous size; others, like the Canine Boa, Garden Boa, the Peruvian and Mourning Snakes, for the beauty or elegant pattern of their colours; others, like the Rattlesnake, *Crotalus Durissus,* or the redoubted Bushmaster, *Fer de Lance* or *Vipera Megæra,* dreaded for the virulence of their poison. The fluviatile fishes of this region are remarkable; but we can only here notice the Electric Gymnote, the Soldier Loricaria, and the *Salmo Rhombeus;* the latter the pest of the South American rivers. The *Papilionidæ* and *Phalænidæ* among its insects, are noted for the splendour of their colours and their size; and the singular Lantern-fly for the brilliancy of its phosphorescence. The wounds inflicted by the large *Aranea Avicularia,* or Bird-catching Spider, the *Scolopendra Morsitans,* which there grow to an enormous size, and by a small species of scorpion, are much dreaded. In these Arachnidæ, dissection shows a tubular offensive weapon, and a poison apparatus resembling that connected with the poison-fangs of serpents.

12. *Mexican Kingdom.*—Its animal productions, though but imperfectly explored, would seem to justify the inference drawn from its peculiarities of climate, that this portion of America should be considered as a distinct zoological kingdom. It has been recognised as the point in which the faunæ of North and South America meet. There the Wolf of a northern climate ranges the same forest as the Monkey of a tropical region; the Bunting and the Titmouse nestle near the Parrot and the Trogon; the Phalarope of the north searches for its food on the same beach with the Jacana and the Boat-bill of Brazil.[1] Lichtenstein has indicated several species of Weasels and Martens as peculiar to Mexico. The *Bassaris Astuta* of Lichtenstein is an intermediate genus between *Viverra* and *Nasua.* The Mexican Wolf is perhaps a peculiar species. Mr Swainson states, that out of 114 species of Mexican birds examined by him, sixty-seven, or more than one half, are peculiar to that country; yet, among so many species, there was but a single new genus, *Ptiliogonys,* which unites the Tyrant Shrikes with the Caterpillar-eaters; thirty-six species are common to Mexico and the United States, and eleven to Mexico and South America. The lakes of the valley of Mexico contain that singular animal the *Axocotl* of the Mexicans, the *Siren Pisciformis* of Shaw, which seems to be intermediate in appearance between the other Sirens and the Protæi.

13. *Bolivio-Chilian Kingdom.*—The vast elevation of the greatest part of this region has strongly impressed its fauna with peculiarities which future research will extend. In the mean time, it is sufficiently characterized as the region of the *Guanaco,* the *Alpaca,* and *Vicuña,* three distinct species, which have sometimes been confounded under the name of Llama. They are the Camels of South America, and were almost the only mammalia subdued and domesticated by the ancient Peruvians. This is the peculiar region of the *Condor,* a bird which, though not so enormous in size as the earlier travellers reported, is still as large as the Læmergeyer of the Alps, the largest of the Raptores of the old world. It loves to dwell amid the snowy solitudes of the Andes, perched on pinnacles from 9700 to 1500 feet above the sea, whence it pounces on its prey in the subjacent valleys. The fauna of these countries is still imperfectly explored.

14. *Austro-American Kingdom.*—This district extends from lat. 30. S. to Cape Horn, and embraces the *Pampas* of Buenos Ayres and the south of Chili. Its fauna has been little explored. Amongst its quadrupeds are the numerous heads of wild horses and sheep, originally introduced by the Spaniards, but now spread over a great part of South America. The *Antarctic* and *Chili Fox* seem to be peculiar; and perhaps the *Felis Colorolo* and *F. Guigna* of Molina should be considered as belonging to it. On its coasts many species of seals are found, especially the *Phoca Longicollis* or *Fur-seal, Ph. Falklandica, Ph. Flavescens, Ph. Leonina* or *Bottle-nosed Seal, Ph. Lupina,* and *Ph. Jubata,* which is also found, it is said, in the seas of Kamtschatka. The extensive *Pampas* of this region are the chosen haunts of the *Rhea,* or *American Ostrich;* and on its southern coasts are found the huge, wingless, Patagonian Penguin, with the whole genus *Pachyptila,* judiciously separated by Illiger from the Petrels.

Such is an imperfect sketch of the distribution of animals over the globe. But the natural limitation of species has been in some measure affected by human agency. The domesticated animals have been by man imported from different parts of Asia into Europe, and finally into America. At the discovery of that continent it was without the horse, the cow, the sheep, the hog, the dog, and our common poultry, all which are spread over it in innumerable herds, and in some places have relapsed into the wild state in countries well suited for their subsistence. The same useful animals have been by Europeans, within the last half century, carried to the larger islands of the Pacific, where they were previously unknown. How many insects may have been propagated by the cargoes of our ships in distant lands, it is easier to conjecture than to estimate; how many have been imported with the cerealia, and other gramineæ of Europe, into newly-discovered regions, it is impossible to say. Human agency has sometimes been the means of propagating in Europe disgusting or destructive species from foreign regions. Thus the commerce of the Dutch wafted the *Teredo Navalis* to the dyke-defended coasts of Holland, to the imminent hazard of that country; the Brown Rat and the *Blatta,* which now infest this country, are believed to be importations from the East Indies; and the white bug that now lays waste our orchards is stated to have reached us with American fruit-trees.

---

[1] Richardson, Report of the British Association, vol. v.; and Address, vol. vi.

Still the effect of human agency is confined, and the limitations imposed by nature upon animal migrations are generally preserved.

SECT. XI.—*Varieties of the Human Species.*

The identity of *species* in the whole human family is indicated in the sacred Scriptures, and is confirmed by the deductions of the physiologist and the anatomist. The true principle which serves to mark identity of species in the animal kingdom, is the propagation, not of *hybrids*, but of fertile progeny between a male and female of a different race. The offspring between individuals of all the known races of mankind are equally fertile with the progeny of a pair of the same nation; and, therefore, it can be no longer doubted that man is everywhere of the same *species*. There are, however, several well-marked *varieties* of the human species, that appear distributed in a peculiar manner over the earth; and hence the *Geographical Distribution of Man* becomes an object of our attention.

Man appears to possess a remarkable pliancy of constitution, and to be the only animal fitted by nature to inhabit every possible variety of climate. His animal existence is not less secured in the frozen regions of the arctic circle, or under the burning climate of the equator, than in the intermediate countries; and he may be said to be the only true denizen of the whole world.

Varieties of the human species.

The classification of Cuvier, in his *Tableau Elémentaire*, divided the human race into five varieties, viz. 1. the White Race; 2. the Lapland, Samoied, and Esquimaux Race; 3. the Mongolian Race; 4. the Negro Race; 5. the American Race. In his *Regne Animal* he seems inclined to confine them to three, of which the characteristics are very strongly marked, the *White*, the *Yellow*, and the *Black* Races; but he admits that the *Malays* and the *Americans* are not easily distinguishable from any of the three great varieties of mankind in the ancient continent. Blumenbach considers the varieties as five, viz. the *Caucasian*, the *Mongolian*, the *Ethiopian*, the *Malayan*, and the *American*; and this distribution, though not altogether free from objection, seems one of the best hitherto proposed.

1. *Caucasian Variety*, is so named, because the traditions respecting the diffusion of the human race seem to point out the region between the Caspian and Black Sea as the cradle of this race, from which there have been numerous radiations; and the most perfect specimens, in point of beauty of form, are found among the Georgians and Circassians, still inhabiting the native seats of their race. The characteristics of the Caucasian Variety are, the fair skin, the oval contour of the head; soft hair, varying from black to light brown or flaxen, waving or slightly curled; eyes varying from blue to dark brown; cranium expanded; facial angle large; nose thin, and rather aquiline or straight; small mouth, perpendicular cutting teeth; lips gently recurved; chin full and rounded. In this race the intellectual qualities have been more strikingly displayed than in any other. Its principal branches may be still traced by certain, though often not very obvious, affinities in the structure of language. The most ancient offsets appear to have been that to the south and the east. The Southern Armenian or Syrian branch seems to have been the parent stock of the Assyrians, the Chaldeans, the Arabs, the Jews, the Phœnicians, and Abyssinians. The examination of the most ancient mummies would lead to the conclusion that the ancient Egyptians belonged to the same stock, though the Ethiopian countenances of some of their sculptures have sometimes led to a different conclusion. We believe, however, that these may be transcripts of venerated originals imported with the religion of Egypt from the Nubian Meröe.

The second branch appears to have given rise to the ancient Medes, the Persians, the Afghans, and the higher castes of India whose language was the Sanscrit; whilst another portion of it, taking a westerly direction, spread itself over Asia Minor, and, under the name of Pelasgians, penetrated into Europe. It seems to have been preceded by an offset from the same branch, the Celts, who early penetrated to the western shores of Europe, where they were found, after the lapse of centuries, by the Teutones, a younger shoot from the same stock. The whole nations already mentioned, and the whole present inhabitants of Europe, with the exception of the Samoieds and Laps, are derived from the Caucasian Variety, the most scattered and most energetic of the human family; and the affinity in descent will account for the strong resemblances which have been traced between the languages of India, of ancient Media, and the principal European tongues. The Scythian branch of the Caucasian race may be considered as the ancestors of the Parthians, the Tatarians of the Taurida, the Turcomans, the Finlanders, the Hungarians, and the tribes about the mouths of the Danube and to the north-east of the Euxine.

2. *The Mongolian Variety* seems to have had its original seat in the vicinity of the Altaian chain of mountains. It is characterized by an olive complexion, and black eyes, the outer angles of which are pointed rather upward; their hair coarse, lank, and thin, their beard scanty; the head of a square form, with a low and narrow forehead, a broad and flattened face, high cheek-bones, flat nose, a wide mouth, and thick lips. Two branches of this race are represented by the Nomade *Kalmucks* and *Kalkas*, whose ancestors spread devastation over a large portion of the earth, under their leaders Attila, Zenghiz Khan, and Timûr. A third branch, the *Mantscheou*, in later times had conquered China, of which they are still the rulers. The ancient Chinese, however, seem to have belonged to the same race; and the Japanese, the Coreans, and people of Thibet, probably are also offsets from the great Mongolian variety. The Esquimaux of America appear from their form to belong also to the Mongolian Variety; and may have passed into America on the arctic ices, just as rein-deer now do annually; or as the Tschutskoi have been frequently known to do in order to attack the American Indians. The Laps, the Samoieds, the Tschutskoi, and the Kamtschatkadales, bear strong marks of their Mongolian origin, though some are disposed to regard them as derived from the Scythian branch of the Caucasian race.

3. The *Ethiopian Variety* owns Africa as its native region. This variety is distinguished by a black or very dark skin; black eyes; woolly, crisp, coarse hair, collected into little knots; a skull laterally compressed; a forehead low and narrow, a small facial angle, produced by the inordinate projection of the maxillary bones, with an oblique position of the front teeth, and a small chin; the nose flat and simous; the lips, especially the upper, thick; the arms long; the legs often slightly bowed. Lawrence has satisfactorily shown that there is not one peculiarity of the negro race, which is not occasionally met with in some of the other races; and that there is no reason to believe that the negro is not of the same origin as the rest of mankind. Mr Browne, and other recent travellers, have stated, that the Furians and Nubians, though black, have often handsome elevated features; and we have seen a jetty negress, from the eastern shores of Africa, with features that might well have been a model for a Grecian statue of Juno in bronze. Those variations are probably from the intermixture of the Caucasian with the Negro race.

In the Malayan peninsula, in Luçonia, and in Borneo, among the mountainous districts, are found a few scattered tribes of black men, who form the chief population of Papua or New Guinea. They have dark skins and woolly hair, and, if we may judge from the native of Papua brought to England by Sir Stamford Raffles, the *Papous* do not materially differ from the natives of the eastern coast of Africa, whence probably their ancestors have emigrated.

4. *The Malayan Variety* has its native seats in the Malayan peninsula and the adjacent islands. The inhabitants of Polynesia, New Holland, and New Zealand, are believed to belong to this race. It is far less characterized than the three races before noticed, and perhaps might be considered as produced by their intermixture. The perspicuous characteristics are a brown colour; sometimes almost approaching to white, as in the inhabitants of Taheite and the Marquesas, at other times very swarthy, as in the New Zealander and Australian. The hair is black, thick, and generally slightly curled; the head is laterally compressed, the forehead rather narrow, but high; the bones of the face large; the nose full, broad at the apex, and passing gradually into the cheeks; the mouth large; the lips rather thick; the eyes sometimes have the Mongolian cut; the hands are small. But many of the islands are occupied by a very handsome race of inhabitants. The Malay language is widely scattered over the islands of the Pacific, which shows a common origin. The recent South Sea voyages show the vast distances to which design or accident has carried the people of one group of islands to another in their frail canoes, and point out how those islands may have been originally peopled.

5. *The American Variety* was spread over all that continent at its discovery in the end of the fifteenth century. This race, like the last, is not very distinctly characterized, but bears a very strong resemblance to some of the Mongolian tribes in the scantiness of the beard, which is general in both parts of that continent. The principal peculiarities of this race, besides the scanty beard, which they generally try entirely to eradicate, are a dark skin, with a tint of red, or what has, not very happily, been termed a *copper-colour*. The hair is black, lank, long, and coarse. The skull is very similar to the Mongolian, but the features are more prominent, especially the nose; the forehead is generally low and retreating; the eyes deeply set; and the face, across the cheek-bones, broad, the mouth large, the lips rather thick. Some of the native tribes singularly flatten the head by compression while in the infant state. This is particularly the case with a tribe on the Columbia. One of their skulls, in the College Museum of Edinburgh, is depressed in a most extraordinary degree, so that the frontal sinus seems almost as high as the vertex; and the head is posteriorly and laterally extended. This was the skull of a person of rank. It was procured by the late Dr Gairdner, along with the skull of a slave of the same tribe, in which this flattening, no doubt esteemed a great beauty, had not been practised, but which exhibited, to our eyes, a much more handsome form than that of his master.

The peopling of America was long a problem of much difficulty; but it has of late years been elucidated in various respects. Strong affinities have been discovered between the languages of America and Eastern Asia, which confirm the inferences drawn from physiognomy. Sidi Melli-melli, Tunisian envoy to the United States in 1804, on seeing the deputies of the Cherokees, the Mianis, and Osages, assembled at Washington, instantly recognised their Tatar physiognomies; and Genet, when minister plenipotentiary of France, was also struck with the resemblance of the Indians of America to the Asiatic Tatars, with whose appearance he was familiar. The late researches of Dr Heckewelder, and other American archaiologists, have reduced the supposed infinite variety of North American tongues to three or four radical languages. According to this authority, all the North American native tongues may be traced to the Floridan, the Lené-Lenapé, the Iroquois, and the Chepewyan; and the researches of Klaproth, and other German philologists, have strengthened the belief in the affinities between the native American languages and those of Eastern Asia.

The traditions of the Mexicans, and their hieroglyphical writings, trace their migrations from the north to the table-land of New Spain. Their mythology and their calendars strongly indicate an Asiatic origin,[1] whilst their architecture and their pyramidal temples have something of an Indian or Egyptian character. The scanty annals of this singular people show, that migrations from the north-west had at different epochs reached the elevated table-land of Mexico.

The first occupiers, or aborigines, are named the *Olmecks*. How long they had been there does not appear; but they were driven out in the year 648 of our era by the *Toltecks*, a people who left their country, which they named *Tlapallan*, supposed to be in Eastern Asia, in the year 544. A pestilence seems to have weakened this nation in 1051; and in 1170 the *Chichimacks* migrated into Mexico, where, eight years afterwards, the *Anahuatlacks* also arrived. This last nation consisted of seven tribes, the principal of which were the *Aztecks*. This tribe called their native country *Aztlan*, which they left in 1064, according to Gama; and, uniting themselves with the Chichimacks and the remnant of the Toltecks, they founded the city of *Tenochtitlan* in 1325. It was this united people whom the Spaniards denominated *Mexicans*, and whose empire was extinguished at the capture of the capital, Tenochtitlan, by Cortez in 1521.

The Toltecks appear to have pushed colonies into South America, either by the Cordillera of the Andes, or by the eastern plains at their feet. When Gonzales Ximenez de Quesada arrived on the table-land of Bogota, he was surprised to find a population on that plateau in a state of considerable civilization. It consisted of four tribes, all clothed in cotton garments, and settled in agricultural communities. The principal tribe was the *Muysca*, who possessed a calendar, the intercalations of which had as striking a similarity to that employed by nations on the banks of the Indus, as that of the Mexicans approached the calendar of the Mantcheous;[2] and it is believed that the Muyscas deduced their calendar from the motions of Jupiter in the ecliptic.

Several travellers have been struck with the resemblance of the Peruvian to the Malayan race; and it is possible that, by the isles of the Pacific, their ancestors reached the southern Cordillera. Their architecture has a sort of Egyptian character in the form of its apertures, and the squaring of its blocks of stone; but their theocracy had much resemblance to that of some nations of Central Asia.

Our limits preclude our pursuing this interesting subject further, or entering on the consideration of the alleged causes of the varieties of the human species. We must refer our readers to the *Researches* of Humboldt, to the *Physiology* of Lawrence, to *L'Histoire Naturelle du Genre Humain* of Virey, to the *Dissertations* of Blumenbach, Cuvier, and Klaproth, to the work of Dr Smith of New Jersey, to Prichard's *History of Man*, and to the article MAN in the present work. Suffice it to state, that whilst some attribute the varieties of the human family to the long-continued action of climate, food, and the external condition or habits of life, others have regarded them as the consequences of accidental peculiarities transmitted to the posterity of the individuals affected by them; and a third class have considered the three great varieties of the human race as directly derived from the individual qualities of the sons of Noah. But whatever view we take, it will not be found the less difficult to account for the marked national peculiarities of people confessedly derived originally from the same stock.

---

[1] Humboldt, *Recherches*.

[2] *Ibid*.

In conclusion, we may remark, that the study of physical geography, both as it regards inorganic and animated nature, tends to exercise the intellect in tracing the connection between natural causes and their consequences, and to expand and elevate the mind to the noblest of human contemplations,—the wisdom and beneficence of the Deity.

> "I cannot go
> Where universal Love not smiles around,
> Sustaining all yon orbs, and all their sons;
> From seeming evil still educing good,
> And better thence again a better still,
> In infinite progression."

(I. I. I.)

PHYSICS.

Introduction.

General definition.

TAKEN in its most enlarged sense, the word *Physics* comprehends the whole study of nature; and *Natural Philosophy* is a term of the same extent; but ordinary language, especially in Britain, employs both of these terms in a much narrower sense, which it is proper in this place to determine with some precision.

Particular explanation.

Under the article PHILOSOPHY, we gave a particular account of that view of nature in which the objects of our attention are considered as connected by causation; and we were at some pains to point out the manner in which this study may be successfully cultivated. By a judicious employment of the means pointed out in that article, we discover that the objects of our contemplation compose an universe, which consists, not of a number of independent existences solitary and detached from each other, but of a number of substances connected by a variety of relations and dependencies, so as to form a whole, which may with great propriety be called the System of Nature.

This assembling of the individual objects which compose the universe into one system is by no means the work of a hasty and warm fancy, but is the result of sober contemplation. The natural historian attempts in vain to describe objects, by only informing us of their shape, colour, and other sensible qualities. He finds himself obliged, in describing a piece of marble, for instance, to tell us that it takes a fine polish; that it strikes fire with steel; that it burns to quicklime; that it dissolves in aquafortis, and is precipitated by alkalies; that with vitriolic acid it forms gypsum, &c.; and thus it appears, that even the description of any thing, with the view of ascertaining its specific nature, and with the sole purpose of discrimination, cannot be accomplished without taking notice of its various relations to other things. But what do we mean by the nature of any thing? We are ignorant of its essence, or what makes it that thing and no other thing. We must content ourselves with the discovery of its qualities or properties; and it is the assemblage of these which we call its nature. But this is very inaccurate. These do not constitute its essence, but are the consequences of it. Yet this is all we shall ever know of its nature. Now the term property is nothing but a name expressing some relation which the substance under consideration has to other things. This is true of all such terms. Gravity, elasticity, sensibility, gratitude, and the like, express nothing but certain matters of fact, which may be observed respecting the object of our contemplation in different circumstances of situation with regard to other things. Our distinct notions of individuals, therefore, imply their relations to other things.

All parts of the universe connected in their various properties.

The slightest observation of the universe shows an evident connection between all its parts in their various properties. All things on this earth are connected with each other by the laws of motion and of mind. We are connected with the whole of the solar system by gravitation. If we extend our observations to the fixed stars, the connection seems to fail; but even here it may be observed. Their inconceivable distance, it is true, renders it impossible for us to obtain any *extensive* information as to their nature. But these bodies are connected with the solar system by the sameness of the light which they emit with that emitted by our sun or any shining body. It moves with the same velocity; it consists, in most of them at least, of the same colours; and it is reflected, refracted, and inflected, according to the same laws.

Primary objects of attention.

In this unbounded scene of contemplation, our attention will be directed to the different classes of objects nearly in proportion to the interest we take in them. There is nothing in which we are so much interested as our fellow men; and one of the first steps that we make in our knowledge of nature, is an acquaintance with them. We learn their distinctive nature by attending to their characteristic appearances; that is, by observing their actions. We observe them continually producing, like ourselves, certain changes in the situation or condition of surrounding objects; and these changes are evidently directed to certain ends which respect themselves. Observing this subserviency of the effects which they produce to their own accommodation, we consider this adjustment of means to ends as the effect of an intention, since we experience it to be so in our own case, where we are conscious of this intention, and of these its effects. We therefore interpret those actions of other men, where we observe this adjustment of means to ends, as marks or signs of intention to them similar to our own; and thus a quality, or power, or faculty, is supposed in them by means of its sign, although the quality itself is not immediately cognisable by our senses. And as this intention in ourselves is accompanied by perception of external objects, knowledge of their properties, desire of good, aversion to evil, volition and exertion, without all of which we could not or would not perform the actions which we daily perform, we suppose the same perception, knowledge, desire, aversion, volition, and exertion in them. Thus, by the constitution of our mind, we consider the employment of means, by which ends terminating in the agent are gained, as the natural signs of design or intention. Art, therefore, or the employment of means, is the natural sign of intention; and wherever we observe this adjustment of means to ends, we infer the agency of design.

Intr c. ti

A small acquaintance with the objects around us, obliges us to extend this inference to a great number of beings besides our fellow men, namely, to the whole animal creation; for in all we observe the same subserviency to the ends of the agent in the changes which we find them continually producing in the objects around them. These changes are all adjusted to their own well-being. In every such case, therefore, we are forced, by the constitution of our own minds, to infer the existence of design or intention in these beings also. But in numberless changes produced by external objects on each other, we observe no such fitness in the effects, no such subserviency to the well-being of the agent. In such cases, therefore, we make no such inference of thought or design.

All ob s divided - to thin g and un thinkin beings.

Thus, then, there is presented to our observation an important distinction, by which we arrange all external objects into two classes. The first resembles ourselves, in giving external marks of that thought or intention of which we are conscious; and we suppose in them the other properties which we discover in ourselves, but cannot immediately observe in them, viz. thought, perception, memory, foresight, and all that collection of faculties which we feel in ourselves, and which constitute the animal. The other class of objects exhibits no such appearances, and we make no such inference. Hence we divide the whole of external nature into the classes of thinking and unthinking beings.

How w come tc e knowle of mind

Our first judgments about these classes will be very inaccurate; and we will naturally ascribe the differences, which we do not very well understand, to the differences in organical structure, which we very clearly observe. But when we have knocked down or perhaps smothered an animal, we find that it no longer gives the former marks of thought and intention, and that it now resembles the class of unthinking beings: and yet it still retains all that fitness of organical structure which it had before; it seems only to want the intention and the will. This obliges us to conclude that the distinction does not arise from a difference in organical structure, but from a distinct substance, common to all thinking beings, though separable from their organical frame. To this substance we ascribe thought, intention, contrivance, and all that collection of faculties which we feel in ourselves. To this substance in ourselves we refer all sensations, pleasures, pains, remembrances, desires, purposes; and to this aggregate, however imperfectly understood, we give the name mind. Our organical frame, which seems to be only the instrument of information and operation to the mind, we call our body.

T nature
o ind as
u rstood
b ankind
i de

As the animating principle is not, like our body, the immediate object of the senses, we naturally conceive it to be a substance essentially different from those which are the objects of our senses. The rudest people have shown a disposition to form this conclusion. Observing that animal life was connected with breathing, it was natural to imagine that breathing was living, and that breath was life. It is a remarkable fact, that in most languages the term for expressing *breath* is at least one of the terms for expressing the soul; רוח, *πνευμα*, *spiritus*, in the Hebrew, Greek, and Latin, express both; *gheist* or *ghost*, in the Teutonic, comes from *gheisen*, to breathe or sigh; *dūcha* or *dūha*, the soul, in Sclavonic, comes from *duichat*, to breathe; so, in the Gaelic, does *anal* come from *anam*; and the same relation is found between the two words in the Malay and other eastern languages. We believe that most persons can recollect some traces of this notion in their early conceptions of things; and many, who do not consider themselves as uncultivated, believe that the soul quits the body along with the last breath. Amongst the Tartar nations hanging is regarded with particular horror, on account of the ungraceful and filthy exit which the soul is obliged to make from the body. But the observation of the same appearances of thought and intention in fishes, and other animals which do not breathe, would soon show that this was but a rude conception. Very little refinement indeed is necessary to convince us that air or breath cannot be the substance which thinks, wishes, and designs; and that the properties of this substance, whatever it is, must be totally different from, and incompatible with, any thing that we know of the immediate objects of our senses.

se

Hence we are led to conclude that there are two kinds of substances in nature; one which is the principle of sensation, and therefore cannot be the object of our senses, any more than light can be the object of the microscope. This substance alone can feel, think, desire, and propose, and is the object of reflection alone. The objects of our senses compose the other class, and therefore can have none of the other properties which are not cognoscible by the senses. These have all the properties which our senses can discover; and we can have no evidence of their having any other, nor indeed any conception of their having them. This class is not confined to the unorganized masses of matter; for we see that the bodies of animals lose after death that organized form, and are assimilated to all the rest of unthinking beings. It has arisen from such views as this, that whilst all nations have agreed to call this class of objects by the name of body, which originally expresses our organical frame, some nations, farther advanced in cultivation or refinement, have contrived an abstract term to express this general substance of which all inanimate beings are composed. Such a term we have in the words *materies* and *ὑλη*.

Th s-
tin n be-
tw ma-
ter and
im erial
sub ces.

Matter, then, is that substance which is immediately cognoscible by our senses. Whatever, therefore, is not thus immediately cognoscible by our senses is not material, and is expressed by a negative term, and called *immaterial*; and hence it is that mind is said to be immaterial. It is of importance to keep in mind this distinction, though merely grammatical. Little more is necessary for detecting the sophisms of Helvetius, Mirabeau, and others, who have been anxious to remove the ties of moral and religious obligation, by lowering our conceptions of our intellectual nature. It will also serve to show how hastily *they* have formed their opinions, who have ascribed to the immediate agency of mind all those relations which are observed in the actions of bodies upon each other at a distance. The connecting principles of such relations *e distante*, if there be any such, are not the immediate objects of our senses; they are therefore immaterial. But it does not follow that they are minds. There may be many immaterial substances which are not minds. We know nothing of any object whatever, except by the observation of certain appearances, which suggest to our minds the existence and agency of its qualities or powers. Such phenomena are the natural signs of these qualities, and it is to such signs that we must always have recourse when we wish to conceive without ambiguity concerning them. What is the characteristical phenomenon of mind, or what is the distinguishing quality which brings it into view? It is intention; and it may be asserted with the utmost confidence, that we have no other mark by which mind is immediately suggested to us, or which would ever have made us suppose that there existed another mind besides our own. The phenomenon by which this quality is suggested to us is *art*, or the employment of means to gain ends; and the mark of art is the supposed conduciveness of these ends to the well-being of the agent. Where this train is not observed, design or intention is never thought of; and therefore where intention is not perceived in any immaterial substance, if any such has ever been observed, it is an abuse of language to call it mind. We do not think that even perception and intelligence entitle us to give the name mind to the substance in which they are inherent, because it is from marks of intention alone that we infer the existence of mind; and although these must be accompanied with perception and intelligence, it does not follow that the substance which can perceive and understand must also desire and propose. However difficult we may find it to separate them, they are evidently separable in imagination. And let not this assertion be too hastily objected to; for the separation has been made by persons most eminent for their knowledge and discernment. When Leibnitz ascribed to his *monades*, or what we call the ultimate *atoms* of matter, a perception of their situation in the universe, and a motion precisely suited to this perception, he was the farthest in the world from supposing them animated or endowed with minds. It is true, indeed, that others, who think and call themselves philosophers, are much more liberal in their application of this term. A modern author of great metaphysical eminence says, "I call that mind which moves, and that body which is moved." This class of philosophers assert that no motion whatever is begun except by the agency of an animating principle, which, after Aristotle, they call Nature, and which has in these days been exalted to the rank of a god. All this jargon, for it is nothing else, has arisen from the puzzle in which naturalists think themselves involved in attempting to explain the production of motion in a body at a distance from that body which is conceived as the cause of this motion. After having been reluctantly obliged, by the reasonings of Newton, to abandon their methods of explaining such phenomena by the impulses of an intervening fluid, nothing seemed left but the assertion that these motions were produced by minds, as in the case of our own exertions. These explanations, if they deserve the name, cannot be objected to in any other way than as an abuse of language, and as the introduction of an unmeaning jargon. We have, and can have, no notion of mind different from those of our

Introduction.

own minds; and we discover the existence of other minds, as we discover the existence of bodies, by means of phenomena which are characteristic of minds, that is, which resemble those phenomena that follow the exertion of our mental faculties, that is, by the employment of means to attain selfish ends; and where such appearances are not observed, no existence of a mind is inferred. When we see a man fall from the roof of a house, and dash out his brains on the pavement, we never ascribe this motion to his mind. Although the fitness of many of the celestial motions for most important purposes makes us suppose design and contrivance somewhere, and therefore a Supreme Mind, we no more think of inferring a mind in the earth from the fitness of its motions for purposes most beneficial to its inhabitants, than of inferring a mind in a bit of bread from its fitness for nourishing our bodies. It is not from the mere motions of animals that their minds are inferred, but from the conduciveness of these motions to the well-being of the animal.

The mind is not that which produces motion, but that which desires and wills.

The term mind, therefore, in the ordinary language of all men, is applied to what desires and wills at the same time that it perceives and understands. If we call that mind which produces motion, we must derive our notions of its qualities or attributes from observing their effects. We must therefore discover the general laws by which they act, that is, the general laws observed in those motions which we consider as their effects. Now these are the general laws of motion; and in none of these can we find the least coincidence with what we are accustomed to call the laws of mind. Nay, it has been the total want of similarity which has given rise to the distinction which all men, in all ages and countries, have made between mind and matter. This distinction is found in all languages; and it is an unpardonable liberty which men take with language when they use a term of distinction, a specific term, to express things of a different species. What these authors have been pleased to call mind, the whole world besides have called by another name, *force;* which, though borrowed from our own exertions, is yet sufficiently distinctive, and never leads us to confound things which are different, except in the language of some modern philosophers, who apply it to the laws of the agency of mind, and, when speaking of the force of motives, &c. commit the same mistakes which the followers of Aristotle commit in the use of the term mind. Force, in the language of these philosophers, means what connects the operations of mind; as mind, in the language of Lord Monboddo, is that which connects the operations of body.

The principle of motion is not distinct from matter and mind.

Those persons are not less to blame who consider this *Nature* of Aristotle, this principle of motion, as an existence or substance different both from matter and from the minds of intelligent creatures. Aristotle calls it in some places ὡσπερ ψυχη. He might with equal propriety, and equal consistency with his other doctrines, have called mind ὡσπερ τελος, or ὡσπερ δυναμις. Besides, we have no evidence for the separability of this ὡσπερ ψυχη from body, as we have for the separability of such minds as our own, the genuine ψυχαι. Nay, his whole doctrines, when maturely considered, assume their absolute inseparability.

Elemental minds an abuse of language.

This doctrine of elemental minds, therefore, as the immediate causes of the phenomena of the material world, is an abuse of language. It is a jargon; and it is a frivolous abuse, for it offers no explanation whatever. The phenomena are totally unlike the phenomena of ordinary minds, and therefore receive no explanation from them; and since our knowledge of these ὡσπερ or *quasi* minds must be derived entirely from the phenomena, it will be precisely the same, although we express it in common language. We shall not indeed raise the wonder of our hearers, as those do who fill the world with minds which they never suspected to exist; but, on the other hand, we shall not bewilder their imaginations, confound their ideas, and mislead their judgments.

Intro tion.

The n e and us t animal stincts.

Some philosophers have attended only to the appearances of fitness which are exhibited in every quarter of the universe; and, by arranging these into different classes, and interpreting them as indications of thought and intention, have acquired the knowledge of many classes of sentient and intelligent beings, actuated by propensities, and directed by reason. Whilst the contemplation of these appearances indicates thought and design in any individual of one of these classes, and brings its propensities and purposes of action, and the ends gained by these actions, into view, the contemplation of these propensities, purposes, and ends, occasions an inference of a much more general kind. All these intelligent beings give indications of knowledge and of power; but their knowledge bears, in general, no proportion to their power of producing changes in nature, and of attaining important ends; and their power is neither always, nor in the most important cases, the consequence of their knowledge. Where the effect of their actions is most eminently conducive to their most important interests, the power of attaining these valuable ends is generally independent of any attention to the fitness of the means, and the exertion is frequently made without even thinking of the important end. The well-being of the individual is secured against any danger from its ignorance, indolence, or inattention, by an instinctive propensity, which leads it to the performance of the necessary action, which is thus made immediately and ultimately desirable, without any regard to its ultimate and important end. Thus, in our own nature, the support of animal life, and the improvement of the means of subsistence by a knowledge of the objects which surround us, are not intrusted to our apprehensions of the importance of these ends, but are committed to the surer guides of hunger and curiosity.

There connec n betwee the ind duals d r- ent fro that o - semblae.

The same observers discover a connection between the individuals of a class, different from that which arises from the mere resemblance of their external appearance, or even of their propensities and pursuits; the very circumstances which produced the classification. They observe, that these propensities are such, that whilst each individual seeks only its own enjoyment, these enjoyments are in general such as contribute to the support of the species, and the enjoyment of other individuals. Thus, in the classes of animals, and in human nature, the continuance of the race, and the enjoyment of the whole, are not intrusted to the apprehension we entertain of the importance of these ends, but are produced by the operation of sexual love and the love of society.

There also a k of con tion b tween en- tient ings o if- ferent classe

The same observers find that even the different classes of sentient beings are connected together; and whilst the whole of each class aim only at their own enjoyment, they contribute, in some way or other, to the well-being of the other classes. Even man, the selfish lord of this sublunary world, is not the unconnected inhabitant of it. He cannot, in every instance, reap all the fruits of his situation, without contributing to the enjoyment of thousands of the brute creation. Nay, it may be proved to the satisfaction of every intelligent man, that whilst one race of animals, in consequence of its peculiar propensities, subsists by the destruction of another, the sum total of animal life and enjoyment is prodigiously increased.[1]

---

[1] See a very judicious dissertation on this curious and puzzling subject, entitled a Philosophical Survey of the Animal Creation; where it appears that the increase of animal life and enjoyment which is produced by this means, beyond what could possibly obtain without it, is beyond all conception. See likewise the edition of King's Origin of Evil, by Dr Law.

Thus the whole assemblage seems connected, and jointly employed in increasing the sum total of possible happiness. This fitness of the various propensities of sentient and intelligent beings, this subserviency to a general purpose, strikes these observers as a mark of intention, evidently distinct from, and independent of, all the particular intentions, and superior to them all; and thus it irresistibly leads them to infer the existence of a Supreme Mind, directing the whole of this intellectual system, whilst the individuals of which it consists appear the unconscious instruments in the hand of a great Artist, with which he executes his grand and beneficent purposes.

But the observation extends yet further. The bodies of the inanimate creation are not only connected with each other by a mutual dependence of properties, and the relation of causation, but they are also connected with the sentient beings by a subserviency to their purposes of enjoyment. The philosopher observes that this connection is admirably kept up by the constancy of natural operations and the expectations of intelligent beings. Had either of these circumstances been wanting, had either the operations of nature been without rule, or had sentient beings possessed no perception or expectation of their uniformity, the subserviency would be totally at an end. This adjustment, this fitness, of which the result is the enjoyment of the sentient inhabitants of the universe, appears to be the effect of an intention of which this enjoyment is the final cause. This constancy, therefore, in the operations of nature, both in the intellectual and material world, and the concomitant expectation of sentient beings, appear to be the effects of laws imposed on the different parts of the universe by the Supreme Mind, who has formed both these classes of beings so admirably suited to each other.

To such observers the world appears a work of art, a system of means employed for gaining certain proposed ends, and it carries the thoughts forward to an artist; and we infer a degree of skill, power, and good intention in this artist, proportioned to the ingenuity, extent, and happy effect which we are able to discern in his works. Such a contemplation of nature, therefore, terminates in natural theology, or the discovery of the existence and attributes of God.

Our notions of this Supreme Mind are formed from the indications of design which we observe, and which we interpret in the same way as in the actions of men. These notions therefore will differ from our notions of other minds only in the degrees which we are able to observe, and which we assign to these faculties; for the phenomenon or the effect is not only the mark, but also the measure of its supposed cause. These degrees must be ascertained by our own capacity of appreciating the extent, the multiplicity, and the variety of the contrivance. Accordingly, the attributes of the Supreme Mind, in the theological creed of a rude Indian, are much more limited than in that of a European philosopher. In proportion as our understandings are enlarged, and as our acquaintance with the operations of nature around us is extended, we shall perceive higher degrees of power, of skill, and of kind intention; and since we find that the scene of observation is unbounded, we cannot affix any boundaries to these attributes in our own imagination, and we are ready to suppose that they are infinite or unbounded in their own nature. When our attentive survey of this universe, and a careful comparison of all its parts, as far as we can understand or appreciate them, have made us conclude that it is one design, the work of one artist, we are under the necessity of inferring, that, with respect to this universe, his power, wisdom, and benevolence, are indeed infinite.

When men have been led to draw this conclusion from the appearances of fitness which are observed everywhere around them, they consider that constancy which they observe in natural operations, whether in the material or the intellectual system, and that expectation of and confidence in this constancy, which renders the universe a source of enjoyment to its sentient inhabitants, as the consequences of laws imposed by the Almighty Artist on his works, in the same manner as they would consider the constancy in the conduct of any people as the consequences of laws promulgated and enforced by the supreme magistrate.

The rise of moral sentiments and of moral duty.

There can be no doubt of this view of nature being extremely captivating, and likely to engage the curiosity of speculative men; and it is not surprising that the phenomena of mind have been keenly studied in all ages. This part of the study of nature, like all others, was first cultivated in subserviency to the wants of social life; and the general laws of moral sentiment were the first phenomena which were considered with attention. This gradually ripened into a regular system of moral duty, accompanied by its congenial study, the investigation or determination of the *summum bonum*, or the constituents of human felicity; and these two branches of intellectual science were always kept in a state of association by the philosophers of antiquity. Jurisprudence, the science of government, legislation, and police, were also first cultivated as arts, or at least in immediate subserviency to the demands of cultivated society; and all these so nearly related parts of the study of human nature had made a very considerable progress, in the form of maxims or precepts for directing the conduct, before speculative men, out of mere curiosity, treated them as subjects of philosophical study. Our moral sentiments, always involving a feeling of obligation, are expressed in a language considerably different from the usual language of pure philosophy, speaking of things which ought to be, rather than of things which are; and this distinction of language was increased by the very aim of the writers, which was generally to influence the conduct as well as the opinions of their scholars. It was reserved for modern times to bring this study into the pure form of philosophy, by a careful attention to the phenomena of moral sentiment, and classing these according to their generality, and ascertaining their respective ranks by an appeal to experiment, that is, to the general conduct of mankind; and thus it happens that in the modern treatises on ethics, jurisprudence, &c. there is less frequent reference made to the *officia* or duties, that is, the constituents of the *summum bonum*, than amongst the ancients, and a more accurate description of the human mind, and discrimination of its various moral feelings.

The origin of logic and other intellectual sciences.

It was hardly possible to proceed far in these disquisitions without attending to the powers of the understanding. Differences of opinion were supported by reasonings, or attempts at reasoning. Both sides could not be in the right, and there must be some court of appeal. Rules of argumentation behoved to be acquiesced in by both parties; and it could hardly escape the notice of some curious minds, that there were rules of truth and falsehood as well as of right and wrong. Thus the human understanding became an object of study, first in subserviency to the demands of the moralist, but afterwards for its own sake; and it gradually grew up into the science of logic. Still further refinement produced the science of metaphysics, or the philosophy of universals. But all these were in fact posterior to the doctrines of morals; and disquisitions on beauty, the principles of taste, the precepts of rhetoric and criticism, were the last additions to the study of the phenomena of mind. And now, since the world seems to have acquiesced in the mode of investigation of general laws by experiment and observation, and to agree that this is all the knowledge which we can acquire of any subject whatever, it is to be expected that this branch of philosophical discussion will attain the same degree of improvement (estimated by the coincidence of the doctrines with fact and experience) that has been attained by some others.

The partial practice of natural philosophy preceded its study as a science.

The occupations, however, of ordinary life have oftener directed our efforts towards material objects, and engaged our attention on their properties and relations; and as all sciences have arisen from arts, and were originally implied in the maxims and precepts of those arts, until separated from them by the curious speculatist, the knowledge of the material system of nature was possessed in detached scraps by the practitioners in the various arts of life long before the natural philosopher thought of collecting them into a body of scientific doctrines. But there have not been wanting in all ages men of curiosity, who, having been struck by the uniformity of the operations of nature in the material world, were eager to discover their causes. Accordingly, whilst the moralists and metaphysicians turned their whole attention to the phenomena of mind, and produced the sciences of pneumatology, logic, ethics, jurisprudence, and natural theology, these observers of nature found sufficient employment in considering the phenomena of the material world.

The nature of the material system.

The bodies of which it consists are evidently connected by means of those properties by which we observe that they produce changes in each other's situations. This assemblage of objects may therefore be justly called a system. We may call it the material system. It is frequently termed nature; and the terms natural appearances, natural causes, natural laws, have been generally restricted to those which take place in the material system. This restriction, however, is improper, because there is no difference in the manner in which we form our notions of those laws, and reason from them, with respect both to mind and to body; or if there is to be any restriction, and if any part of the study of the universe is to be excluded in the application of these terms, it is that part only which considers moral obligation, and rather treats of what ought to be than of what actually is. As has already been observed, there is a considerable difference in the language which must be employed; but still there is none in the principles of investigation. We have no proof for the extent of any moral law but an appeal to the feelings of the hearts of men, indicated by the general laws or facts which are observed in their actions.

The unrestricted sense in which some of these terms are used, and its consequences.

But this is only a question of the propriety of language. And no great inconvenience would arise from the restriction now mentioned if it were scrupulously adhered to; but unfortunately this is not always the case. Some authors use the term *natural law* to express *every* coincidence of fact; and this is certainly the proper use of the term. The French writers generally use the term *loi physique* in this enlarged sense. But many authors, misled by, or taking advantage of, the ambiguity of language, after having established a law founded upon a copious and perhaps unexcepted induction of the phenomena of the material system (in which case it must be considered in its restricted sense), have, in their explanation of phenomena, extended their principle much farther than the induction on which they had founded the existence of the physical law. They have extended it to the phenomena of mind, and have led their followers into great and dangerous mistakes. Languages, like every other production of human skill, are imperfect. They are deficient in terms, and are therefore figurative. The most obvious, the most frequent, and the most interesting uses of language, have always produced the appropriate terms, and the progress of cultivation has never completely supplied new ones. There are certain analogies or resemblances, or certain associations of ideas, so plain that a term appropriated to one very familiar object will serve to suggest another analogous to it, when aided by the concomitant circumstances of the discourse; and this with sufficient precision for the ordinary purposes of social communication, and without leading us into any considerable mistakes; and it is only the rare and refined disquisitions of the curious speculatist that bring the poverty and imperfection of language into view, and make us wish for words as numerous as our thoughts. There is hardly a sentence, even of common discourse, in which there are not several figures either of single words or of phrases; and when very accurate discrimination is required, it is almost impossible to find words or phrases to express distinctions which we clearly feel. We believe it impossible to express, by the scanty vocabulary of the Hebrews, the nice distinctions of thought which are now familiar to the European philosopher. In nothing does this imperfection of language appear so remarkably as in what relates to mind. Being a late subject of separate discussion, and interesting only to a few speculatists, we have for it no appropriate vocabulary; and all our disquisitions concerning its operations are in continual metaphor or figure, depending on very slight analogies or resemblances to the phenomena of the material world. This renders the utmost caution necessary; and it justifies the British philosophers, who have been the most successful in prosecuting the study of the intellectual system, for having, almost without exception, restricted the terms natural laws, natural causes, natural philosophy, and such like, to the material system. With us pneumatology forms no part of physics. And we may venture to affirm, that the sciences have fared better by the restriction of the terms. In no country has the spirit of liberal discussion been more encouraged and indulged than in Britain, and her philosophers have been equally eminent in both branches of science. Their performances in ethics, jurisprudence, and natural theology, are considered by all our neighbours as the fountains of knowledge upon these subjects; and Locke and Clarke are names not less familiar on the continent than that of Newton.

The t *physic* fined t is gen ly und stood Britai

Physics, then, is with us the study of the material system, including both natural history and philosophy. The term is not indeed very familiar in our language; and instead of *physicus* and *disciplina physica*, we more generally employ the terms naturalist and natural knowledge. The term natural philosophy, in its common acceptation, is of less extent. The field of physical investigation is still of prodigious extent; and its different quarters require very different treatment, make very different returns, and accordingly have engaged in their particular cultivation persons of very different talents and tastes. It is of some importance to perceive the distinctions, and to see how the wants and propensities of men have led them into the different paths of investigation; for, as has been more than once observed, all sciences have sprung from the humble arts of life, and both go on improving by means of a close and constant correspondence.

The p nomen of the m rial sy m.

All the phenomena of the material system may be arranged into two classes, distinguished both by their objects and by the proper manner of treating them. The first class comprehends all the appearances which are exhibited in the *sensible motions* of bodies, and their actions on each other producing *sensible motion*. The second class comprehends the appearances which are exhibited in the *insensible* motions and actions of the invisible particles of matter.

Exam s of th of the fi and se nd class.

Of the phenomena of the first class we have examples in the planetary motions, the motions of heavy bodies, the phenomena of impulse, the motions and actions of machines, the pressure and motions of fluids, the sensible actions of magnetical and electrical bodies, and the motions of light. We have examples of the second class in the phenomena of heat and mixture, those exhibited in the growth of animals and vegetables, and many phenomena oduc- on.

Introduction.

of solid, fluid, magnetical, electrical, and luminous bodies, in which no change of place can be observed.

ar- ement parent- tural.

Thus it appears that there is a distinction in the phenomena sufficiently great to warrant a division of the study, and to make us expect a more rapid improvement by this division. Nay, the division has been made by nature itself, in the acquaintance which men have attained with her operations without study, before science appeared, and whilst art constituted all our knowledge.

origin ricul- phy- ur- and istry.

Before man had recourse to agriculture, as the most certain means of procuring subsistence, our acquaintance with external substances was principally that of the natural historian; consisting of a knowledge of their fitness for food, medicine, or accommodation, their places of growth or habitation, and the means of procuring them, depending upon their manner of life or existence. It required a studied attention to these circumstances to give rise to agriculture, which therefore generally made its appearance after men had been in the practice of keeping flocks; by which means they were more at their ease, and had some leisure to attend to the objects around them, and in particular to those circumstances of soil and weather which affected the growth of their pasture.

When agriculture and a rude medicine were thus established, they were the first arts which had their foundation in a system of laws, by which the operations of nature were observed to be regulated; and with these arts we may begin the *general study of nature*, which was thus divided into two different branches. The rude physician would at first be a collector of specifics; but by degrees he would observe resemblances amongst the operations of his drugs, and would class them according to these resemblances. He would thus come to attend less to the drug than to its mode of operation; and would naturally speculate concerning the connection between the operation and the economy of animal life. His art now became a scientific system, connected by principle and theory, all proceeding upon the observation of changes produced by one kind of matter on another, but all out of sight. The frequent recourse to the vegetable kingdom for medicines would cause him to attend much more minutely to the few plants which he had occasion to study than the husbandman can do to the multitude which he is obliged to rear. The physician must learn to think, the husbandman to work. An analogy between the economy of animal and vegetable life could hardly fail to engage the attention of the physician, and would make him a botanist, both as a classifier of plants and as a philosopher.

He would naturally expect to unite the services of his drugs by combining them in his recipes, and would be surprised at his disappointments. Curious and unexpected changes would frequently occur in his manipulations: the sensible qualities, and even the external appearances, of his simples, would be often changed and even inverted by their mixture; and their medicinal properties would frequently vanish from the compound, and new ones be induced. These were curious, and to him interesting facts; and he would naturally be inquisitive after the principles which regulated these changes. His skill in this would by degrees extend beyond the immediate use for the knowledge of them; and the more curious speculatist would lay the foundations of a most extensive and important science, comprehending all the phenomena of heat and mixture.

Along with this, and springing from the same source, another science must arise, contemplating the appearances of animal and vegetable life, and founded upon a careful observation and accurate description of the wonderful machine. The most incurious of men have in all ages been affected by the displays of wisdom and contrivance in the bodies of animals, and immediately engaged in investigation into the uses and functions of their various parts and organs. The phenomena have been gradually discriminated, and arranged under the various heads of nutrition, concoction, secretion, absorption, assimilation, rejection, growth, life, decay, disease, and death; and, in conformity to the doctrines which have with greater or less evidence been established on these subjects, the action of medicines, and the whole practice of physic and surgery, has been established in the form of a liberal or scientific art.

The origin of the knowledge of the mechanical powers.

The husbandman, in the mean time, must till or labour the ground which lies before him. He, too, is greatly interested in the knowledge of the vegetable economy, and forms some systems on the subject by which he regulates his labours; but he sees, that whatever is the nature of vegetable life, he must work hard, and he searches about for everything which can tend to diminish his labour. The properties of the lever, the wedge, and the inclined plane, soon become familiar to him; and, without being able to tell on what their efficacy depends, he uses them with a certain sagacity and effect. The strength of timber, the pressure and force of water, are daily seen and employed by him and other artisans who labour for their mutual accommodation; and some rude principles on these subjects are committed to memory. Many tools and simple machines are by this time familiar; and thus the *general properties* of matter, and the general laws of the actions of bodies upon each other, become gradually matter of observation and reflection; and the practical mechanic will be frequently improving his tools and machines. The general aim is to produce a greater quantity of work by the same amount of exertion. The attempts at improvement will be awkward, and frequently unsuccessful. When a man finds, that by increasing the length of his lever he increases his power of overcoming a resistance, a small degree of curiosity is sufficient to make him inquire in what proportion his advantage increases. When he finds that a double length gives him a double energy, he will be surprised and mortified to find, that at the end of the day he has not performed twice the quantity of work; but, after much experience, he will learn that every increase of energy, by means of a machine, is nearly compensated by an increase of time in the performance of his task; and thus one of the great and leading principles of practical mechanics is inculcated in a manner not to be forgotten, and the practical mechanic brought to speculate about motion and force; and by gradual and easy steps the general laws of simple motions are established.

The origin of mathematics.

It is evident that these speculations cannot be carried on, nor any considerable knowledge acquired, without some acquaintance with the art of measurement; and the very questions which the mechanic wishes to solve presuppose some advances in this art, which in process of time refined itself into mathematics, the most perfect of all the sciences. All the phenomena of sensible motion afford employment to the mathematician. It is performed in a double or triple time, through a double or triple space, by a double or triple body, by the exertion of a double or triple force; produces a double or triple effect; is more to the right or to the left, upwards or downwards, &c.; in short, every affection of motion is an object of mathematical discussion. Such a science must have ere now appeared in the form of an art, in consequence of the mutual transactions of men. These amongst an uncultivated people are chiefly in the way of barter. If I want corn from a peasant, and have nothing to give for it but the cloth which I have made, we must fall on some way of adjusting our terms in respect of the quantity. We should soon discover that the length, and breadth, and depth of the box or bag were equally important; and it would not be difficult to see, that if any of them were doubled or tripled, the quantity of grain would be so too; if two of them were doubled, the grain would be quadrupled; and if all the three were doubled the quantity of grain would be increased eight times. The same thing would also be observed with respect to my cloth. By such transactions as these, a few of the properties of plane and solid numbers and figures would become known, and the operations of multiplication and division, where arithmetic is combined with geometry; and daily observation shows us, that the more abstruse properties of number and figure, which to the generality of mankind are so insignificant, lay hold on the fancy of some individuals with such force, as to abstract them from every other intellectual entertainment, and they are studied with a keenness and perseverance almost unequalled in any other walk of science. To most men the performance of a machine is a more attractive object than the properties of a figure, and the property of a figure more entertaining than that of a number; but the fact seems to be otherwise. Before Pythagoras had invented the theorem which bears his name, and which is amongst the first elements of geometry, he had reformed the Grecian music by the addition of a note to their scale; and this addition proceeds on a very refined speculation respecting the properties of numbers. Hence amongst the Greeks arithmetic must have made considerable progress, whilst geometry was yet in its cradle; and we know to what astonishing length they prosecuted the science of pure geometry, whilst their knowledge of mechanical principles was almost nothing. The Arabs also made hardly any addition to the geometry of the Greeks, if they did not rather almost completely forget it; whilst they improved their arithmetic into algebra, the most refined and abstract branch of human knowledge. There is such a distance, in point of simplicity, between pure mathematics and the most elementary mechanics, that the former continued to make rapid steps to improvement in more modern times, whilst the latter languished in its infancy, and hardly deserved the name of science till latterly, when the great demand for it, by the increase and improvement in manufactures, interested many in the study, and facilitated its progress, by the multitude of machines which were contriving on all hands by the manufacturers and artisans: and even at present it must be acknowledged, that it is to them that we are indebted for almost every new invention in mechanics, and that the speculatist has seldom done more than improve the invention, by exhibiting its principles, and thus enabling the artist to correct its imperfections; and now science and art go hand in hand, mutually giving and receiving assistance. The demands of the navigator for mathematical and astronomical knowledge have dignified these sciences; and they are no longer the means of elegant amusement alone, but merit the munificence of princes, who have erected observatories, and furnished voyages of discovery, where the mathematical sciences are at the same time cherished, and applied to the most important purposes.

This short sketch of what may be called *the natural history of the physical sciences* will not, we hope, be thought improper or unprofitable. It tends to confirm an assertion often alluded to, that the prosecution of the study of nature will be more successful, if we imitate her mode of proceeding, and divide the labour. It will be still further confirmed by attending to the scientific difference of the phenomena, which marks out a different mode of proceeding, and a difference in the knowledge which we shall ultimately acquire, after our most successful researches.

The connecting principle of concomitant events.

In both classes of phenomena already distinguished, we must grant, that the principle which connects the pairs of concomitant events, rendering the one the inseparable companion of the other, is totally unknown to us, because it is not the immediate object of our perception. But in the phenomena of the first class, we see the immediate exertion of this principle, whatever it may be; we can observe the exertion with accuracy; we can determine its kind and degree, which are the signs and measures of the kind and degree of the unperceived cause. This exertion, being always some modification of motion, allows us to call in the aid of mathematical knowledge, and thus to ascertain with the precision peculiar to that science the energy of the cause, judging of the tendency and quantity by the tendency and the quantity of the observed effect. But in the second class of phenomena the case is very different. In the operations of chemistry, for instance, the *immediate* exertion of the cause is not perceived; all that we observe is the assemblage of particles which obtains before mixture, and that which takes place when it is completed, and which we consider as its result. The procedure of nature in producing the change is unseen and unknown. The steps are hid from our observation. We are not only ignorant of the cause which determines one particle of our food to become a part of our body whilst others are rejected, but we do not see the operation. We are not only ignorant of the cause which determines a particle of vitriolic acid to quit the fossil alkali with which it is united in Glauber's salt, and to attach itself to a particle of magnesia already united with the muriatic acid, which also quits it to unite with the alkali; but we do not see the operation. The particles and their motions are not the objects of our senses; and all that we see is the Epsom salt and common salt separated from the water in which we had formerly dissolved the *sal mirabile* and the muriated magnesia. The motions, which are the *immediate* effects of the changing causes, and therefore their only indications, characteristics, and measures, fitted to show their nature, are hidden from our view.

The phenomena of the second class; less understood.

Our knowledge therefore of these phenomena must be less perfect than that of the phenomena of the former class; and we must here content ourselves with the discovery of more remote relations and remote causes, and with our ignorance of the very powers of nature by which these changes are brought about, and which are cognoscible only by their immediate effects, namely, the motions which they produce unseen. The knowledge which we really do acquire is somewhat similar to what the mechanical philosopher has acquired when he has discovered, by many experiments and investigations, that magnets attract each other by their dissimilar, and repel each other by their similar poles, and do not act at all upon any bodies except loadstones and iron. Here we leave undiscovered all that is most curious in the phenomenon, namely, how these attractions and repulsions are produced; and even here the magnetical philosopher has the advantage of seeing the agents and the operation.

Some philosophers have attempted to explain the phenomena by the doctrine of motion.

But philosophers attending to this circumstance, that, even in these cases, the changes are produced by motions, or consist in motions, however unperceived these may be, have concluded, that the laws according to which nature operates in producing these changes are similar to the laws which regulate her operations in the sensible actions of bodies, or are included in them; and that the motions, although unseen, and the moving forces, are perfectly similar. They have therefore employed similar modes of investigation, applying the laws of impulse, and calling in the aid of mathematical knowledge. Of this we have many examples in the writings of Dr Freind, Keill, Bernoulli, Helsham, Boerhaave, Hartley, and others, who have delivered theories of fermentation, solution, precipitation, crystallization, nutrition, secretion, muscular action, nay, even of sensation and intelligence, founded, as they think, upon the laws of motion, and illustrated and supported by mathematical reasoning. Lord Bacon himself, that careful and sagacious distinguisher of intellectual operations, has gone into the same track in his explanation of the phenomena of fire and combustion; and Sir Isaac Newton has made several attempts of the same kind, although with peculiarities which always characterize his discussions, and render them very different from those of an inferior class.

But the success of these philosophers has hitherto been very discouraging; indeed they had no title to expect any; for their whole trains of reasoning have proceeded upon analogies which were not observed, but assumed or *supposed* without any authority. There is not that similarity in the phenomenon, or in the visible effect, which is absolutely necessary for a successful reasoning by analogy. We do not observe any local motion, any change of place, which alone enables us to reason mathematically on the subject. And to render the case desperate, this ill-founded analogy has been mixed with hypotheses completely gratuitous. Certain forms have been assigned to the particles, and certain modes of action have been laid down for them, for the reality of which we have not the least argument or indication; and, to complete the matter, these fancied forms and laws of action have been such as are either self-contradictory and inconsistent, or they have been such as, if allowed to act in a way analogous to what we observe in the sensible motions of bodies, would produce effects totally different from those which are observed. These atomical theories, as they are called, transgress every rule of philosophical discussion; and even the best of them are little better than trifling amusements. By far the greatest part of them only serve to raise a smile of pity and contempt in every person who is at all acquainted with mechanical philosophy. Whenever we see an author attempting to explain these hidden operations of nature by invisible fluids, by ethers, by collisions, and vibrations, and particularly if we see him introducing mathematical reasonings into such explanations, the best thing we can do is to shut the book, and take to some other subject. That we may not be thought to speak presumptuously upon this occasion, we only beg leave to remind our readers, that the united knowledge of the most eminent mathematicians of Europe has not yet been able to give any thing more than an approximation to the solution of the problem of three bodies, that is, to determine with accuracy the motions of three particles of matter acting on each other in the simplest of all possible manners, viz. by forces varying as the squares of the distances inversely; and the vibrations of elastic bodies, of any but the very simplest possible forms, are to this day beyond the reach of investigation. What then should be our expectations in cases where millions of particles are acting at once, of forms unobserved, and with forces unknown, and where the object is not a determination of an average result of many, where the precise state of an individual article need not be known, but where it is this very precise state of each single particle that we want to know? What can it be but uncertainty and mistake?

Notwithstanding these discouraging circumstances, we must observe that this kind of inquiry has greatly improved, alongst with the improvement and extension of mathematical philosophy, and since philosophers have given over their incessant attempts to explain everything by impulse; and we need not despair of making still further advances, if we will content ourselves with going no farther than Newton has done in his explanation of the planetary motions. He has immortalized his own name, and has added immensely to our stock of useful knowledge; yet he has stopped short at the discovery of the fact of universal gravitation; and all who have endeavoured to explain or account for this fact have only exposed themselves to pity. We may perhaps be one day able to demonstrate from the phenomena that the particles of matter have certain mutual tendencies to or from each other, exerted according to fixed or invaried rules; and from these tendencies we may be able to explain many other phenomena, and predict the consequences, with as much certainty and evidence as an astronomer calculates a future eclipse. This would be a great acquisition, and perhaps more is impossible; and the road to this has been indicated by Sir Isaac Newton, who has expressed his suspicion, that as the great movements of the solar system are regulated by universal gravitation, so the mutual actions of the particles of matter are produced and regulated by tendencies of a similar kind, *equally* but not *more* inexplicable, and of which the laws of action are to be discovered by as careful an attention to the phenomena, and by the same patient thinking, which he has employed on the planetary motions.

The particular divisions of physical science in Britain.

The above distinction in the nature of the phenomena, the difference in the nature of the knowledge which is to be acquired, and the means which are to be employed for the successful prosecution of the two branches of general physics, have occasioned a still farther restriction (at least in Britain) of the term *Natural Philosophy*. It is particularly applied to the study of the phenomena of the first class, whilst those of the second have produced the sciences of *Chemistry* and *Physiology*.

The phenomena of the first class have been usually called *mechanical*, in order to distinguish them from those observed in the operations of chemistry, and in the animal and vegetable economy; and the explanations which have been attempted of some of the last, by applying the laws observed in the phenomena of the first class, have been called *mechanical explanations*.

As this first class is evidently but a part of general physics, there is some impropriety in giving the name *natural philosophy* to a course of doctrines which is confined to these alone. Indeed at the first institution of universities, the lectures given in the *Schola Physica* were much more extensive, comprehending almost all the phenomena of the material world; but as all arts and sciences have improved most where the labour has been most divided, it was found more conducive to the advancement of knowledge that separate institutions should be founded for the studies of natural history, chemistry, physiology, &c.; and thus the phenomena, purely mechanical, and a few others in magnetism, electricity, and optics, which either were susceptible of mathematical treatment, or had little connection with the studies of chemistry and physiology, were left to the care of the professor of natural philosophy.

As the terms *chemistry* and *physiology* have been applied to two very important branches of general physics, we think that a more specific or characteristic name might be appropriated to the other, and that it might very properly be termed *Mechanical Philosophy*.

It only remains to make a few observations on the distinctive means of prosecuting these studies with success; and to point out some of the advantages which may reasonably be expected from a careful prosecution of them; but in doing so, we shall confine ourselves to what is usually called *Natural Philosophy*, referring generally to the articles CHEMISTRY and PHYSIOLOGY for what belongs to these branches.

Mechanical philosophy defined.

MECHANICAL PHILOSOPHY may, in conformity with the foregoing observations, be defined, the study of the sensible motions of the bodies of the universe, and of their actions producing sensible motions, with the view to discover their causes, to explain subordinate phenomena, and to improve art.

The principle upon which all philosophical discussion proceeds is, that every change which we observe in the condition of things is considered by us as an effect, indicating the agency, characterizing the kind, and measuring the degree of its cause. In the language of mechanical philosophy, the cause of any change of motion is called a moving or changing *force*. The disquisitions of natural philosophy must therefore begin with the consideration of motion, carefully noticing every affection or quality of it, so as to establish marks and measures of every change of which it is susceptible; for these are the only marks and measures of the changing forces. This being done, it only remains to apply them to the motions which we observe in the universe.

The laws of motion, and their application.

From the general principle of philosophical discussion already mentioned, there flow directly two axioms. 1. Every body perseveres in a state of rest, or of uniform rectilineal motion, unless affected by some moving force. 2. Every change of motion is in the direction and in the degree of the force impressed. These are usually called the *laws of motion.* They are more properly laws of human judgment with respect to motion. Perhaps they are necessary truths, unless it be alleged that the general principle, of which they are necessary consequences, is itself a contingent though universal truth. By these two axioms, applied *in abstracto* to every variety of motion, we establish a system of general doctrines concerning motions, according as they are simple or compounded, accelerated, retarded, rectilineal, curvilineal, in single bodies, or in systems of connected bodies; and we obtain corresponding characteristics and measures of accelerating or retarding forces, centripetal or centrifugal, simple or compound.

We have an illustrious example of this abstract system of motion and moving forces in the first book of Sir Isaac Newton's Mathematical Principles of Natural Philosophy. Euler's *Mechanica sive Scientia Motus*, Herman's *Phoronomia sive de Viribus Corporum*, and D'Alembert's *Traité de Dynamique*, are also excellent works of the same kind. In this abstract system no regard is paid to the casual differences of moving forces, or the sources from which they arise. It is enough to characterize a double accelerating force, for instance, that it produces a double acceleration. It may be a weight, a stream of water, the pressure of a man; and the force of which it is said to be double may be the attraction of a magnet, a current of air, or the action of a spring.

Having established these general doctrines, the philosopher now applies them to the *general* phenomena of the universe, in order to discover the nature of the forces which really exist, and the laws by which their operations are regulated, and to explain interesting but subordinate phenomena. This is the chief business of the mechanical philosopher; and it may with some propriety be called the *mechanical history of nature.*

Mechanical phenomena of the universe.

Some method must be followed in this history of mechanical nature. The phenomena must be classed by means of their resemblances, which infer a resemblance in their causes; and their classes must be arranged according to some principle. We have seen no method which appears to us less exceptionable than the following.

The generality of the phenomena the principle of arrangement.

The principle of arrangement is the generality of the phenomena; and the propriety of adopting this principle arises from the probability which it gives us of more readily discovering the most general actuating forces, whose agency is implicated in all other phenomena of less extent, and therefore should be previously discussed, that we may detect the discriminating circumstances which serve to characterize the subordinate phenomena, and are thus the marks of the distinguishing and inferior natural powers.

The laws of motion are first applied to astronomical phenomena.

The most general of all phenomena is the curvilineal motion of bodies in free space; it is observed throughout the whole extent of the solar system. The mechanical history of nature begins therefore with astronomy. Here, from the general phenomena of the planetary motions, is evinced the fact of the mutual deflection of every body towards every other body, and this in the inverse proportion of the squares of the distance, and the direct proportion of the quantity of matter. This is the fact of *universal gravitation*, indicating the agency, and measuring the intensity, of the universal force of mutual gravity.

Having established this as an universal fact, the natural philosopher proceeds to point out all the particular facts which are comprehended under it, and the peculiarities of which characterize the different movements of the solar system. That is, in the language of philosophy, he gives a theory or explanation of the subordinate phenomena, the elliptical motions of the planets and comets, their mutual disturbances, the lunar irregularities, the oblate figure of the planets, the nutation of the earth's axis, the precession of the equinoxes, and the phenomena of the tides and trade winds; and he concludes with the theory of the parabolic motion of bodies projected on the surface of this globe, and the motion of pendulums.

As he goes along, he takes notice of the applications which may be made to the arts of life, of the various doctrines which are successively established; such as chronology, astronomical calculation, dialling, navigation, gunnery, and the measuring of time.

If a square parcel of sand be lying upon the table, and the finger be applied to any part of it to push it along the table, that part is removed where you will, but the rest remains in its place; but if it be a piece of sand-stone of the same materials and shape, and the finger be applied as before, the whole is moved, and the other parts accompany the part impelled by the finger in all its motions. From the moon's accompanying the earth in all its motions round the sun, we infer a moving force which connects the moon and earth. In like manner we must conclude, that a moving force connects the particles of the stone; for we give the name *force* to everything which produces motion. We call it the force of *cohesion*, a term which, like gravitation, expresses merely a fact. This seems to be the next phenomenon of the universe in point of extent.

Having, from the general phenomenon, established the existence of this force, the philosopher proceeds to ascertain the laws by which its exertions are regulated; which is the ascertaining its distinctive nature and properties. This he does in the same way that he ascertained the nature of planetary gravitation, namely, by observing more particularly the various phenomena. Here is opened a most extensive and varied field of observation, in which it must be acknowledged that very little regular and marked progress has been made. The variety of the phenomena, and the consequent variety in the nature of the connecting forces, appear as yet inconceivably great; and there seems little probability of our being able to detect in them all any sameness, combined with the other distinguishing circumstances, as we have done in the case of gravity. Yet we should not despair. Boscovich has shown, in the most unexceptionable manner, that although we shall suppose that every atom of matter is endowed with a perfectly similar force, acting in a certain determined ratio of the small and imperceptible distances at which the particles of matter are arranged with respect to each other, the external or sensible appearances may, and must, have all that variety which we observe. He also shows very distinctly how, from the operation of this force, must arise some of the most general and important phenomena which characterize the different forms of tangible bodies.

We observe the chief varieties of the action of this corpuscular force upon the bodies which we denominate hard, soft, solid, fluid, vaporous, brittle, ductile, elastic. We see instances where the parts of bodies avoid each other, and require external force to keep them together, or at certain small distances from each other. This is familiar in air, vapours, and all compressible and elastic bodies, and is evidently a most curious and interesting subject of investigation. On the nature and action of these corpuscular forces depend the strength or firmness of solids, their elasticity, their power of communicating motion, the pressure, and motion, and impulse of fluids; nay, on the same actions depend all the chemical and physiological phenomena of expansion, fusion, congelation, vaporisation, condensation, solution, precipitation, absorption, secretion, fermentation, and animal and vegetable concoction and assimilation. Out of this immense store of phenomena, this inexhaustible fund of employment for our powers of investigation, the natural philosopher selects those which lead directly to the production or modification of sensible motion.

T ro-
du n of
m n by
im e.

He will therefore consider, firstly, the communication of motion amongst detached and free bodies, establishing the laws of impulse or collision. This has always been considered as the elementary doctrine of mechanical philosophy, and as the most familiar fact observed in the material world; and in all ages philosophers have been anxious to reduce all actions of bodies upon each other to impulse, and have never thought a phenomenon completely explained or accounted for until it had been shown to be a case of impulse. This it is which has given rise to the hypotheses of vortices, ethers, magnetic and electric fluids, animal spirits, and a multitude of fancied intermediums between the sensible masses of matter, which are said in common language to act upon each other. A heavy body is supposed to fall, because it is impelled by a stream of an invisible fluid moving according to certain conditions suited to the case. The filings of iron are supposed to be arranged round a magnet by means of a stream of magnetic fluid issuing from one pole, circulating perpetually round the magnet, and entering at the other pole, in the same manner as we observe the flote-grass arranged by the current of a brook.

But the philosopher who has commenced the mechanical study of nature by the abstract doctrines of dynamics, and made its first application to the celestial phenomena, and who has attended carefully to the many analogies between the phenomena of gravitation and cohesion, will be at least ready to entertain very different notions of this matter. He will be so far from thinking that the production of motion by impulse is the most familiar fact in nature, that he will acknowledge it to be comparatively very rare; nay, there are some appearances in the facts, which are usually considered as instances of impulsion, which will lead him to doubt, and almost to deny, that there has *ever been observed* an instance of one body putting another in motion by coming into absolute contact with it, and striking it; and he will be disposed to think that the production of motion in this case is precisely similar to what we observe when we gently push one floating magnet towards another, with their similar poles fronting each other. There will be the same production of motion in the one and diminution of it in the other, and the same uniform motion of the common centre of gravity: and, in this case of the magnets, he sees completely the necessity of a law of motion, which is not an axiom, but is observed throughout the whole of nature, and which receives no explanation from any hypothesis of an intervening fluid, but is even totally inconsistent with such a supposition. We mean, "that every action of one body on another is accompanied by an equal and opposite action of that other on the first." This is usually called the *equality of action and re-action*. It is not intuitive, but it is universal; and it is a necessary consequence of the perfect similarity of the corpuscular forces of the same kinds of matter. This general fact, unaccountable on the hypothesis of impelling fluids, is considered in the planetary motions as the unequivocal indication of the sameness of that gravity which regulates them all. The rules of good reasoning should make us draw the same conclusion here, that the particles of tangible matter are connected by equal and mutual forces, which are the *immediate causes* of all their sensible actions, and that these forces, like gravitation, vary with every change of distance and situation.

Of motion
as it respects the
theory of
machines,
&c.

The laws of collision and impulsion being now established, either as original facts, or as consequences of the agency of equal and mutual forces which connect the particles of matter, the philosopher considers, secondly, the production of motion by the intervention of solid bodies, where, by reason of the cohesion of matter, some of the motions are necessarily confined to certain determinate paths or directions. This is the case in all motions round fixed points or axes, or along planes or curves which are oblique to the action of the forces.

Mechanics.

This part of the study contains the theory of machines, pointing out the principles on which their energy depends, and consequently furnishing maxims for their construction and improvement. But these observations do not complete the discussion of the mechanism of solid bodies. They are not only solid and inert, but they are also heavy; and therefore the action of gravity must be combined with the consequences of solidity. This will lead to discussions about the centre of gravity, the theory and construction of arches and roofs, the principles of stability and equilibrium, the attitudes of animals, and many particulars of this kind.

The nature
and definition of fluidity.

Thirdly, the philosopher will now turn his attention to another form in which tangible matter exhibits many interesting phenomena, namely, *fluidity*. The first thing to be attended to here is, What is that particular form of existence? What is the precise phenomenon which characterizes fluidity? What is the definition of a fluid? This is by no means an easy question, and considerable objections may be stated against any definition that has been given of it. Sir Isaac Newton says, that a fluid is a body whose particles yield to the smallest impression, and by so yielding are easily moved amongst themselves. It may be doubted whether this be sufficiently precise; what is meant by the smallest impression? and what is easily moving? Is there any precise degree of impression to which they do not yield; and do they oppose any resistance to motion? And a still stronger objection may be made. It is not clear that a body so constituted will exhibit all the appearances which a body acknowledged to be fluid does really exhibit. Euler offers some very plausible reasons for doubting whether it will account for the horizontal surface, and the complete propagation of pressure through the fluid in every direction; and therefore prefers selecting this last phenomenon, the propagation of pressure *quaqua versum*, as the characteristic of fluidity, because a body having this constitution (on whatever circumstance it may depend) will have every other observed property of a fluid. But this definition is hardly simple or perspicuous enough; and we think that the objections against Newton's more simple and intelligible definition are not unanswerable. Boscovich defines a fluid to be *a body whose particles exert the same mutual forces in all directions*, and shows that such particles must be indifferent, as to any position, with respect to each other. If no external force act upon them, they will remain in every position, and will have no tendency to arrange themselves in one position rather than another; differing in this respect from the particles of solid, or soft, or viscid bodies, which require some force to change their respective positions, and which recover these positions again when but gently disturbed. He illustrates this distinction very beautifully, by comparing a parcel of balls thrown on quicksilver, and attracting each other, with a parcel of magnets in the same situation. The balls will stick together, but in *any position*; whereas the magnets will always affect a particular arrangement.

When the characteristic phenomenon of fluidity has been selected, the philosopher proceeds to combine this property with gravity, and establishes the doctrine of hydrostatics, or of the pressure and equilibrium of heavy fluids, the propagation of this pressure in every direction; and demonstrates the horizontality of surface assumed by all perfect fluids. These doctrines and principles enable us to determine several very interesting circumstances respecting the mutual pressure of solids and fluids on each other, such as the pressures exerted on the bottoms and sides of vessels, and the support and whole mechanism of floating bodies.

Of the pressure and equilibrium of fluids, or hydrostatics.

Of the motion of fluids, or hydraulics.

He then considers how fluids will move when their equilibrium of pressure is destroyed; and establishes the doctrines of hydraulics, containing all the modifications of this motion, arising from the form of the vessels, or from the intensity or direction of the pressure which occasions it. And this subject is completed by the consideration of the resistance which fluids oppose to the motion of solid bodies through them, and their impulse on bodies opposed to their action. These are very important matters, being the foundations of many mechanical arts, and furnishing us with some of our most convenient and efficacious powers for impelling machines. They are also of very difficult discussion, and have by no means been completely investigated or established. Much remains yet to be done, both for perfecting the theories, and for improving the arts which depend upon them.

Importance of these branches of science.

It is evident that upon these doctrines depend the knowledge of the motions of rivers and of waves; the buoyancy, equilibrium, and stability of ships; the motion of ships through the waters; the action of the winds on the sails; and the whole arts of marine construction and seamanship.

The nature and definition of vapour.

There is another general form of tangible matter which exhibits very different phenomena, which are also extremely interesting; we mean that of vapour. A vapour is a fluid, and all the vapours that we know are heavy fluids; they are therefore subject to all the laws of pressure and impulse. But they are susceptible of great compression by the action of external forces, and expand again when these forces are removed. In consequence of this compression and expansion, the general phenomena of fluidity receive great and important modifications; and this class of fluids requires a particular consideration. As air is a familiar instance, this branch of mechanical philosophy has been called pneumatics.

The doctrine of air, or pneumatics.

Under this head we consider the pressure of the atmosphere, and its effects both on solid and on fluid bodies. It produces the rise of waters or other fluids in pumps and syphons, and gives us the theory of their construction. It explains many curious phenomena of nature, such as the motions in the atmosphere, and their connection with the pressure of the air, and its effect upon the barometer or weather-glass. Air, when in motion, is called *wind;* and it may be employed to impel bodies. The theory of its action, and of its resistance to moving bodies, is therefore to be considered in this place.

But besides their motions of progression, &c. such as we observe in winds, compressible or elastic fluids are susceptible of what may be termed internal motion; a kind of undulation, where the contiguous parts are thrown into tremulous vibrations, in which they are alternately condensed and rarefied; and these undulations are propagated along the mass of elastic fluid, much in the same way in which we observe waves to spread on the surface of water. What makes this an interesting subject of consideration is, that these undulations are the more ordinary causes of sound. A trembling chord, or spring, or bell, agitates the air adjoining to it. These agitations are propagated along the air, and by its intervention agitate the organ of hearing. The mechanism of these undulations has been much studied, and furnishes a very beautiful theory of musical harmony.

Of the pressi of elas fluids.

The philosopher examines the *law of compressibility* of air and other elastic fluids, and thus gets the knowledge of the constitution of the atmosphere, and of the action of those fluids when employed to impel solid bodies. Gunpowder contains an immense quantity of permanently elastic air, which may be set at liberty by inflammation. When this is done at the bottom of a piece of ordnance, it will impel a ball along the barrel, and discharge it from the muzzle, in the same way that an arrow is impelled by a bow. And thus having discovered in what degree this air presses in proportion to its expansion, we discover its action on the ball throughout the whole length of the piece, and the velocity which it will finally communicate to the ball. Here then is contained a theory of artillery and of mines.

Of the versio bodie elastic by fir

Chemistry teaches us, that most bodies can be converted by fire into elastic fluids, which can be employed to act upon other bodies in the way of pressure or impulse. Thus they come under the review of the mechanical philosopher; and they have become interesting by being employed as moving forces in some very powerful machines.

These discussions will nearly exhaust all the general mechanical phenomena. There remain some, however, which are much more limited, but furnish very curious and important subjects of investigation.

Of the nome loads or ma tism.

The phenomena exhibited between loadstones or magnets and iron have long attracted attention; and the use to which the polarity of the loadstone has been applied, namely, the directing the course of a ship through the pathless ocean, has rendered these phenomena extremely interesting. They are specified by the term magnetism. Considerable progress has been made in the arrangement and generalization of them; but we have by no means been able hitherto to bring them all under one simple fact or law. The attention has been too much turned to the discovery of the ultimate cause of magnetism; whereas we should have rather employed our ingenuity in discovering all the general laws, in the same manner as Kepler and Newton did with respect to the celestial phenomena, without troubling themselves with the cause of gravitation. Dr Gilbert of Colchester was the first who considered the magnetical phenomena in a truly philosophical manner; and his treatise *De Magnete* may be considered as the first, and one of the most perfect specimens of inductive logic. It is indeed an excellent performance; and when we consider its date, 1580, it is almost a wonder. Æpinus's *Tentamen Theoriæ Magnetismi* is a most valuable work, and contains nearly all the knowledge which we have as yet of the subject.

Of el cal pl mena.

There is another class of mechanical phenomena which have a considerable affinity with the magnetical; we mean the phenomena called electrical. Certain bodies, when rubbed or otherwise treated, attract and repel other bodies, and occasion a great variety of sensible motions in the neighbouring bodies. Philosophers have of late years paid much attention to these appearances, and have established many general laws concerning them. But we have not been more successful in bringing them all under one fact or law, and thus establishing a complete theory of them, than in the case of magnetism. Franklin and Æpinus are the authors who have been most successful in this respect. Dr Franklin, in particular, has acquired great celebrity by his most sagacious comparison of the phenomena; which has enabled him to establish a few general laws, almost as precise as those of Kepler, and of equally extensive influence. His discovery, too, of the identity of thunder and electricity has given an importance and dignity to the whole subject. There are many phenomena of electricity which cannot be called mechanical, and are of the most curious and interesting kind. As these have little connection with any of the other great branches of physical science, they have generally been considered in treatises of natural philosophy; and, along with inquiries into the original cause of electricity in general, continue to engage much of our attention.

phe- a of

The appearances which are presented to us by our sense of seeing form another class, which has always been considered as forming a branch of natural philosophy in all seminaries of learning. It does not, however, obviously appear that they are mechanical phenomena. The intimate nature of light is still a secret. Fortunately it is not necessary to be known to give us a very perfect theory of the chief phenomena. The general laws of optics are so few, so simple, and so precise, that our theories are perhaps more perfect here than in any other branch of physics; but these theories are as yet far removed from the rank of primary facts. Many unknown events happen before the phenomenon comes under the hands of the ordinary optician, so as to become the subjects of the simple laws of reflection and refraction. It may even be doubted, and has been doubted, whether the phenomena of optics are cases of body in motion; whether all the lines which the optician draws are any thing but the directions along which certain qualities are exerted. The side of a ball which is next the candle may be bright and the other side dark, just as the side of a ball which is next the electrical globe is *minus* and the other side *plus*; and all this without any intervening medium. Apparition or visibility may be a quality of a body, depending on the proximity and position of another body, without any thing between them, just as weight is; and this quality may be cognizable by our faculty of seeing alone, just as the pressure of a heavy body is by our feeling alone.

optics to be ered art of nical ophy.

The first thing which made it probable that mechanical philosophy had any thing to do with the phenomena of optics, was the discovery of Mr Roemer, "that apparition was not instantaneous;" that some time elapsed between the illumination of a body and its being seen at a distance. He discovered that it was not till forty minutes after the sun illuminated one of Jupiter's satellites that it was seen by the inhabitants of this globe. If therefore a sun were just created, it would be forty minutes before Jupiter would be illuminated by him, and two hundred before the Georgian planet would be illuminated. Here then is motion. It is therefore highly probable that there is something moved; but it is still doubted whether this something, which we call *light*, is a matter emitted from the shining body, and moving with great velocity, and acting upon and affected by other bodies in the various phenomena of optics, or whether it is a certain state of a medium which is thus propagated, as we see that waves are propagated along the surface of water, or sonorous undulations through the mass of air, whilst the water or air itself is hardly moved out of its place. Either of these suppositions makes optics a legitimate branch of mechanical philosophy; and it is the philosopher's business to examine both by the received laws of motion, and to see which of them gives consequences which tally with the phenomena. This has been done; and we imagine that a complete incompatibility has been demonstrated between the consequences of the undulations of an elastic medium and the phenomena of optics, whilst the consequences of the other or vulgar notion on this subject are perfectly consistent with mechanical laws. There are some things in this hypothesis very far beyond our power to conceive distinctly; but they are all similar in this respect to many facts acknowledged by all, and there is no phenomenon that is inconsistent with the legitimate consequences of the hypothesis. This gives it great probability; and this probability is confirmed by many chemical facts, and by facts in the vegetable economy, which give strong and almost undeniable indications of light being a body capable of a chemical union with the other ingredients of sublunary bodies, and of being afterwards set at liberty under its own form, as the cause or medium of vision. But these are questions similar to those about the cause of gravity, and totally unnecessary for establishing a complete theory of the optical phenomena for explaining the nature of vision, the effects of optical instruments, the cause of colours, the phenomena of the rainbow, halos and parhelia, &c. Only all this theory is unconnected with the principles called mechanical.

The probable increase of this extensive field of observation.

Such is the field of observation laid open to the mechanical philosopher of the present day. We may hope to extend it, and by degrees apply its doctrines even to the unseen motions which take place in chemistry and physiology. But we must, in the first place, perfect our knowledge and description of the sensible motions and actions of bodies. Those of fluids still demand much investigation; and till these are thoroughly understood, it is not time to attempt penetrating further into the recesses of nature.

Investigation of the law that action is always equal and opposite to re-action.

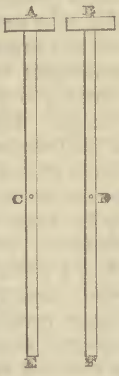
In the prosecution of this study, it is found that every change which can be observed in the state of a body, with respect to motion by the action of another body, is accompanied by an equal and opposite change in the state of that other body. Thus, in the phenomena of gravitation, it is observed that the deflections of the sun and planets are mutual. The same thing is observed in the actions of magnets on each other and on iron; it is also observed in the attractions and repulsions of electrical bodies; and it also obtains in all the phenomena of impulse and of corporeal pressure. It is therefore an universal law of motion, that *action is always equal and opposite to re-action;* but this must be considered merely as a matter of fact, a contingent law of nature, like that of gravitation. The contrary is perfectly conceivable, and involves no contradiction. That this is so, is evident from the proceedings of philosophers, who in every new case make it their business to discover by experiment whether this law was observed or not. It was amongst the last discoveries made by Sir Isaac Newton in his examination of the celestial motions. This being the case, it should never be assumed as a principle of reasoning until its operation has been ascertained by observation. It has been owing to this improper procedure that much false reasoning has been introduced into mechanical philosophy, and more particularly into the theory of impulsion, or the communication of motion by impulse. In considering this subject, a term has been introduced which has occasioned much wrangling and misconception; we mean the term *inertia*. It serves indeed to abbreviate language, but it has often misled the judgment. When used with cautious attention to every circumstance, it expresses nothing but the necessity of a cause to the production of any effect; but it is generally used as expressing a quality inherent in matter, by which it *resists* any change of state, or by which it maintains its present state. Matter is said to be inert; and as everything which changes the motion of a body is called a *force*, and as the inertia of A is supposed to change the motion of B, it is called *vis inertiæ;* and yet matter is said to be indifferent as to motion or rest, and to be inactive. These are surely very incongruous expressions. This obscure discourse has arisen from the poverty of all languages, which are deficient in original terms, and therefore employ figurative ones. Force, action, resistance, are all appropriated terms relating to our own exertions; and some resemblance between the external effects of these exertions and the effects of the connecting qualities of natural bodies, has made us use them in our disquisitions on these subjects. And as we are conscious that, in order to prevent our being pushed by another from our place, we must resist, exerting force; and that our resistance is the reason why this other man has not accomplished his purpose; we say, that the quiescent body resists being put in motion, and that its inertia is discovered by the diminution made in the motion of the impelling body. And upon the authority of this *vis inertiæ* as a first principle the phenomena of impulsion are explained, and the law of equal action and re-action is established.

But all this procedure is in contradiction to the rules of inductive logic; and the obscurity and confusion which have arisen from this original misconception, the consequent incongruity of language, and the awkward attempts that have been made to botch and accommodate it to the real state of things, have occasioned a dispute, and the only dispute, in natural philosophy, which has not yet been settled, and never can be settled, whilst such misconceptions are allowed to remain.

Proper meaning of the term *inertia.*

If the word *inertia* be taken as expressing, not a quality of matter, but a law of human judgment respecting matter, as expressing our necessity of inferring the agency of a moving force whenever we observe a change of motion, all difficulties will vanish, and the equality of action and re-action will be inferred, as it should be, from the phenomena of collision. There will be inferred a *vis insita corpori impellenti*, not *qua moventi*, but *qua corpori;* and this inference will carry us through all the mysteries of corporeal action, as it conducted Sir Isaac Newton in his grand researches.

Let us just consider how we reason in a new case. Let A and B be two magnets fastened on the ends of two long wooden laths AE, BF, which turn horizontally on pivots C, D, like compass needles, with their north poles fronting each other, twelve inches apart; and let A be pushed towards B, so that it would move uniformly with the velocity of two inches in a second. The phenomena *which have been observed* are as follow: A will gradually diminish its velocity; and when it has advanced about nine inches, will stop completely. B in the mean time will gradually acquire motion; and when it has advanced about nine inches, will have a velocity of about two inches per second, with which it will continue to move uniformly. Now, what is inferred from these phenomena? Because the motion of A is gradually retarded, we infer that a retarding force, that is, a force in the direction BA, has acted on it. And since this would not have happened if B had not been there, and always happens when B is there, we infer that B is either its cause or the occasion of its action. The vulgar say that B repels A; and so also say the dynamists. The abettors of invisible fluids say that a stream of fluid issuing from B impels A in the opposite direction. All naturalists agree in saying, that an active force connected with B has destroyed the motion of A, and consider this curious phenomenon as the indication and characteristic of a discovery. The same inference is made from the motion produced in B; it is considered by all as effected by a force exerted or occasioned by the presence of A; wherefore the dynamists and the vulgar say that A *repels* B. And both parties conclude, from the equal changes made on both bodies, that the changing forces are equal; here acknowledging that they *observe* an equality of action and re-action; and they add this to the other instances of the extent of this law of motion. All this while no one thinks of the inertia or inactivity of B, but, on the contrary, conclude this to be a curious instance of its activity, and most people conclude that both bodies carry about with them a *vis insita* both when at rest and when in motion.



Doubtful whether actual contact has ever been observed.

If other phenomena give unquestionable evidence that in ordinary collisions there is the same changes of motion, produced without mathematical contact, the same inferences must be drawn; and a scrupulous naturalist will doubt whether contact should make any change in our reasonings on the subject, and whether actual contact ever has been or can be observed. He will also be convinced, that whilst this is the general, or perhaps universal, process of nature in producing motion by impulse, all explanations of the action of bodies *e distanti*, by the intervention of ethers and other invisible fluids, are nothing but multiplying the difficulties; for instead of one fact, the approach of one magnet, for instance, to another, they substitute millions of unseen impulses, each of which equally needs an explanation. And if this fluid be supposed to produce its effects by any *peculiarity* in its constitution, as in the case of Newton's elastic ether, proposed by him to explain gravitation, the hypothesis substitutes, in the most unqualified manner, millions of similar phenomena for the one to be explained; for there is the same want of a second fluid in order to produce that mutual recess of the particles of the ether which constitutes its elasticity.

And this seems to be the limit to our inquiries into all the classes of natural phenomena. We find the masses or the particles of matter endued, in fact, with qualities which affect the state of other particles or masses, at smaller or at greater distances from each other, according to certain general rules or laws. This ultimate step in the constitution of things is inscrutable by us. It is arrogance in the highest degree for us to say, that because we do not comprehend how there is inherent in a body any quality by which another body may be affected at any distance from it, therefore no such quality *is possible*. It is no less so to say, that matter has no active property but that of moving other matter by impulse; and that because it may be so moved, and also by the agency of our own minds, therefore, when it is not moved by impulse, it is moved by minds. The same almighty FIAT which brought a particle of matter into existence could bring those qualities equally into existence; and the *how* in both is equally beyond our comprehension.

But, on the other hand, we must carefully guard against the incurious resting on this consideration, as a stop to further inquiry. There may be species of matter possessed of the mechanical powers, and which notwithstanding is not cognisable by our senses. All the properties of matter are not known to a person who is both deaf and blind; and beings possessed of more senses may perceive matter where we do not; and many phenomena may really be produced by the action of intervening matter, which we, from indolence or from haste, ascribe to the agency of inherent forces. The industry of philosophers has already discovered *intermedia* in some cases. It is now certain that air is the conductor of sound, and it is almost certain that there is such a thing as light. Let us therefore indulge conjectures of this kind, and examine the conjectures by the received laws of motion, and reject them when we find the smallest inconsistency; and always keep in mind, that even the most coincident with the phenomena is still but a possibility.

We may conclude the whole of these observations with the remark, that the questions about the activity or inactivity of matter are not *physical*, but *metaphysical.* Natural philosophy, it is true, commonly takes it for granted that matter is wholly inactive; but it is not of any moment in physics whether this opinion be true or false. Whether matter be acted on according to certain laws, or whether it act of itself according to the same laws, makes no difference to the natural philosopher. It is his business to discover the laws which really obtain, and to apply these to the solution of subordinate phenomena; but whether these laws arise from the nature of some agent external to matter, or whether matter itself is the agent, are questions which may be above his comprehension, and do not immediately concern his proper business.

The account we have now given of natural philosophy points out to us in the plainest manner the way in which the study must be prosecuted, and the helps which must be taken from other branches of human knowledge. The causes, powers, forces, or by whatever name we choose to express them, which produce the mechanical phenomena of the universe, are not observed, and are known to us only in the phenomena themselves. Our knowledge of the mechanical powers of nature must therefore keep pace with our knowledge of the motions, and indeed is nothing different from it. In order to discover and determine the forces by which the moon is retained in her orbit round the earth, we must know her motions. To a terrestrial spectator she appears to describe an ellipse, having the earth in one focus; but, in the mean time, the earth is carried round the sun, and the moon's real path, in absolute space, is a much more complicated figure. Till we know this figure, and the variations in the velocity with which it is described, we know nothing of the forces which actuate the moon in her orbit.

When Newton says that the forces by which she is retained in this elliptical orbit are directed to the earth, what does he mean? Only this, that the deflections from that uniform rectilineal motion which she would otherwise have performed are always in this direction. In like manner, when he says that these forces are inversely proportional to the squares of her distances from the earth, he only means that the deflections made in equal times in different parts of her motion are in this proportion. These deflections are considered as the characteristics and measures of the forces. We imagine that we have made all plain when we call this indicated cause a *tendency* to the earth; but we have no notion of this tendency to the earth different from the approach itself. This word tendency, so fashionable amongst the followers of Sir Isaac Newton, is perverted from its pure and original sense. *Tendere versus solem*, is, in the language of Rome, and also of Newton, to go towards the sun; but we now use the words tend, tendency, to signify, not the approach, but the *cause* of this approach; and when called upon to speak still plainer, we desert the safe paths of plain language, and express ourselves by metaphor, speaking of *nisus, conatus, vis centripeta*, and the like. When these expressions have become familiar, the original sense of the word is forgotten, and we take it for granted that the words never had another meaning; and this metaphor, sprung from the poverty of language, becomes a fruitful source of misconception and mistake. The only way to secure ourselves against such mystical notions as are introduced by these means into philosophy, is to have recourse to the way in which we acquire the knowledge of these fancied powers; and then we see that their names are only names for phenomena, and that universal gravitation is only an universal mutual approach amongst the parts of the solar system.

There is one case in which we fondly imagine that we know the cause independently of the effect, and that we could have predicted the phenomenon *a priori;* we mean the case of impulse: and hence it is that we are so prone to reduce everything to cases of impulsion, and that we have fallen upon all those subterfuges of ethers and other subtile fluids. But we might have saved ourselves all this trouble; for after having, by much false reasoning and gratuitous assumptions, shown that the phenomenon in question *might have been produced* by impulse, we are no nearer our purpose, because that property by which matter in motion puts other matter in motion, is known to us only by and in the effect. The fair and logical deduction from all this is, that we must not expect any knowledge of the powers of nature, the immediate causes of the motions of bodies, but by means of a knowledge of the motions themselves; and that every mistake in the motions is accompanied by a similar mistake in the causes. It is impossible to demonstrate or explain the gravitation of the planets to him who is ignorant of the properties of the ellipse, or the theory of gunnery to him who does not know the parabola.

A man cannot be a good natural philosopher without being a mathematician.

A notion has been sometimes advanced, that a man may become a natural philosopher without mathematical knowledge; but this is entertained by none who have any mathematics themselves; and surely those who are ignorant of mathematics should not be sustained as judges in this matter. We need only appeal to fact. It is only in those parts of natural philosophy which have been mathematically treated, that the investigations have been carried on with certainty, success, and utility. Without this guide, we must expect nothing but a school-boy's knowledge, resembling that of the man who takes up his religious creed on the authority of his priest, and can neither give a reason for what he imagines that he believes, nor apply it with confidence to any valuable purpose in life. These observations, on the other hand, show us the nature of the knowledge which may be acquired, and the rank which natural philosophy holds among the sciences.

The motions of bodies are subjects of pure mathematical disquisition.

Motions are the real and only objects of our observation, the only subjects of our discussion. In motion are included no ideas but those of space and time, the subjects of pure mathematical disquisition. As soon, therefore, as we have discovered the fact, the motion, all our future reasonings about this motion are purely mathematical, depending only on the affections of figure, number, and proportion, and must carry along with them that demonstration and irresistible evidence which is the boast of the science. To this we are indebted for that accuracy which is attained, and the progress which has been made, in some branches of mechanical philosophy; for when the motions are distinctly and minutely understood, and then considered only as mathematical quantities, independently of all physical considerations, and we proceed according to the just rules of mathematical reasoning, we need not fear any intricacy of combination or multiplicity of steps; we are certain that truth will accompany us, even though we do not always attend to it, and will emerge in our final proposition, in the same manner as we see happen in a long and intricate algebraic analysis.

Mechanical philosophy is almost wholly a mathematical study.

It appears from what has been said, that mechanical philosophy is almost wholly a mathematical study, and that it is to be successfully prosecuted only under this form; but in our endeavours to initiate the young beginner, it will be often found to require more steadiness of thought than can generally be expected for keeping the mind engaged in such abstract speculations. The object presented to the mind is not readily apprehended with that vivacity which is necessary for enabling us to reason upon it with clearness and steadiness, and it would be very desirable to have some means of rendering the conception more easy, and the attention more lively. This may be done by exhibiting to the eye an experiment, which, though but a single fact, gives us a sensible object of perception, which we can contemplate and remember with much more steadiness than any mere creature of the imagination. We could, by an accurate description, give such a conception of a room that the hearer should perfectly comprehend our narration of any occurrence in it; but one moment's glance at the room would be infinitely better. It is usual therefore to employ experiments to assist the imagination of the beginner; and most courses of natural philosophy are accompanied by a series of such experiments. Such experiments, connected by a slight train of argumentative discourse, may even serve to give a notion of the general doctrines, sufficient for an elegant amusement, and even tending to excite curiosity, and engage in a serious prosecution of the study. Such are the usual courses which go by the name of *Experimental Philosophy.* But this is a great misapplication of the term; such courses are little more than *illustrations* of known doctrines by experiments.

Experimental philosophy defined and explained.

EXPERIMENTAL PHILOSOPHY is the investigation of general laws, as yet unknown, by experiment; and this is the most infallible, and indeed the sole, way of arriving at the knowledge of them. This is the *Novum Organum Scientiarum* strongly recommended by Lord Bacon. It was new in his time, though not altogether without example; for it is the procedure of nature, and is followed whenever curiosity is excited. There was even extant in his time, as we have already mentioned, a very beautiful example of this method, namely, the Treatise of the Loadstone, by Dr Gilbert of Colchester; a work which has hardly been excelled by any, and which, when we consider its date, about the year 1580, is really a most wonderful performance. The most perfect model of this method is the Optics of Sir Isaac Newton. Dr Black's Essay on Magnesia is another very perfect example; and Dr Franklin's Theory of Electricity is a third example of great merit. That the investigation is not complete, nor the conclusions certain, is not an objection. The method is without fault; and a proper direction is given to the mind for the experiments which are still necessary for establishing the general laws.

A good treatise on the method of inquiry by experiment very necessary.

It were much to be wished that some person of talents and of extensive knowledge would give a treatise on the method of inquiry by experiment. Although many beautiful and successful examples have been given as particular branches of inquiry, we have but too many instances of very inaccurate and inconclusive investigations. Experiments made at random, almost without a view, serve but little to advance our knowledge. They are like shapeless lumps of stone merely detached from the rock, but still wanting the skill of the builder to select them for the different purposes which they may chance to serve; whilst well-contrived experiments are blocks cut out by a skilful workman, according as the quarry could furnish them, and of forms suited to certain determined uses in the future edifice. Every little series of experiments by Margraaf terminates in a general law, whilst hardly any general conclusion can be drawn from the numberless experiments of Pott. Lord Bacon has written much on this subject, and with great judgment and acuteness of distinction; but he has exceeded in this, and has fatigued his readers by his numerous rules; and there is in all his philosophical works, and particularly in this, a quaintness and affectation which greatly obscure his meaning, so that this most valuable part of his writings is very little read.

An objection to experimental inquiry.

A formidable objection has been made to this method of inquiry. Since a physical law is only the expression of a general fact, and is established only in consequence of our having observed a similarity in a great number of particular facts; and since the great rule of inductive logic is to give the law no greater extent than the induction on which it is founded; how comes it that a few experiments must be received as the foundation of a general inference? This has been answered in very general terms in the article PHILOSOPHY. But it will be of use to consider the subject a little more particularly. Our observations on this subject are taken from the dissertation on evidence by Dr Campbell in his Philosophy of Rhetoric.

This objection answered.

An attentive consideration of the objects around us will inform us that they are generally of a complicated nature, not only as consisting of a complication of those qualities of things called accidents, such as gravity, mobility, colour, figure, solidity, which are common to all bodies; but also as consisting of a mixture of a variety of substances, very different in their nature and properties; and each of these is perhaps compounded of ingredients more simple. Moreover, the farther we advance in the knowledge of nature, we find the more reason to be convinced of her constancy in all her operations. Like causes have always produced like effects, and like effects have always been preceded by like causes. Inconstancy sometimes appears in nature's works at *first sight;* but a more refined experience shows us that this is but an appearance, and that there is no inconstancy; and we explain it to our satisfaction in this way.

Most of the objects being of a complicated nature, we find, upon an accurate scrutiny, that the effects ascribed to them ought often to be solely ascribed to one or more of these component parts, whilst the others either do not contribute to them, or hinder their production; and the variety of nature is so great, that hardly any two individuals of the same species are in every respect like any other. On all these accounts we expect dissimilitudes in the phenomena accompanying perfectly similar treatment of different subjects of the same kind; but we find, that whenever we can be assured that the two substances are perfectly alike, the phenomena arising from similar treatment are the same; and long and extensive observation teaches us, that there are certain circumstances which insure us in the perfect similarity of constitution of some things. Whenever we observe the effect of any natural agent on one, and but one, of these, we invariably expect that the same will be produced on any other.

Should a botanist meet with a plant new to him, and observe that it has seven monopetalous flowers, he will conclude with the utmost confidence that every plant of this species will have monopetalous flowers; but he will not suppose that it will have seven, and no more than seven, flowers. Now these two facts seem to have no difference to warrant such a difference in the conclusion; which may therefore seem capricious, since there is but one example of both. But it is not from this example only that he draws the conclusion. Had he never before taken notice of any plant, he would not have reasoned at all from these remarks. But his mind runs immediately from this unknown species to all the known species of this genus, and to all the genera of the same order; and having experienced in the *figure* of the flower an uniformity in every species, genus, and order, which admits of no exception, but, in the *number* of flowers, a variety as boundless as are the circumstances of soil, climate, age, and culture, he learns to mark the difference, and draws the above-mentioned conclusions. Thus we learn, that *perfect* uniformity is not to be expected in any instance whatever, because in no instance is the simplicity of constitution sufficiently great to give us assurance of perfect uniformity in the circumstances of the case; and the utmost that our experience can teach us is a quick discrimination of those circumstances which produce the occasional varieties.

The nearer that our investigations carry us to the knowledge of elementary natures, the more are we convinced by general experience of the uniformity of the operations of real elements; and although it may perhaps be impossible for us ever to arrive at the knowledge of the simplest elements of any body, yet when any thing appears simple, or rather so exactly uniform, as that we have invariably observed it to produce similar effects, on discovering any *new* effect of this substance, we conclude, from a general experience of the efficient, a little constancy in the energy as to the rest. Fire consumes wood, melts lead, and hardens clay. In these instances it acts uniformly, but not in these only. We have always found, that whatever of any species is consumed by it in one instance, has been consumed by it upon trial at any time. If therefore a trial be made for the first time of its influence on any particular substance, he who makes it is warranted to conclude that the effect, whatever it may be, is a faithful representative of its effects on this substance in all past and future ages. This conclusion is not founded on this single instance, but upon this instance combined with the general experience of the regularity of this element in its operations.

This general conclusion, therefore, drawn from one experiment, is by no means in opposition to the great rule of inductive logic, but, on the contrary, it is the most general and refined application of it. General laws are here the real subject of consideration; and a law still more general, *that nature is constant in all its operations*, is the inference which is here applied as a principle of explanation of a phenomenon which is itself a general law, viz. *that nature is constant in this operation.*

The foundation of this general inference from one experiment being so firmly established, it is evident that experiments must be an infallible method of attaining to the knowledge of nature; and we need only be solicitous that we proceed in a way agreeable to the great rule of inductive logic; that is, the subject must be cleared of every accidental and *unknown* circumstance, and put into a situation that will reduce the interesting circumstance to a state of the greatest possible simplicity. Thus we may be certain that the event will be a faithful representative of every similar case; and unless this be done in the preparation, nothing can result from the most numerous experiments but uncertainty and mistakes.

The account which has been given of mechanical philosophy would seem to indicate that experiment was not of much use in the farther prosecution of it. The two laws of motion, with the assistance of mathematics, seem fully adequate to the explanation of every phenomenon; and so they are to a certain degree. But this degree is as yet very limited. Our mathematical knowledge, great as it is in comparison with that of former times, is still insufficient for giving accurate solutions even of questions, comparatively speaking, very simple. We can tell, with the utmost precision, what will be the motions of two particles of matter, or two bodies, which act on each other with forces proportioned to the squares of the distances inversely; but if we add a third particle, or a third body, acting by the same law, the united science of all Europe can only give an approximation to the solution.

What is to be done, then, in the cases which come continually before us, where millions of particles are acting at once upon each other in every variety of situation and distance? How shall we determine, for instance, the motion of water through a pipe or sluice when urged by a piston or by its own weight? what will be its velocity and direction? It is impossible, in the present state of mathematical knowledge, to tell with any precision or certainty. And here we must have recourse to experiment. But if this be the case, must the experiment be made in every possible variety of situation, depth, figure, pressure? or is it possible to find out any general rules, founded on the general laws of motion, and rationally deduced from them? Or, if this cannot be accomplished, will experiment itself furnish any general coincidences which show such mutual dependences, that we may consider them as indications of general principles, though subordinate, complicated, and perhaps inscrutable? This can be discovered by experiment alone.

The attention of philosophers has been directed to each of these three chances, and very considerable progress has been made in them all. Numerous experiments have been made, and are almost sufficient to direct the practice in many important cases, without the help of any rule or principle whatever. But there are many cases, and these of by far the greatest importance, such as the motion of a ship impelled by the winds, resisted by the water, and tossed by the waves, where distinct experiments cannot be made.

Newton, Bernoulli, D'Alembert, and others, have laboured hard to deduce from the laws of motion rules for determining what may be called the average motion of water in these circumstances, without attempting to define the path or motion of any individual particle; and they have actually deduced many rules which have a great degree of probability. It may here be asked, Why do you say *probability?* The rules, as far as they go, should be *certain.* So they are; they are strict deductions from their premises. But the premises are only *suppositions,* of various degrees of probability, assumed in order to simplify the circumstances of the case, and to give room for mathematical reasoning; therefore these deductions, these rules, must be examined by experiment. Some of the suppositions are such as can hardly be refused, and the rules deduced from them are found to tally precisely with the phenomena. Such is this, that the velocities of issuing water in similar circumstances are in the subduplicate ratio of the pressures. And this rule gives most important and extensive information to the engineer. Other suppositions are more gratuitous, and the rules deduced from them are less coincident with the phenomena. The patient and sagacious Newton has repeatedly failed in his attempts to determine what is the absolute velocity of water issuing from a hole in the bottom of the vessel when urged by its weight alone, and the attempts of the others have hardly succeeded better. Experiment is therefore absolutely necessary on this head.

Example of the necessity of experiment.

Those who have aimed at the discovery of rules purely experimental on this subject, have also been pretty successful; and the Chevalier de Buat has, from a comparison of an immense variety of experiments made by himself and various others, deduced an empirical rule, which will not be found to deviate from truth above one part in ten in any case which has yet come to our knowledge.

This instance may serve to show the use of experiments in mechanical philosophy. It is highly proper in all cases by way of illustration; and it is absolutely necessary in most, either as the foundation of a characteristic of a particular class of phenomena, or as argument in support of a particular doctrine. Hydrostatics, hydraulics, pneumatics, magnetism, electricity, and optics, can hardly be studied in any other way.

The advantages derived from the study of philosophy.

Having in the preceding paragraphs given a pretty full enumeration of the different subjects which are to be considered in the study of natural philosophy, it will not be necessary to spend much time in a detail of the advantages which may reasonably be expected from a successful prosecution of this study. It stands in no need of panegyric; its intimate connection with the arts gives it a sufficient recommendation to the attention of every person. It is the foundation of many arts, and it gives liberal assistance to all. Indebted to them for its origin and birth, it has ever retained its filial attachment, and repaid all their favours with the most partial affection.

To this science the navigator must have recourse for that astronomical knowledge which enables him to find his place in the trackless ocean; and although very small scraps of this knowledge are sufficient for the mere pilot, it is necessary that the study be prosecuted to the utmost by some persons, that the unlearned pilot may get that scanty pittance which must direct his routine. The few pages of tables of the sun's declination, which he uses every day to find his latitude, required the successive and united labours of all the astronomers of Europe to make them tolerably exact; and in order to ascertain his longitude with precision, it required all the genius of a Newton to detect the lunar irregularities, and to bring them within the power of the calculator; and, until this was done, the respective position of the different parts of the earth could not be ascertained. Vain would have been the attempt to do this by geodetical surveys, independently of astronomical observation. It is only from the most refined mechanics that we can hope for sure principles to direct us in the construction and management of a ship, the boast of human art, and the great means of union and communication between the different quarters of the globe.

A knowledge of mechanics not much inferior to this is necessary for enabling the architect to execute some of his greatest works, such as the erection of domes and arches, which depend on the nicest adjustment of equilibrium. Without this he cannot unite economy with strength, and his works must either be clumsy masses or flimsy shells. The effects of artillery cannot be understood or secured without the same knowledge. The whole employment of the engineer, civil or military, is a continual application of almost every branch of mechanical knowledge; and whilst the promises of a Smeaton, a Watt, a Belidor, may be confided in as if already performed, the numberless failures and disappointments in the most important and costly projects show us daily the ignorance of the pretending crowd of engineers.

The microscope, the steam-engine, the thunder-rod, are presents which the world has received from the natural philosopher; and although the compass and the telescope were the productions of chance, they would have been of little service had they not been studied and improved by Gilbert, Halley, and Dollond.

But it is not in the arts alone that the influence of natural philosophy is perceived; it lends its aid to every science, and in every study. It is often necessary to have recourse to the philosopher in disputes concerning property; and many examples might be given where great injustice has been the consequence of the ignorance of the judges. Knowledge of nature might have prevented many disgraceful condemnations for sorcery. The historian who is ignorant of natural philosophy easily admits the miraculous into his narrations, accompanies these with his reflections, draws consequences from them, and fills his pages with prodigies, fables, and absurdity.

It is almost needless to speak of the advantages which will accrue to the physician from this study. So close is the connection between it and medicine, that our language has given but one name to the naturalist and to the medical philosopher. Indeed the whole of his study is a close observation of the laws of material nature, in order to draw from them precepts to direct his practice in the noble art of healing. During the immaturity of general knowledge, whilst natural philosophy was the only study which had acquired any just pretension to certainty either in its principles or method of investigation, the physicians endeavoured to bring the objects of their study within its province, hoping by this means to get a more distinct view of it; and they endeavoured to explain the abstruse phenomena of the animal functions by reducing them all to motions, vibrations, collisions, impulses, hydrostatic and hydraulic pressures and actions, with which the mechanical philosophers were so ardently occupied at that time. But unfortunately their acquaintance with nature was then very limited, and they were but little habituated to the rules of just reasoning; and their attempts to explain the economy of animal life by the laws of mechanics did them but little service either for the knowledge of diseases or for that of the methods of cure. The mechanical theories of medicine, which had considerable reputation about the end of the seventeenth century, were many of them very ingenious, and had an imposing appearance of symmetry and connection; but they are now forgotten, having all been formed on the narrow supposition that matter was subject only to mechanical laws.

The discovery of error, however, diminishes the chance of again going wrong, especially when the cause of error has been discovered, and the means pointed out of detecting the mistakes; and the vital principle must combine its influence with, or operate upon, the properties of rude matter. It appears therefore evident that a knowledge of the mechanical laws of the material world is not only a convenient, but a necessary, accomplishment to the physician. We are fully justified in this opinion, by observing medical authors of the present day introducing into medicine theories borrowed from mechanical philosophy, which they do not understand, and which they continually misapply. Appearance of reasoning frequently conceals the errors in principle, and seldom fails to mislead.

But there is no class of men to whom this science is of more service than to those who hold the honourable office of the teachers of religion. Their knowledge in their own science, and their public utility, are prodigiously hurt by ignorance of the general frame and constitution of nature; and it is much to be lamented that this science is so generally neglected by them, or considered only as an elegant accomplishment. Nay, it is too frequently shunned as a dangerous attainment, as likely to unhinge their own faith, and taint the minds of their hearers. We hope, however, that few are either so feebly rooted in the belief of the great doctrines of religion as to fear this, or of minds so base and corrupted as to adopt and inculcate a belief which they have any suspicion of being ill founded. But many have a sort of horror at all attempts to account for the events of nature by the intervention of general causes, and think this procedure derogatory to the Divine nature, and inconsistent with the doctrine of his particular providence; believing that "a sparrow does not fall to the ground without the knowledge of our heavenly Father." Their limited conceptions cannot perceive, that, in forming the general law, the Great Artist did at one glance see it in its remotest and most minute consequence, and adjust the vast assemblage so as completely to answer every purpose of his providence. There never was a more eager inquirer into the laws of nature, or more ardent admirer of its glorious Author, than the Honourable Robert Boyle. This gentleman says, that he will always think more highly of the skill and power of that artist who should construct a machine, which, being once set a-going, would of itself continue its motion for ages, and from its inherent principles continue to answer all the purposes for which it was first contrived, than of him whose machine required the continual aid of the hand which first constructed it. It is owing to great inattention that this aversion to the operation of secondary causes has any influence on our minds. What do we mean by the introduction of secondary causes? How, in fact, do we infer the agency of any cause whatever? Would we ever have supposed any cause of the operations of nature, had they gone on without any order or regularity? Or would such a chaos of events, any more than a chaos of existences, have given us any notion of a forming and directing hand? No, surely. We see the hand of God in the regular and unvaried course of nature, only because it is regular and unvaried. The philosopher expresses this by saying that the phenomena proceed by unalterable laws. Greatly mistaken therefore are they who think that we supersede the existence of mind and of providence when we trace things to their causes. A physical law being an unvaried fact, is an indication, and the strongest possible indication, of an unerring mind, who is incapable of change, and must do to-day what he always did; for to change is to deviate from what is best.[1] The operations of unerring mind will therefore be regular and invariable.

---

[1] Ferguson's Lectures on Ethics.

Physical laws, therefore, or secondary causes, are the best proofs of unerring wisdom. Such regularity of conduct is universally considered as an indication of wisdom amongst men. The wise man is known by the constancy of his conduct, whilst nobody can depend upon the future conduct of a fool.

And what astonishing evidences of wisdom do we not observe in the general laws of the material world? They will ever be considered by the intelligent philosopher as the most glorious display of inconceivable wisdom, which has been able, by means so few and so simple, to produce effects which by their grandeur astonish our feeble understandings, and by their inexhaustible variety elude all possibility of enumeration. Whilst the teachers of religion remain ignorant of the beautiful laws of nature, the great characteristics of the wisdom and goodness of the Almighty Creator, their hearers are deprived of much sublime pleasure; God is robbed of that praise which he would have received from an enlightened people; and the only worship he receives is tainted with mean notions of his attributes, and groundless fears of his power.

But besides those advantages which accrue to different classes of men from this study, there are some effects which are general, and are too important to be passed over unnoticed. That spirit of dispassionate experimental inquiry which has so greatly promoted this study, will carry with it, into every subject of inquiry, that precision and that constant appeal to fact and experience which characterize it. And we may venture to assert, that the superior good order and method which distinguish some of the later productions in other sciences, have been in a great measure owing to this mathematical spirit, the success of which in natural philosophy has gained it credit, and thus given it an unperceived influence even over those who have not made it their study.

The truths also which the naturalist discovers are such as do not in general affect the passions of men, and have therefore a good chance of meeting with a candid reception. Those whose interest it is to keep men in political or in religious ignorance cannot easily suspect bad consequences from improvements in this science; and, if they did, have hardly any pretext for checking its progress. Besides, discoveries accustom the mind to novelty; and it will no longer be startled by any consequences, however contrary to common opinion. Thus the way is paved for a rational and discreet scepticism, and a free inquiry on other subjects. Experiment, not authority, will be considered as the test of truth; and under the guidance of fair experience we need fear no ill as long as the laws of nature remain as they are.

More general advantages of philosophy.

Lastly, since it is the business of philosophy to describe the phenomena of nature, to discover their causes, to trace the connection and subordination of these causes, and thus to obtain a view of the whole constitution of nature, it is plain that it affords the surest path for arriving at the knowledge of the great cause of all, of God himself, and for forming proper conceptions of him and of our relations to him; notions infinitely more just than can ever be entertained by the careless spectator of his works. Things which to this man appear solitary and detached, having no other connection with the rest of the universe but the shadowy and fleeting relation of co-existence, will, to the diligent philosopher, declare themselves to be parts of a great and harmonious whole, connected by the general laws of nature, and all tending to one grand and beneficent purpose. Such a contemplation is in the highest degree pleasant and cheering, and cannot fail to impress us with the wish of co-operating in this glorious plan, by acting worthy of the place we hold amongst the works of God, and with the hopes of one day enjoying all the satisfaction which can arise from conscious worth and consummate knowledge; and this is the worship which God will approve. "This universe," says Boyle, "is the magnificent temple of its great Author; and man is ordained, by his powers and qualifications, the high priest of nature, to celebrate divine service in this temple of the universe." (B. B. B.)

PHYSIOGNOMY is a word formed from the Greek *φυσις, nature*, and *γινωσκω, I know*, and it is the name of a science which occupied much of the attention of ancient philosophers, but since the revival of learning has in a great degree been disregarded.

It does not appear that the ancients extended the compass of physiognomy beyond man, or at least animated nature. But the study of that art was revived in the middle ages, when those who treated of the subject strained their speculations far beyond the ancient limits. The extension of the signification of the term was adopted universally by those naturalists who admitted the theory of signatures; and physiognomy came thus to mean the knowledge of the internal properties of any corporeal existence from the external appearances. Baptista Porta, for instance, a physiognomist and philosopher of considerable eminence, wrote a treatise on the physiognomy of plants, in which he employs physiognomy as the generic term; and there is likewise a treatise *de Physiognomia Avium*, written, we believe, by the same person. In the *Magia Physiognomica* of Gaspar Schottus, human physiognomy is described as merely a subdivision of the science.

Boyle, too, adopts the same extensive signification. At present, however, physiognomy seems to mean no more than a knowledge of the moral character and extent of intellectual powers of human beings, from their external appearance and manners. In the Berlin Transactions for 1769 and 1770, there appears a controversial discussion on the subject of the definition of physiognomy, between Pernetty and Le Cat, two authors of some note. The former contends, that all knowledge whatever is physiognomy; the latter confines the subject to the human face. Soon afterwards appeared the celebrated book of Lavater, who defines physiognomy to be the art of discovering the interior of man by means of his exterior; but in different passages of his work he evidently favours the more extended signification of Pernetty.

Physiognomy was much cultivated in Egypt and India; and from these countries Pythagoras probably introduced the rudiments of this science, as he did those of many others, more important, into Greece. Plato also mentions the subject; and it is formally treated of by Aristotle, in a book which he has allotted to the purpose.

Pythagoras probably brought this science into Greece.

Physiognomy, he conceives, had been treated of in three ways. Some philosophers classed animals into genera, and ascribed to each genus a certain mental disposition, corresponding to their corporeal appearance; whilst others made a further distinction by dividing the genera into species. Amongst men, for instance, they distinguished the Thracians, the Scythians, the Egyptians, and whatever nations were strikingly different in manners and habits, to whom accordingly they assigned the distinctive physiognomical characteristics. A third set of physiognomists judged of the actions and manners of the individual, and presumed that certain manners proceeded from certain dispositions. But according to the method of treating the subject adopted by Aristotle, a peculiar form of body is invariably accompanied by a peculiar disposition of mind, and a human intellect is never found in the corporeal form of a beast. The mind and body reciprocally affect each other. Thus in intoxication and mania the mind exhibits the affections of the body; and in fear, joy, and other emotions, the body displays the affections of the mind.

From such facts he argues, that when in man there appears a particular bodily character, which by prior experience and observation has been found uniformly accompanied by a certain mental disposition, and with which therefore it must have been necessarily connected, we are in all such cases entitled to infer the disposition from the appearance. Such observations, he conceives, may be drawn from other animals as well as from men. For, as a lion possesses one bodily form and mental character, a hare another, the corporeal characteristics of the lion, such as strong hair, deep voice, large extremities, discernible in a human character, denote the strength and courage of that noble animal; whilst the slender extremities, soft down, and other features of the hare, visible in a man, betray the mental character of that pusillanimous creature. Upon this principle Aristotle treats of the corporeal features of man, and the corresponding dispositions, as far as these have been observed; he illustrates them by the analogy just mentioned, and in some instances attempts to account for them by physiological reasoning.

Aristotle was followed by Theophrastus, whose ethical characters form a distinct treatise on that branch of physiognomy which may be called the physiognomy of manners; and the latter was in his turn succeeded by others. There is indeed a considerable collection of Greek authors on physiognomy, entitled *Physiognomicæ Veteris Scriptores Græci, Græce et Latine*, 1780, in 8vo. From these authors, it appears that the science was much cultivated in Greece; but the professors seem soon to have connected with it something of the marvellous. This we are led to suspect from the story told by Apion of Apelles. The noviciates of the Pythagorean school were subjected to physiognomical observation by their teachers, and it is probable the first physiognomists by profession amongst the Greeks were of this sect. They, too, to whom, from the nature of their doctrines and discipline, mystery was familiar, were probably the first who, in Greece, exposed the science of physiognomy to disgrace, by blending it with the art of divination. From the period of which we have been treating to the close of the Roman republic, nothing worthy of remark occurs in the literary history of physiognomy. About the last-mentioned era, however, and thence to the decline of the empire under the later emperors, the science appears to have been cultivated as an important branch of erudition.

In the works of Hippocrates and Galen there occur many physiognomical observations. Cicero appears to have been peculiarly attached to the science. In his oration against Piso, and in that in favour of Roscius, the reader will at the same time perceive in what manner the orator employs physiognomy to his purposes, and find a curious instance of the ancient manner of oratorical abuse. Many physiognomical remarks are likewise to be found in the writings of Sallust, Suetonius, Seneca, Pliny, Aulus Gellius, Petronius, Plutarch, and others. That the science was practised as a profession in the Roman empire, ample evidence may be discovered in the writings of the authors just mentioned. Suetonius, for instance, in his Life of Titus, mentions that Narcissus employed a physiognomist to examine the features of Britannicus, and he predicted that the empire would devolve on Titus.

The science of physiognomy shared the fate of all others, when the Roman empire was overthrown by the northern barbarians. But about the beginning of the sixteenth century it began to attract notice; and from that time till the close of the seventeenth, it was one of the most fashionable studies. Within the space here mentioned appeared almost all the modern authors who have written upon this subject.[1]

Lavat celeb work.

Soon after the controversy in the Berlin Transactions, the great work of Lavater attracted the attention of the literary world. The work itself is magnificent; and that circumstance, as well as the nature of the subject, has contributed to extend its fame. With the scholastic and systematic method adopted by the physiognomists of the last and preceding centuries, Lavater rejected their manner of writing, which was dry, concise, indeterminate, and general. His own remarks are, for the most part, precise, and frequently founded on distinctions extremely acute. His opinions on the physiognomy of the ears, hands, nails, and feet of the human species, on hand-writing, on the physiognomy of birds, insects, reptiles, and fishes, are obviously premature, as hitherto no sufficient number of accurate observations have been made, in regard to these particulars, to authorize any conclusion. He has also erred in the opposite extreme, when treating of the important topic of national physiognomy, where he has by no means prosecuted the subject so far as facts might have warranted.

In the Berlin Transactions for the year 1775, there appears a formal attack upon Lavater's work by M. Formey. After disputing the propriety of the extensive signification applied by Lavater and Pernetty to the term physiognomy, Formey adopts nearly the same definition which we have proposed near the beginning of this article. He allows that the mental character is intimately connected with, and sensibly influenced by, every fibre of the body; but his principal argument against physiognomy is, that the human frame is liable to innumerable accidents, by which it may be changed in its external appearance, without any correspondent change of the disposition; so that it surpasses the extent of the skill of mortals to distinguish the modifications of feature which are natural from those which may be accidental. Although, therefore, the science of physiognomy may be founded in truth, he infers that the Deity only can exercise it. Formey further contends, that education, diet, climate, and sudden emotions, nay, even the temperaments of our ancestors, affect the cast of human features; so that the influence of mental character on these features may be so involved with, or hidden by, accidental circumstances, that the study of physiognomy must ever be attended with hopeless uncertainty.

---

[1] Such as Cocles, Baptista Porta, Honoratus Nuquetius, Jacobus de Indagine, Alstedius, Michael Schottus, Gaspar Schottus, Cardan, Taisnierus, Fludd, Behmen, Barclay, Claromontius, Conringius, the commentaries of Augustin Niphus and Camillus Balbus on the Physiognomica of Aristotle; Spontanus, Andreas Henricus, Joannes Digander, Goclenius, Alexander Achillinus, Prætorius, Belot, Grataiorus, and others, noticed in the Polyhistor of Morhoff (vol. i. lib. i. cap. 15, sect. 4, and vol. ii. lib. iii. cap. i. sect. 4).

PHYSIOLOGY.

CHAPTER I.—GENERAL VIEWS OF PHYSIOLOGY.

mology

(1.) Physiology, or the science of animal life, has been variously defined by different writers. If the term were interpreted strictly according to its etymology, it would carry a meaning much more extensive than is warranted by common usage; for, being derived from φυσις, *nature*, and λογος, *discourse*, its proper signification should be, the *science of nature*. It might accordingly be understood to comprehend inquiries in every department of nature, both animate and inanimate; and might indeed be regarded as synonymous with *physics*, or *natural philosophy*, which are other expressions of corresponding import, but which at present are themselves restricted in their meaning to a special department of nature. There can be do doubt, indeed, that such must originally have been the real signification of these terms; but it is needless now to inquire by what gradual transitions they have at length come to bear such different, and even in some respects, opposite significations. If we were desirous of substituting a term which would accurately express the idea now associated with the word physiology, we should adopt that of *biology*, from βιος, life, first introduced by Treviranus, who has written a German work on this subject, which bears that title.

(2.) Natural philosophy, or physics, is now understood as designating that class of sciences, which have for their object the examination of the properties of lifeless matter; whilst physiology, in its modern acceptation, is in like manner limited to the consideration of the properties which are peculiar to organized and living bodies. The former is conversant only with nature in her dead or inanimate condition; the latter with nature endowed with life, and in all its various forms and modifications.

Thus mechanics, hydrostatics, and pneumatics, wholly relate to the general phenomena exhibited by matter in its solid, liquid, and gaseous forms; optics, which relates to the phenomena of light, together with electricity, magnetism, and the science of heat, which regard other classes of phenomena produced by peculiar agents, are all considered as branches of natural philosophy. Chemistry, which is concerned with the changes of composition in bodies, resulting from the mutual action of their particles at insensible distances, ranks also with the sciences relating to the properties of inorganic matter, and of which the assemblage constitutes what are more correctly termed in the present day, *the physical sciences*.

B ches of tural hi y.

(3.) On the other hand, the study of animated nature does not admit of the same extent of subdivision. Nature has indeed traced a broad and obvious line of demarcation between the *vegetable* and the *animal* kingdoms; the first being the province of *botany*, the second of *zoology*; both of which departments offer us a wide field of inquiry, and inexhaustible subjects of speculation. But it is in the animal world, more especially, that the busy and ever-changing scene is calculated to awaken the most lively curiosity, and inspire the deepest interest. The multiplied relations which connect us with the lower animals, the obvious analogies which subsist between them and our own species, and the striking evidences of power, intelligence, and benevolent design displayed in all the phenomena they present to our observation, confer on the study of animal life a degree of importance which belongs to scarcely any other study.

(4.) But the foundations of all science must be laid by drawing accurate distinctions among the objects which come within its cognizance; by making a strict analysis of the ideas it comprehends, and by establishing precise definitions of the terms it employs. As in all the other departments of human knowledge, we can arrive at general facts, or comprehensive laws, only by submitting to the previous task of ascertaining and collecting individual facts; so in natural history we find it necessary to subdivide our labours into that which takes cognizance of individual objects only, and that which inquires into their more general relations with one another. The first is properly the *history*, the second the *philosophy* of nature; and this distinction we may observe to run through all the branches into which the subject is divisible. It applies even to astronomy, in which the mere physical history of the phenomena forms a preliminary body of knowledge, yet subordinate to that higher range of inquiry which establishes connections between these phenomena, and unites them into comprehensive laws or theories. Mineralogy, again, must be studied as the foundation of geology; the former being the history of the actual appearances; the latter, the theory of the series of changes which have led to these observed phenomena. Thus, also, the external forms, and more obvious habitudes of plants, and their classifications in conformity with these forms and properties, constitute the subjects of *botany*, properly so called; whilst the study of their internal structure and economy, with relation to the more general phenomena of vegetation, is comprised under the head of *phytology*, or the physiology of vegetables.

Provinces of zoology and physiology.

(5.) In like manner, the proper objects of *Zoology* are to trace the external forms of animals, to distribute and arrange them in systematic order, and to record the particular facts relating to their history; that is, to the more obvious phenomena which they present to our observation. *Physiology* embraces a wider field of research, inquires into the connexions between the phenomena, and investigates the causes from which they spring, and the laws by which they are governed. The zoologist is content with collecting observations on the visible actions of animals, on their peculiar habits, modes of life, and the manifestation of those faculties with which they are respectively endowed by the Author of nature; a pursuit which affords inexhaustible sources of amusement, and furnishes abundant matter of admiration and of wonder. But the physiologist aims at far higher objects; and considering the external phenomena presented by animals as lying merely at the surface, seeks for information relative to the causes of all the facts which are furnished to him by zoology, by examining the interior structure of their bodies, by inquiring into the movements of that interior mechanism, and the sources of those various actions which give rise to all the complicated phenomena of life. An extensive and even boundless region of knowledge opens to his view in these highly curious and interesting subjects of research, constituting one vast science, which, although considerable progress has been made in it by the labours of our predecessors, is yet destined to occupy, for an incalculable period of time, the unremitting efforts of succeeding generations.

Organic phenomena.

(6.) The phenomena of living beings have a totally different character from the changes which take place in inanimate matter; and are with more difficulty subjected to the severe analysis required by inductive philosophy. The properties of inorganic bodies are of a simpler and more definite nature, and however variously they may be combined in their effects, admit, in general, of a reduction to general laws. This is most effectually accomplished by means of experiments, varied in such a manner as to reduce each class of phenomena to its simplest conditions, and afterwards combined in such a way as to allow of a comparison of their results with the appearances presented by nature, and of thus verifying their identity.

But it is hardly possible to pursue the same process of investigation to any extent in the diversified phenomena of organization. So complicated is the mechanism, and so fine the minuter structure of animal and vegetable bodies, that they elude the cognizance of our senses, even when assisted by the utmost refinement of optical and mechanical art. All that chemistry has yet achieved in disclosing to us the properties of different species of matter, and of their various combinations, falls infinitely short of that knowledge which could enable us to follow and to understand the curious and elaborate series of chemical changes which take place in the interior of the living body. Far less are we competent to trace the operation of those more subtle and mysterious principles, which are the springs of motion, and which regulate the actions of the machine, and connect the whole of its movements into one harmonious system. Judging from their more obvious effects, indeed, these principles appear to be quite of a different nature from those which produce the phenomena of the inorganic world. The series of changes which are exhibited by an animal or a vegetable, from the first moment of its separate existence, through all the stages of its growth, maturity, and decline, to the period of its death, are far too complicated and multifarious to admit of being reduced to one single principle, in the same way as the movements of the heavenly bodies, for instance, are reducible to the simple law of gravitation.

Vital principle.

(7.) Physiologists, indeed, not deterred by these difficulties, which are inherent in the subject of their researches, have in all ages attempted generalizations of this kind. They have considered all the actions and phenomena which are peculiar to living beings, and which differ from those exhibited by the same bodies after death, as resulting from the operation of a single principle of life. Different designations have been given to this power by different theorists; thus, some have called it the *vital principle*, others the *spirit of animation*, the *archæus*, the *organic force*; and many other appellations have been given to it, according to the particular taste or fancy of the writer. Nothing, indeed, can be more specious than this reference to unknown facts, which have a manifest connexion with one another, to a common principle of action, or in other words, to a vital power. The only idea we can form of life appears to imply the unity of such a principle. This idea, as is well remarked, by Cuvier, is suggested by the observation of a certain class of phenomena, succeeding each other in an invariable order, and having certain mutual relations with one another; yet it is but a vague and indistinct idea. We are ignorant of the nature of that link which unites the whole of these phenomena; but the existence of some such link forces itself upon our belief, and we are compelled to give it a particular designation, and speak of it as if it were something more than a mere fiction of the intellect.

(8.) Those who are unaccustomed to philosophical reasonings, may be, indeed, and often are, deceived by the employment of these abstract terms, and regard them as the expressions of a simple law of nature, of the same comprehensive, yet definite character, as those of gravitation, cohesion, heat, and electricity. A more careful and profound analysis, however, will convince us that the power inherent in organization, upon which its infinitely diversified actions depend, is not a simple agency, but a combination of several powers, not only different from the physical agents which actuate the inorganic world, but differing also very widely amongst each other. In order to arrive at this conclusion, however, it will be necessary to take a review of the phenomena themselves, and we shall therefore defer the consideration of this subject to a future chapter.

Final cause.

(9.) Although the peculiar nature of the phenomena which physiology embraces has hitherto baffled all our endeavours to obtain results of the same general and comprehensive nature as those which have rewarded our efforts in the purely physical sciences, yet other resources are open to us, capable of conducting us to a still more ample and inviting field of inquiry. Living nature is impressed with a character, which at once raises it to a higher order among the objects of human intellect, and invests the science which regards it with a more lofty and ennobling sentiment. Life is peculiarly characterised by the manifestation of INTENTION. Adaptation of means to an end is visible throughout the whole of this animated scene. Express design is palpably discernible in every formation, in every arrangement, in every series of changes which this vast theatre of nature displays. Utility is the governing principle of all; intelligence and power far exceeding the utmost stretch of our imagination, are revealed to us in language not to be mistaken, and carrying with it irresistible conviction. Thus, while the sciences of inorganic matter are founded on the relations of cause and effect, physiology takes cognizance more especially of the relations of means to ends, which the phenomena present to our view. Hence we obtain a new principle of arrangement among these phenomena; hence also arises a new source of interest, of a kind very superior to that which mere physical relations can ever inspire.

Study of functions.

(10.) The purposes to which, pursuing this new principle of arrangement, we can perceive the different structures which compose an animal body, are subservient, are termed, in the language of physiology, the *functions* of those parts. Life results from the exercise of these functions, and consists in the continued accomplishment of their respective objects. The principal object of physiology, then, is the study of the functions of life; that is, the investigation of the changes occurring in the living system with reference to their respective objects, and in their subservience to the maintenance of life, and the various purposes for which life was bestowed. We shall now proceed to take a general review of these functions, in order to establish a foundation for the divisions of the science we are now treating.

Gradation of functions.

(11.) The most cursory view that we can take of the phenomena of life will be sufficient to shew that the functions to which they are referable are of different degrees of importance with relation to the objects of life. Some are so closely connected with these objects, that their continued exercise is indispensable to the very existence of life, which would cease if they were for a moment interrupted. Others which are less immediately concerned in the actual maintenance of the vital actions, are yet essential to its preservation, and cannot, with safety, be suspended but for a very short interval. Some are only occasionally called into play, and others are so remotely useful, as to admit of lying dormant for a considerable period, or even of being dispensed with altogether. Some functions require for their performance the concurrence of others, and these, again, imply the exercise of many more. Some are of a more isolated nature, and have less connexion with the general system of functions. By studying these relations, we are enabled to trace a certain plan in the designs of nature, and a certain subordination of functions sufficient to guide us in our studies, and to enable us to trace out a tolerably connected order of subjects.

(12.) It will be useful, before proceeding to the details of the subject, to present our readers with a general sketch of the system of the animal economy, which may serve, indeed, the same purpose, as a map does to a traveller, imparting a general notion of the bearings and relations of the several objects of interest in the country he is about to traverse. We shall, for this purpose, embrace in one view that assemblage of functions which constitutes animal life in its most complete and perfect form, and in the attainment of its full developement.

morial tions.

(13.) All the functions of the animal economy, all the mechanical dispositions of the system, and all the movements of its parts, are subordinate to two great objects; first, the preservation and welfare of the individual being which they compose; and, secondly, the continuance of the race to which it belongs. It is evident that the first great purpose to be accomplished is the conferring of the powers of *sensation* and *perception*, these being the essential attributes of animal nature, and the characteristics which distinguish it from the mineral or vegetable world. Next to these is the power of *voluntary motion*, by which the animal is enabled to change its place, to procure for itself those objects which are necessary for its subsistence or gratification, and to repel those which are noxious or painful.

vous em.

(14.) The power of being affected by external objects, or of receiving impressions of which we are conscious, is connected, in the more perfect animals, with a part of the body having a more peculiar organization, and very remarkable properties. It is a soft and pulpy substance, of a whitish colour, with different shades of gray, opaque, and exhibiting slight traces of a fibrous structure. It is termed *medullary* or *nervous substance*. Of this substance are composed the *brain*, which is a large mass of medullary matter; and also the *nerves*, which have the appearance of white cords, extending from the brain to almost every other part of the body. The nerves establish a communication between these parts and the brain, so that impressions made upon the former, are communicated, along the nerves, and by their intermedium, to the brain, where they excite their appropriate sensations, corresponding to the nature of the impression, and to the structure of the organ that originally received it. By what agency, or in what way affections of the brain, thus induced, are instrumental in producing sensation, or how the sentient principle is connected with the physical constitution of the brain, are subjects of which we have no knowledge; nor have we, in our present state, the smallest ground of hope that the mystery in which it is involved, will ever be dispelled. Sufficient let it be for us that such is the fact; and resting on this as an ultimate fact, let us proceed in our inquiries, as to the occasions on which this power, assuming it to exist, is called into action.

(15.) Experience shews that the impressions conveyed by each nerve, or class of nerves, are of different kinds, for they are capable of being readily distinguished from one another by the percipient being whose brain receives them. Hence he acquires a knowledge of the presence, of the situation, and of the different properties of external bodies, which are the source of those impressions. The nature of that power with which the nerves are endowed is such as to convey the impressions from which this knowledge is derived, from the external organ to the brain, with a velocity that exceeds all imagination. This instantaneous transmission is evidently a provision of the highest importance both for the welfare and preservation of the individual.

xter- nses.

(16.) The different powers of perception, corresponding to different qualities of external objects, constitute the *external senses*; and each has its appropriate organ, furnished with its separate system of nerves. The skin, which is the organ of *touch*, receives the largest share of nerves, as it is evidently of the greatest consequence that the surface of the body should receive impressions from every substance with which it may happen to come in contact. The nerves of the skin are also susceptible of various impressions, besides those of mere impulse or resistance from solid bodies. They are affected, for instance, by variations of temperature; and when acted upon in any way that may be injurious to the part impressed, or to the system generally, they give suitable warning to the individual, by exciting a sense of pain. Hence he is admonished of impending evil, and is incited to the prompt adoption of the means of averting it.

Sight.

(17.) Next in importance to the sense of touch are those of *sight* and of *hearing*; but for the communication of distinct impressions relating to these senses, a much more refined apparatus is requisite than for that of touch. The structure of the eye is calculated to combine, upon a thin expansion of nervous substance, the *retina*, the rays of light proceeding from distant objects, so as to form a picture of these objects, and thus convey to the mind an exact knowledge of the relative situation of all their parts that are within the sphere of vision. Hence are derived the perceptions of their distance and position with respect to the observer.

Hearing.

(18.) In like manner are the sonorous undulations of the air collected into a kind of focus by the structure of the ear, and impressed upon the sensitive expansions of nervous matter in the inner regions of the organ. Thus an important avenue of communication is opened with the external world, highly useful in an infinite variety of ways.

Smell.

(19.) The existence and properties of various objects at a distance are also recognized by the sense of *Smell*, which enables us to appreciate the presence of the subtle effluvia which they emit, and which affect the atmosphere often to a considerable distance around. The olfactory nerves are adapted to the impressions of this kind, and are situated on the surface of those passages destined for the transmission of the air in subservience to another function hereafter to be noticed, namely, that of respiration.

Taste.

(20.) The sense of *Taste* is exercised on the substances employed as aliment, and has its seat at the entrance of the passages appropriated to the reception of food, and which are subservient to another class of functions presently to be described.

Sensation, &c.

(21.) The faculty of Sensation consists merely in the excitation of a simple mental change, known to every one, although incapable, in consequence of this very character of simplicity, of either analysis or definition. With reference to its physiology, we know that it is effected through the intermedium of certain nerves, connected, on the one hand, with the organs on which impressions of various kinds are made by the physical action of external objects, and on the other, with those parts of the brain, of which the physical affections are, by some inscrutable link, connected with the affections of the soul, or sentient principle. These simple and preliminary phenomena, composed of both physical and mental changes, are to be carefully distinguished from those subsequent operations that constitute perception, thought, volition, and the whole series of psychical phenomena, which we are in the habit of referring to a distinct branch of human knowledge, and which is generally denominated *Metaphysics*, *Psychology*, or the *Philosophy of Mind*; in contradistinction to *Physics*, *Somatology*, or the *Philosophy of Matter*.

(22.) There can be little doubt that these operations, which we are naturally accustomed to consider as being purely of a mental character, are, in some unknown degree, connected with physical changes taking place in the cerebral substance; but as we are utterly unconscious of these changes, and as we are totally precluded from arriving at any knowledge of their nature, or even of conceiving the manner in which a connexion between mind and matter has been established, we are compelled, in this branch of the inquiry, to direct our attention exclusively to the mental phenomena, to study their laws by the evidence of our own consciousness, and to resort to processes of analysis and methods of inductive investigation, in many respects different from those which are successfully employed in the more arable fields of physical science.

Whenever we are fortunate enough to trace some portions of the mysterious but broken thread which unites the material changes occurring in our bodily organs, with the operations of the intellect, or the affections of the soul, we may then occasionally re-enter the territory of Physiology; and while the two sciences are thus capable of being studied in conjunction, they will derive mutual advantage and illumination.

Voluntary motion.

(23.) Yet, with regard to the mere physiological study of the animal functions, it cannot escape our observation, that a vast variety of phenomena in the economy have a direct reference to the mental constitution of our nature, and are to be studied, with relation to final causes, in immediate connexion with these objects. Thus, although the special purposes served by the multiplicity, the curious arrangement, and intricate structure of the parts of the brain, are as yet wholly unknown, and as we still are, and shall probably ever remain, in utter darkness as to the mode in which they perform their respective offices as instruments of perception, thought, and volition, yet when we return to the observation of the bodily actions consequent on these mental processes, as well as contributing to their performance, we are enabled to resume our physiological inquiries, and trace the continuity of design in the exercise of the faculties of voluntary motion, by which the mind exerts a power of reacting on matter, employs its properties for beneficial ends, and exercises that partial dominion over nature, which has been granted to it by the Divine Author of its being. The possession of voluntary motion is directed, first, to enlarge the sphere of our perceptions, by directing our organs of sense to their respective objects; secondly, to bring the objects themselves within the reach of those organs by which they are to be examined; thirdly, to alter their forms and combinations, and modify them in various ways, so that the mind may, from these different modes of examination, derive accurate and extensive information of their properties, and apply these properties to use; and lastly, to effect the locomotion of the whole body, and thus extend widely the range of its operations, and spread the dominion of man over every kingdom of nature, and over every region of the globe.

Voice, &c.

(24.) But the relations of man with the external world comprehend a much larger and more important field, since they are not limited to the sphere of the material world, but embrace the intellectual and moral existences of other percipient and sentient beings. Through the intermedium of signs, the results of movements of our bodily organs acting on the senses, communications are established, not merely between mind and matter, but between mind and mind. Mutual interchanges take place, of thoughts, of opinions, of feelings, and of affections; and the value of existence is, to an incalculable degree, augmented by the operations of sympathy, the impulses of benevolence, and all the potent and benign influences of social union. Hence, physiologically considered, the function of the voice, and its modulation into articulate sounds, ranks as an important part of the animal economy.

Sensiferous and motor nerves.

(25.) The faculty of *Voluntary Motion*, like that of Sensation, is derived from the peculiar properties of the nervous substance. In the instance of sensation impressions are conveyed by means of the nerves from the external organs of sense to the general centre of the sensitive faculty, the brain. A similar power, we find, is exercised, though in a contrary direction, in transmitting the actions arising from the determinations of Volition, and which produce their first effects on the brain, towards those parts which are capable of executing these determinations. Modern discoveries have shewn, that for this latter purpose sets of nervous fibres are employed different from those instrumental in conveying sensitive impressions from the organs of sense to the brain. Hence a distinction is established between the *Nerves of Sensation*, and the nerves of motion, or the *Motor Nerves*.[1] While the nerves of sensation should properly be considered as commencing at the organs of sense, and terminating in the brain, the nerves subservient to volition have their proper origin in the brain, and proceed thence to the organs of motion. Let us next examine in what these organs of motion consist.

Muscul power.

(26.) The principal source of motion, in the animal body, resides in the *Muscles*, which taken altogether, usually compose by far the largest part of the bulk of the animal. Muscles consist of a collection of fleshy fibres, proceeding for the most part in parallel directions, and extending from the two points in the limb, or parts of the body, which are designed to be brought nearer to each other. The fibres of which the muscles are composed are endowed with the remarkable property of contracting, under certain circumstances, with prodigious power, so as to move the parts to which they are attached with sudden and enormous force. The impulse given to them by the nerves of volition, by which they are connected with the brain, in every effort of volition, excites them to contraction, and produces those movements of the body which are the objects of that volition.

(27.) The movements required for the purposes of animal life, are of course infinitely diversified in their kind, and scarcely admit of any distinct classification. Amongst the objects of these movements, however, we may notice two, which are of essential importance; the first is that of *Locomotion*, the second that of *Prehension*.

Locomo tion.

(28.) Locomotion is one of the faculties more particularly distinctive of animal life in opposition to that of vegetable. Plants are more or less rooted to the soil where they originally sprung: animals, destined to a wider sphere of action, are endowed with the power of transporting their bodies from place to place, on the one hand, of pursuing, and on the other, of flying from pursuit; of choosing their habitations, or of changing regions and climes according to their wants or necessities.

Prehen sion.

(29.) The power of detaining and laying hold of objects, is another mode in which the faculty of voluntary motion may be highly advantageous to the animal possessing it. With these may be associated the various actions requisite for defence or attack, rendered necessary by the conflicts incident to their condition.

Mechan functio

(30.) For the performance of all these actions, there is required in the first place, a solid and unyielding structure, capable of sustaining the weight of the body, and of furnishing to the muscles or agents of motion, fixed points of attachment. The *bones*, the union of which constitutes the *skeleton*, are provided for these objects. They are formed into separate pieces, with a view to their being moveable upon one another. Their extremities are connected together by smooth surfaces, which are bound together by firm bands or *ligaments*, bracing them on the sides where they are exposed to the greatest strain. An apparatus of this kind constitutes a *joint*.

(31.) The due performance of these mechanical objects, implies a variety of subsidiary contrivances and adjustments, too diversified in their nature and objects to admit of particular specification. It is evident that the particular texture of each part must be adapted to the actions it has to perform. Flexibility and compressibility are required in one organ; rigidity and hardness in another. Some parts must readily yield to an extending force, others must resist such a force with extraordinary tenacity. Some must exert elastic power, others must be devoid of this quality. Some textures must be permeable to fluids, others must deny them all transmission. Hence, the variety of structures composing the mechanical frame-work of the system.

---

[1] We would suggest the propriety of designating these two classes of nerves respectively, by the terms *Sensiferous* and *Voluntiferous* as more distinctly expressing their proper functions.

ular re.

(32.) But in all the variations of conformation, it would appear that nature has employed the same ultimate structure as the basis of her work. All the solid parts of the animal fabric are formed of fibres, variously united and interwoven; in some cases only loosely connected, so as to constitute a spongy or cellular mass, flexible in every direction, and forming a medium of connexion between adjacent parts of various degrees of cohesion. This substance, which is found universally to pervade the body, is termed the *cellular substance* or *texture.* It is eminently endowed with elasticity, and thus contributes essentially to preserve the natural figure of every organ, and to restore it to its proper situation, after any displacement by a foreign cause.

brane.

(33.) When condensed into a firmer layer or sheet of animal matter, the same substance assumes the form of *membrane,* and is extensively employed as such, to supply organs with external coverings, or to afford them attachments to surrounding parts for the purpose of protection and support. Membranes are also used as barriers, for intercepting the communication of fluid from one cavity to another; and they are also employed to form receptacles for the retention of fluids, and tubes for conveying them from one part of the system to another.

ous es.

(34.) The fibrous structures, comprehending *ligaments, tendons,* and *fasciæ,* are composed of still a denser approximation of fibres, are endowed with a higher degree of toughness and strength, and are capable of exerting great resistance to any stretching force. Hence, they are extensively employed in the construction of parts where these properties are required.

ous c.

(35.) The organs specially appropriated to touch, are generally also those of prehension: and progressive motion is accomplished by means of limbs, which act either upon the ground, the waters, or the air, according to the element in which the animal resides. But, in order to give proper effect to these movements, the agency of levers is required; and we accordingly find a provision made for this purpose in the construction of the bones, which, as we have before observed, are capable of supplying the fulcra or fixed centres of motion, and allow of the application of the moving powers. It often happens that the actual attachment of muscles to the points required to be moved, would be attended with inconvenience. In this case, an intermediate structure is employed, analogous to that of a ligament, but here denominated a *tendon,* serving as a strap to connect the muscle to a distant bone, or other part on which the action of the muscle is to be exerted.

don.

(36.) All the functions, which have for their object some mechanical effort of the kind we have now described, may be comprehended under the general head of the *mechanical functions.*

rition, death.

(37.) The consideration of the chemical condition of the animal system, introduces us to a class of functions of a totally different nature from any of the preceding, yet equally essential to the maintenance of life. The solids and fluids of which organized structures are composed, differ materially in their chemical constitution from the products of the mineral kingdom. Their elements are combined by a much more complicated arrangement, and united by less powerful affinities; or rather the balance of affinities, by which they are held together, is more easily destroyed, and thus, proneness to decomposition is constantly present. One of the most remarkable and important of the operations of the vital functions, is to repress this tendency to decomposition; for no sooner is life extinct, than we find both the solids and fluids of the body hastening to assume new forms and combinations of their elements; and nothing can now prevent the final disorganisation of that fabric which so lately delighted the eye with its beauty, and in which dwelt the genial warmth of life, and the elastic vigour of youth. If we watch the progress of those changes which take place in the body, we shall find it characterised by a perpetual renovation of materials, continual losses of substance on the one part, being compensated by an equally constant supply on the other. From an atom of imperceptible minuteness we trace its gradual increase of size, by the reception of nutritious matter from without, by the incorporation of this matter with that which had before existed, by the consolidation of the fluid, by the extension of the solid parts. We see all the organs expanding by a slow, but uniform increase, and in regular proportion, till they arrive at a certain limit. Having attained this limit, the body remains stationary for a certain period; that is, the waste of substance is exactly compensated by the supplies furnished by the food received into the body. At length, however, the compensation is less perfectly maintained; the powers which carry on the functions begin to decline, the solids dry up and harden, and a general torpor gradually pervades the system. Life is sooner or later brought to a close by the natural progress of these changes, even if its course be not sooner arrested by causes of an accidental nature.

Chemical functions.

(38.) The functions of nutrition embrace a class of operations, destined to supply the materials wanted for the growth of the body, and for the supply of those materials which either may have been expended in the natural exercise of the other functions, or lost in various ways, or else employed in the reparation of injuries, which the organs may have accidentally sustained. The nutritive, or as they may also be termed the *chemical functions,* since they relate to the chemical condition of the body, comprehend a long series of processes, which, in order to study them successfully, require many successive subdivisions.

The first division includes all those functions which contribute to the reduction of the food to a substance of similar chemical composition with the materials of which the body already consists; processes which are comprehended under the general term of *Assimilation.*

The second and third divisions relate to the collection of the nutriment thus prepared, or assimilated, into a general reservoir; and its subsequent distribution throughout the body, so as to admit of being applied to use whenever it may be wanted. These objects are attained by the functions of *Absorption* and of *Circulation.*

A fourth division refers to the purification of the general mass of nutritious fluid existing in the great reservoir of the body, by the separation of its superfluous combustible portion, and more especially of its carbon; a change which is effected by the function of *Respiration.*

The last division of this class of functions comprehends the several processes by which certain materials are separated from the blood in a solid or fluid form; some with a view to their final expulsion from the system, some to answer purposes connected with other functions, and the remaining part being expended in repairing the waste which the solids of the body undergo in the exercise of their respective offices. To the former of these functions the term of *Secretion* is applied; whilst the last is more especially regarded as the proper and final process of *Nutrition.* We shall examine each of these divisions more particularly.

Assimilation, mastication, deglutition, and digestion.

(39.) Assimilation is effected by a long series of processes, which are partly of a mechanical and partly of a chemical nature. The food taken into the mouth is first masticated by the action of the teeth and jaws, so as to break down the cohesion of its parts, and prepare it for the chemical action of the fluids to which it is afterwards to be subjected. There is at the same time added to it a quantity of liquid, termed the *saliva,* prepared by a set of glands, to be hereafter specified, and poured out into the mouth in large quantities during the act of mastication. By these means the food is softened in its texture, and reduced to the form of a pulp, in which state it is swallowed, by the organs of deglutition, and conveyed through a tube called the *æsophagus* into the *stomach.* The stomach is a capacious bag, or receptacle, capable of holding a considerable quantity of food, and of retaining it for a certain period. The inner membrane which lines the cavity of the stomach prepares a fluid termed the *gastric juice*, which acts chemically upon the food in that cavity, while this food is at the same time subjected to a degree of pressure from the action of a set of muscular fibres which are interposed between the interior and exterior coats of the stomach. The food is also slowly moved by the successive contractions of these muscles, so that every part of it comes in its turn to be acted upon by the gastric juice, until the whole is converted into a soft and smooth mass of uniform consistence which is termed *chyme;* the operation itself by which this conversion is effected being termed *digestion.*

Chylification, lacteal absorption, and defecation.

(40.) The aliment thus digested, or reduced to the state of chyme, passes onwards from an orifice at the farther end of the stomach into a tube of great length, several portions of which have received different names, but which are comprised under the general term of the *intestines.* In the first portion, the *duodenum*, the aliment undergoes still further changes; it is mixed with two fluids, the one called the *bile*, which is prepared by a large glandular organ, termed the *liver;* and the other called the *pancreatic juice*, prepared by another gland, the *pancreas.* Secretions also take place from the inner membrane of the intestines themselves, and the result of the united action of all these fluids, aided by the movements imparted to the aliment by the contractions of the muscular fibres contained in the coats of the intestines, is gradually to convert part of what was chyme into a new substance called *chyle*, which is the most nutritious portion of the aliment, and has the appearance of a milky fluid. The chyle is received into a set of very minute tubes called *lacteals*, which are exceedingly numerous, and arise by open mouths from the inner surface of the duodenum and its prolongations, the *jejunum* and *ileum.* They collect the chyle together, and pour it into an intermediate receptacle, whence it is conveyed along a large tube, called the *thoracic duct*, into other cavities, of which we shall presently speak. That portion of the chyme which is not converted into chyle, descends into the lower portions of the intestinal canal, is collected in the larger intestines, of which the *colon* is the principal one, and finally ejected from the body.

Sanguification.

(41.) The next step in the assimilatory process is the conversion of the chyle into blood, a change which has been termed *sanguification.* It is in the great system of vessels which contain the blood already formed, and in the course of the passages through which the blood is moved, that this gradual change is effected. The great reservoir of this important fluid, on which the nutrition of every part of the body, and its maintenance in a state of action, immediately depend, is the *heart.* The thoracic duct opens into one of the veins or tubes leading directly to the heart; the chyle is therefore immediately conducted into this reservoir, and thoroughly mixed with the general mass of food.

Circulation.

(42.) The heart is a powerful muscular organ; from its cavity arise the trunks of large tubes, called *arteries*, which subdivide and ramify as they proceed in their course to every part of the body, being distributed in abundance to every organ, with a very few exceptions. No sooner are the cavities of the heart distended with blood, than the muscular structure which surrounds their cavities contract with enormous force, and propel their fluid contents through the system of arteries, sending it in one great wave, even to the extremities of its minutest ramifications. From these extremities of the arteries it passes into corresponding branches of another set of vessels, the *veins*, which proceed in the opposite direction, towards the heart, uniting in their course into larger and larger trunks, till they reach the heart, to which they deliver back the portion of blood that has thus percolated through every part of the body. No sooner has it again filled the cavities of the heart, than it is again sent with renewed force into the same arterial channels, and again brought back by the veins. The functions by which this circular course is given to the blood, is termed *the circulation.*

Secretio

(43.) The blood, in the course of its circulation, furnishes to all the organs the materials which are necessary for their growth, for the renovation of their powers, and for the supply of those fluids and other animal products which are wanted in various parts of the economy. The separation of these fluids, and the formation of these peculiar animal products, are the objects of another function, that of *secretion.* Particular organs are in most cases provided for the purpose of effecting these processes. These are the glands, which are variously constructed according to the particular offices they have to perform; each is furnished with an elaborate apparatus of vessels; and the fluid which is formed by them, is generally conducted to the place of its destination by a pipe, or *excretory duct*, as it is termed.

(44.) The fluids which are thus separated from the blood are, for the most part, applied to useful purposes in different parts of the economy; some for the repair of that loss of substance in the part of the body incident to the exercise of their respective functions, others for different subsidiary purposes related to those functions. The substance of the bones, for example, undergoes a gradual change during the whole of life; each particle is removed in succession and is replaced by others, so that in the course of time the whole substance of the body undergoes renovation. Two important functions are called into action for the completion of these processes; the first of these is concerned in the removal of the old and decayed materials; the second, in the due application of those which are to replace them.

Lymphat absorptio

(45.) The removal of those particles which have become useless, and whose presence might be injurious, is effected by a distinct set of vessels, called *lymphatics.* The lymphatics are met with in almost every part of the body; and resemble, both in structure and mode of distribution, the lacteal vessels already described. The mode of their origin is not well ascertained, but, like the lacteals, the smaller branches successively unite into trunks, which terminate either in the thoracic duct, or into the larger veins leading directly to the heart. Through these channels, then, it is that all the particles which require removal are conveyed away, and deposited into the general mass of circulating fluids. The function thus performed by the lymphatics in common with the lacteals, is termed *absorption.*

Nutrition growth, a reparatio

(46.) The function having for its object the reparation of the substance of the different organs, is designated by the general name of *Nutrition.* It includes the developement and growth of the parts, and their maintenance in the healthy state, that is the state in which they are fitted for the exercise of their several functions; as well as the restoration of what they may have lost from accidental causes, such as mechanical injuries.

When a bone is broken, for instance, a solid union is by degrees effected by the deposit of new ossific materials, consisting chiefly of phosphat of lime, which is secreted or separated from the blood by the irritated vessels in the neighbourhood of the injury. In all these cases the absorbents are also at work in modelling the shape of the part to be restored, in removing all roughnesses or angular projections, and making room for the new formations which are to take place. The functions of absorption and nutrition are thus, in some respects, opposed to each other, producing contrary effects, though both co-operating in the accomplishment of one final purpose, and balanced and adjusted to one another with that manifest intention. The general bulk of the body, and of its parts, varies according to the predominance of the one or the other of these actions of absorption and nutrition; wasting when the former is in excess; thriving and enlarging when the latter prevails.

(47.) There is one peculiar mode in which superabundant nutrition manifests itself. When the supply of nutriment is greater than what the wants of the system require, the superfluous portion is converted into an oily fluid, which is laid up in store for future use. This fluid is the *fat;* and it is accumulated in various parts of the body, and especially between the skin and the muscles, and in other places, where it may also serve a subsidiary purpose of mechanical protection against inequalities of pressure. The fat is thus useful as a soft cushion on which delicate organs, such as the eye, may move in security; and also as a convenient material for filling up hollows in various unoccupied situations. The chief use, however, of large accumulations of fat, is to serve as a magazine of nutriment, out of which the body may be supported in those seasons when the supply of food is deficient, and more particularly during those periods which are, by some animals, passed in a state of complete inactivity. This is the case in those animals which are said to *hybernate,* or continue during the whole of winter in a perfectly torpid state.

(48.) Whilst some of the products of secretion are thus employed in nutrition, others are subservient to the functions of particular organs. Thus, the tears are useful in washing away from the surface of the eye, dust, and other materials which might obstruct vision; the gastric juice is subservient to digestion; and the mucilaginous secretion of the wind-pipe and nostrils defend those passages from the acrimony of the air. But, in other cases, these secreted matters have noxious qualities; and it is the object of their separation from the blood, to get rid of them altogether. This is the case with the secretions from the kidneys, and from the skin, and perhaps, also, partly with that from the liver. These are termed the *excretions,* in contradistinction to the proper *secretions,* and the organs which separate them are termed the *emunctories.*

(49.) The organs which, in this sense of the term, must be considered as the principal emunctory of the body are the *lungs.* It would appear that the blood, from which the animal solids and fluids derive their nourishment, contains a larger proportion of carbon than what is required for the formation and reparation of these solids and fluids; the elements abstracted from the blood by the processes of secretion and nutrition, being principally oxygen, hydrogen, and nitrogen.

The continuance of these processes must tend therefore, to produce an accumulation of carbon in the blood; and accordingly we find that this fluid, in the course of its circulation, gradually acquires a darker colour. From being of a vivid scarlet hue in the trunks of the arteries, it has changed to a dark purple by the time it has reached the veins. It is returned to the heart, therefore, in a state unfit for the purposes of nutrition, and not proper to be again circulated through the vessels of the body. In order to restore it to its original state, it is necessary to deprive it of the ingredient it contains in excess, that is, of carbon, which, when thus present in the blood, is found to exert a positively deleterious power on the parts to which it is applied.

For this purpose the blood is transmitted by an appropriate system of arteries, to the lungs, where it is exposed to the influence of atmospheric air, alternately received into, and expelled from that organ. By a process which appears to be analogous to slow combustion, the superfluous carbon of the blood combines with the oxygen of the atmospheric air, and is expelled, in the form of carbonic acid gas, along with the air expired. The blood thus purified, and restored to its salutary qualities, is conducted back again, by a corresponding set of veins, to the heart, and is again sent, by the contractions of that organ, into the arteries of the body, and performs the same round of circulation as before. *Respiration,* which is the title of the function we have now been describing, completes this class, which we have termed the chemical functions of the economy.

The reproductive functions.

(50.) The three classes of functions we have been reviewing, namely, the *mechanical,* the *chemical,* and the *sensitive,* relate only to the preservation and welfare of the individual alone. But as nature has assigned a limit to the duration of life, it became necessary that a provision should be made for the multiplication of individuals, and the conservation of the race. Such, then, is the object of a fourth class of functions, namely the *reproductive functions,* including the processes of *fecundation,* of *evolution,* of *gestation,* and of *parturition,* and the auxiliary function of *lactation,* provided for the supply of the new-born infant with nourishment adapted to the tender condition of its organs of assimilation.

Developement.

(51.) Having studied the phenomena and the circumstances which lay the foundations of individual existence, the physiologist has next to occupy himself with the consideration of the long series of changes which intervene between the cradle and the grave, and constitute the "strange eventful history" of the physical life of man. He follows the rise and developement of the several organs, and the occasions on which their functions are called forth: he notices their entry on the stage of life, in which they are destined to play more or less important parts; he watches their progress, maturity, and decay, till they finally disappear from the scene, when their functions having successively declined, and passed away, the vital spark becomes extinguished, and the curtain drops on the fleeting drama of our probationary existence. A multitude of interesting subjects press on his attention in this division of his subject, so replete with wonder, and so calculated to impress us with exalted ideas of divine prescience, and of the unbounded resources of creative power.

To this department of physiology properly belong, first, the history of the changes which take place in the organs, during their natural course of developement, in what has been styled their *normal condition,* such as the formation of the vital organs, the process of ossification, the general growth of the body, the changes occurring at the period of puberty, the slow but sure progress of consolidation attending the decline of life, and the successive decay and obliteration of the faculties which precede death; and, secondly, the study of phenomena exhibiting the operation of those powers of repair and renovation, which exist in the constitution, and which are called forth only on certain occasions, when the organization has been injured or destroyed, or when the functions have been deranged or suspended, by various accidental causes.

Temperaments.

(52.) These topics introduce to our notice the varieties which are observable in different classes of individuals in the general mode in which the functions are performed with reference to their balance, or relative preponderance: conditions which constitute the different *temperaments,* as they are called, and which are severally characterised by peculiar external indications.

Varieties in the race.

(53.) Physiology, lastly, comprehends within the scope of its inquiries, those more strongly marked diversities that are met with in the inhabitants of different regions of the globe, and which appear to form separate races of mankind. These constitutional peculiarities, as shown by differences both in external conformation, and in the internal endowments of an intellectual and moral nature, are of so distinct and permanent a character, as to have suggested the hypothesis of their indicating, in a zoological sense, not merely varieties of a single species, but several different species of the genus *Man.*

Plan of this treatise.

(54.) The present treatise is intended to exhibit a condensed view of the actual state of our knowledge on all the subjects comprised in the above outline, and to conclude with a review of the progressive history of the science from the earliest periods to the present time.

Pathology.

(55.) It is hardly necessary to remark, that the province of *Physiology*, is restricted to the consideration of the phenomena of the living body in its perfectly *normal* or healthy state: while those which are presented when these limits of healthy action are passed, and the *abnormal*, or diseased state commences, are the subjects of another branch of science, denominated *Pathology*, no less interesting and important than the former, as furnishing the principles by which the art of medicine derives all its powers; but which, it must be obvious, must have its foundations laid in an extensive and correct knowledge of *physiology*.

Physiology founded on anatomy.

(56.) It is evident that the foundations of all physiological knowledge must be laid in a thorough acquaintance with the structure or internal mechanism of animals. The study of anatomy, indeed, derives its chief interest from its connexion with physiology; for unless viewed with reference to their uses, or subserviency to particular purposes, the examination of the forms and properties of the parts of a machine would be a barren and an irksome task. Let us imagine, for example, a person, who had never seen a ship, and had no idea of the object for which it is intended, to visit it for the first time, and to be at liberty to examine at his leisure every part of its rigging and internal construction. A restless curiosity might indeed lead him to handle the ropes and blocks, and climb upon every mast; to descend between the decks, and minutely inspect every part of its fabric; to explore, in a word, the whole anatomy of this most stupendous product of human ingenuity. But his labour would avail him nothing. The most complete survey would afford him no instruction, or leave any distinct impression as long as he had no principle to connect them in his mind. But let him review the same objects with an experienced guide, instructing him, as he proceeds, with the general purposes of the whole machine, and the particular uses of every part, as well as the mode in which they operate and concur in the production of the intended effect. Then it is that he will feel a real interest in the examination: then it is that he will attach due importance to each part of the inquiry. Perceiving the relations which connect the objects, and understanding the functions of the several instruments he sees, he is no longer perplexed and bewildered; individual facts arrange themselves in a natural order, and the whole forms in his mind one connected system of knowledge, readily retained and easily communicated.

The case is perfectly similar with regard to the body of an animal, of which anatomy lays open to us the structure. Dissection can only shew us that it consists of various parts, some hard, some soft, and others fluid. The harder parts, such as the bones, are of various forms, perforated by numerous apertures, and joined together in different ways. The soft parts are found to be composed of various kinds of textures, of which the elements appear to be collections of fibres or plates, curiously disposed and interwoven, so as to constitute a cellular or spongy tissue, and, occasionally, more extended layers of membrane. In every part we find innumerable tubes and passages, branching out and again uniting, in an infinite variety of ways. We arrive at cavities of different forms and extent, enclosing organs of various descriptions, or containing fluids which pass through appropriate channels of communication to very distant parts; composing altogether a vast and complicated system of mechanical and hydraulic apparatus. Thus whilst we confine our attention to the mere anatomy, all is perplexity and confusion; we are overwhelmed by the multiplicity of objects, and lost in the immense mass of unconnected detail. But no sooner do we study the parts of the animal frame with reference to their uses, and their subserviency to the several functions of the living body, than the whole appears under a new aspect. Aided by the light of physiology, we trace order and connexion in every part, and gather increasing delight and instruction as we proceed. The requisite adaptation of the organs to their respective offices, and the correspondence established between these offices, by which they concur in the same ultimate object, must ever excite our most profound admiration, and exalt our ideas of that infinite intelligence which planned, and that transcendent power and beneficence which executed the vast and magnificent system of creation.

CHAP. II.—APPLICATIONS OF PHYSIOLOGY.

Applica- tions o physio

(57.) Physiology claims our attention, not merely as an ornamental branch of speculative knowledge, but as a science of immediate and vast practical utility. Numerous are the occasions on which a scientific knowledge of the structure of our own bodies, and of the operations that are carried on within us, is highly valuable to its possessor; and more especially if combined with the more enlarged views derived from the study of comparative physiology. It may be useful here to point out some of the most important applications of physiological knowledge.

1. Me cine.

(58.) It is scarcely necessary to dwell on the utility of a knowledge of anatomy, enlightened by physiology, in its application to the art of medicine; for the very foundations of that art must be laid by these sciences. It is, however, proper to advert to the limited advantage which would accrue from such application if those sciences were confined to the human structure and the human functions, instead of comprehending within its range the whole of the animal creation. All the important discoveries of modern times with regard to the economy of the human body have been derived from observations made on the lower animals. That of the circulation of the blood, for instance, which has immortalised the name of Harvey, was obtained principally from this source. John Hunter, one of the greatest benefactors to the healing art in modern times, was so deeply impressed with the necessity of an extended study of comparative physiology, that he devoted his whole life to its cultivation, with an ardour and a perseverance that have been rarely equalled, and never surpassed; as is attested by the unrivalled museum of preparations in every department of comparative anatomy, which he formed by his own unaided exertions, and which will ever remain an imperishable monument to his fame.

(59) The various combinations of faculties, which are met with in the different tribes of animals, exhibit in a most striking manner the mutual dependence and relations of the animal and vital functions. As if with the express intention of assisting us in our physiological researches on the attributes of that vitality which eludes our experimental investigations, nature offers to our view, in the diversified structures of each successive order of animals, a series, as it were, of varied experiments; and exhibits the several organs under every degree of simplicity and complication of structures, and every possible mode of combination. The application of all this knowledge comes home to our own bosoms; for the human race is then viewed as composing a member of the great family of nature; and we ourselves, as well as all the individuals of that race, are placed under the governance of those general laws which regulate all animated beings. Our deepest interests, our future comforts and enjoyments, our powers of action, our intellectual existence, our capacities of feeling and of reasoning, all that renders life desirable, nay, that very life itself, are wholly dependent on the operation of those laws, and on the minutest results produced by their varied combinations. In a word, we ourselves are animals, and nothing that relates ever so remotely to animal life can be to us a matter of indifference.

(60.) Although the researches into comparative physiology necessarily imply a knowledge of the forms and history of the different races of animals, it tends to reflect, in its turn, the most important light on the science of zoology; and more especially on that department which relates to the classification of animals. All scientific knowledge must be founded on correct classification; but in zoology a methodical arrangement is indispensable; for scarcely any progress could be made without it. The number of animals in the habitable globe is immense, while our faculties and means of observation are extremely limited. Of insects alone, the number of distinct species which have been already determined considerably exceeds one hundred thousand. Of the other classes of animals, though less numerous, the catalogue of known species is at least half as great. Each of these races of beings has its distinct and characteristic form, its peculiar organization, habits, and faculties. It is obvious that if, at the outset of our inquiries, we were to attempt describing, or even of taking an inventory of all the living objects that presented themselves to our notice without regard to any principle of order, our attention would soon be distracted, and our memory overwhelmed by the confused accumulation of details; and it would not be possible to deduce from them any useful result. Classification affords the only clue which can extricate us from this intellectual labyrinth, which can resolve this state of chaos, and reduce this crude and indigested mass of materials into the form of regular science. It is only by a methodical arrangement of objects that we can arrive at the perception of the more extended relations which subsist among them, or establish general propositions, embracing a multitude of subordinate facts, and capable of an indefinite number of useful applications.

ifica-

(61.) In framing a system of classification of the animal kingdom, there are two objects which we may have in view; first, that of being able readily to ascertain the name of any animal which may present itself to our notice, and of recognising its identity with a species already known and described; or, secondly, that of becoming acquainted with the general nature and character of the animal in question; with the affinities which it has with others of the same class, and with the rank which it holds in the scale of animation. The first of these objects is attained by what are called *artificial methods* of classification; the second by what are called *natural methods*. Much error and confusion have prevailed in the reasonings of naturalists from their neglecting to discriminate the respective objects of these two kinds of methods, which nevertheless are perfectly distinct from each other.

icial ods.

(62.) In endeavouring to accomplish the first of these objects, we take, as it were, an inventory of nature, we record all her productions, and follow her in all her variations; we collect the fullest and most faithful description of every known species, and assign to each a particular name.

The end we have in view being simply to devise a ready method of identifying animals, we follow a process of this kind. We first unite those species which are most nearly allied to each other into one genus. We observe, for example, several species which have much resemblance to the stag; such as the rein-deer, the elk, the roebuck, the fallow-deer, the axis, the muntjac, and several others: we assemble all these into one genus, which we call the *deer* kind. By a similar process we form another genus of animals resembling the bull; such as the buffalo, &c. The genus *antelope* will, in like manner, comprehend the gazelle, the chamois, the nylghau, the oryx, the saiga, the gnu, and a multitude of others. In the same way, the *camelleopard*, the *goat*, *sheep*, *camel*, and *musk*, may be regarded as so many generic terms, each including a number of different animals, distinct in race, but similar in appearance. Having thus constituted the genera, we may apply to them the same principle of generalization that we did to the species; uniting them, according to their similitudes, into more comprehensive assemblages. Thus the genera above mentioned, having many features of resemblance, are considered as composing a tribe or order, to which Linnæus has given the name of *pecora*.

(63.) We may continue this process till we have gone through the whole animal kingdom; but it will then be necessary to adopt in some respects a contrary method; and instead of ascending as we have done from particulars to generals, to descend from generals to particulars. Regarding the animal kingdom as one entire subject, we must partition it into provinces, and again subdivide these into smaller portions. All these divisions and subdivisions must be founded upon distinct variations of external organs, and must be characterised by concise definitions, enumerating the leading circumstances common to all the animals they comprehend, and by which they may be contrasted with those included in the collateral divisions. The great primary divisions of the animal kingdom are the *classes;* the subdivisions of these form the *orders;* these comprehend the *genera*, which again include the separate races or *species;* while the ultimate ramifications of the system, expressive merely of diversities arising in the same race, constitute what are called *varieties*. By thus confining our attention to a small number of essential characters, we are enabled to ascertain, by a sort of analytical process, the name of any animal that we may wish to examine or identify. We have converted our rude inventory into a convenient dictionary of nature, where every object may be found at its appropriate place. The characters of the classes resemble in their office the initial letter of a word; the characters of the subsequent divisions that of the succeeding letters, conducting us with certainty and precision to the place we seek. The full developement of this method, and of the logic which should regulate it, and its successful application to natural history, we owe to the genius and industry of Linnæus, to whom the science will ever have to record a lasting obligation.

(64.) But however perfectly we may have accomplished the purpose we had in view in these artificial arrangements, it is impossible not to perceive that we have obtained them by the sacrifice of that order which nature herself points out. A strict adherence to any arbitrarily assumed principle of classification, is, in truth, incompatible with the preservation of the natural affinities of animals. Thus, in the system of Linnæus, the order *primates*, among the mammalia, presents the incongruous association of man with monkeys, lemurs, and bats. In the order *belluæ*, the horse is placed by the side of the hog. The *feræ* offer us the unnatural association of the seal, the dog, the bear, the opossum, the hedgehog, and the mole, merely because these animals, in most respects totally dissimilar, happen to agree in having the incisor teeth of a conical shape. The continual violation of natural analogies, which is yet necessarily incident to all artificial systems, has exposed them to much censure and ridicule, from those who forget that the purpose for which they are framed, is that of convenient reference, and that it is essential to arrangements adapted to that end, that they should be arbitrary. As well might it be made the subject of complaint, that, in a dictionary, words having very different meanings, are found placed in juxtaposition.

Natural methods.

(65.) Cuvier has justly remarked that a perfect natural method should be the expression of the science itself, that is, of its most general propositions. By assembling animals in groups, according to their general resemblances in the more important circumstances of their organization and functions, we are enabled to connect them under one description, and afterwards apply to each individual species all the particulars comprised in this description, and thus we obtain more or less comprehensive statements, or, as it were, zoological laws, enabling us both to acquire and to retain the facts with greater facility, and to apply them with readiness in every case; in a word, it gives us the entire command of that knowledge, by imparting to it the form of science. The tribe of *pecora*, formerly mentioned, may be taken as an excellent example of a natural family of animals; for they consist of species which bear a striking resemblance with one another in form, organization, and manners. If we meet with a new animal having one or two of the leading characters of this tribe, we deduce at once all the most important features of its history. We know, for instance, from its possessing a double hoof, that it belongs to this tribe, and consequently that it feeds on herbage, that it has four stomachs, and that it ruminates its food; that it belongs to a species disposed to assemble in flocks or herds, and that it has a disposition to be domesticated. We may pronounce that its upper jaw has no incisor teeth, and so forth.

(66.) It is evident that from the discovery of these analogies, on which the arrangement into natural families is founded, we must resort to the aid of comparative physiology. It is this science alone that can teach us to discriminate the circumstances which are of real importance in the animal economy, and on which their very nature and character depend. The immense progress which has been made in this branch of knowledge since the time of Linnæus, has enabled us to determine with much greater precision the relative affinities of animals, and the rank which each tribe is entitled to hold in the natural system of classification.

Method of Duméril.

(67.) Attempts have often been made to combine these two methods into one, by a sort of mutual compromise between them, that is, by an arrangement partly natural and partly artificial, to obtain the principal advantages of both. The most perfect specimen of this union of the two methods is that of Duméril, which he has published under the title of *Zoologie Analytique*. The characters on which his divisions are founded are distributed in a strictly analytical order, and they conduct us to classes much more natural than those of Linnæus. Thus he divides the Linnæan class of insects into two, namely, *crustacea*, and *insects* properly so called. The very miscellaneous class of *vermes*, in which animals very dissimilar in their nature had been thrown together as it were in a lumber closet, compose in this system the more natural assemblages of *mollusca*, *vermes*, and *zoophytes*. Duméril has pursued this plan throughout the whole of the animal kingdom, reducing all the characters which lead to the determination of classes, orders, families, and genera, to the form of synoptic tables.

Cuvier.

(68.) The arrangement which makes the nearest approach to a natural distribution is that adopted by Cuvier, in his celebrated work entitled *Le Régne Animal Distribué d'après son Organization*; as it is founded chiefly on the structure of the organs most essential to life, and having most influence in determining the intelligence, sensibilities, activity, habits, and manners of animals. Physiology is, in fact, the basis of Cuvier's classification, for it proceeds on the following principles.

(69.) The powers of sensation and of voluntary motion being the chief attributes of animal life, it follows that the organs of primary importance in the economy are those which are immediately subservient to the performance of these functions. They are, as we have seen, the organs composing the nervous system; and the general form and distribution of the nervous system, therefore, should lay the foundation of the primary divisions of the animal kingdom. There appear to be four general types or models of structure of these organs presented in the animal creation. The first consists of a brain, or large mass of nervous substance, from which a cylindrical process, called the *spinal marrow*, is continued; and these are protected respectively by the bones of the skull, and by a series of bones, called *vertebræ*, which form a jointed column along the whole length of the back. Animals formed on this construction are called *vertebrated animals*, a division which comprehends all the higher classes of the animal kingdom, namely, *mammalia*, *birds*, *reptiles*, and *fishes*.

In the second form of the nervous system, there is properly but one central mass of nervous substance, or brain, without any spinal marrow, and from this mass filaments of nerves proceed, in various directions, to be distributed to all the other parts. This division comprehends all the *mollusca*, including both the mollusca and testacea of Linnæus.

The third form is that of a longitudinal series of masses connected together by lateral filaments, and sending out, as from so many centres, ramifications of nerves. This structure is the distinctive mark of *articulated animals*, and may be recognised in insects, and worms properly so called.

The fourth and last division of Cuvier, he denominates *radiated animals*, in which, wherever nerves are found, they appear as a number of equal masses disposed in a circle, and sending out fibres, which diverge like rays from a common centre. Hence the whole body of the animal, or at least some of its principal organs, has a radiated or star-like form. This is the case with the *asterias*, *medusæ*, *polypi*, and all the other animals comprehended under the name of zoophytes.

As frequent reference will be made, in this treatise, to the zoological classification of Cuvier, we shall here give a table of the principal divisions which it comprises, together with examples of animals included in each order.

I. VERTEBRATA.

1. MAMMALIA.

1.	Bimana	*Man.*
2.	Quadrumana	*Monkey, ape, lemur.*
3.	Cheiroptera	*Bat, colugo.*
4.	Insectivora	*Hedgehog, shrew, mole.*
5.	Plantigrada	*Bear, badger, glutton.*
6.	Digitigrada	*Dog, lion, cat, martin, weasel, otter.*
7.	Amphibia	*Seal, walrus.*
8.	Marsupialia	*Opossum, kanguroo, wombat.*
9.	Rodentia	*Beaver, rat, squirrel, porcupine, hare.*
10.	Edentata	*Sloth, armadillo, anteater, pangolin, ornithorynchus.*
11.	Pachydermata	*Elephant, hog, rhinoceros, tapir, horse.*
12.	Ruminantia	*Camel, musk, deer, giraffe, antelope, goat, sheep, ox.*
13.	Cetacea	*Dolphin, whale.*

2. AVES.

1.	Accipitres	*Vulture, eagle, owl.*
2.	Passores	*Thrush, swallow, lark, crow, sparrow, wren.*
3.	Scansores	*Woodpecker, cuckoo, toucan, parrot.*
4.	Gallinæ	*Peacock, pheasant, grouse, pigeon.*
5.	Grallæ	*Plover, stark, snipe, ibis, flamingo.*
6.	Palmipedes	*Auk, grebe, gull pelican, swan, duck.*

3. REPTILIA.

1.	Chelonia	*Tortoise, turtle, emys.*
2.	Sauria	*Crocodile, lizard, gecko, chameleon.*
3.	Ophidia	*Serpents, boa, viper.*
4.	Batrachia	*Frog, salamander, newt, proteus, siren.*

4. PISCES.

1.	Acanthopterygii	*Perch, mackerel, sword-fish, mullet.*
2.	Malacopterygii	*Salmon, herring, pike, carp, silurus, cod, sole, remora, eel.*
3.	Lophobranchii	*Pipe-fish, pegasus.*
4.	Plectognathi	*Sun fish, trunk-fish.*
5.	Chondropterygii	*Lamprey, shark, ray, sturgeon.*

II. MOLLUSCA.

1.	Cephalopoda	*Cuttle-fish, calamary, nautilus.*
2.	Pteropoda	*Clio, hyalæa.*

3. Gasteropoda	*Slug, snail, limpet, whelk.*
4. Acephala	*Oyster, muscle, ascidia.*
5. Brachiopoda	*Lingula, terebratula.*
6. Cirrhopoda	*Barnacle.*

III. ARTICULATA.

1. ANNELIDA.

1. Tubicola	*Serpula, sabella, amphitrite.*
2. Dorsibranchia	*Nereis, aphodrite, lob-worm.*
3. Abranchia	*Earth-worm, leech, nais, hair-worm.*

2. CRUSTACEA.

1. Malacostraca	
Decapoda	*Crab, lobster, prawn.*
Stomapoda	*Squill, phyllosoma.*
Amphipoda	*Gammarus, sand-hopper.*
Læmodipoda	*Cyamus.*
Isopoda	*Wood louse.*
2. Entomostraca	*Monoculus.*

3. ARACHNIDA.

1. Pulmonalia	*Spider, tarantula, scorpion.*
2. Trachealia	*Phalangium, mite.*

4. INSECTA.

1. Aptera	*Centipede, podura.*
2. Coleoptera	*Beetle, glow worm.*
3. Orthoptera	*Grasshopper, locust.*
4. Hemiptera	*Fire-fly, aphis.*
5. Neuroptera	*Dragon-fly, ephemera.*
6 Hymenoptera	*Bee, wasp, ant.*
7. Lepidoptera	*Butterfly, moth.*
8. Rhipiptera	*Xenos, stylops.*
9. Diptera	*Gnat, house-fly.*

IV. ZOOPHYTA.

1. Echinodermata	*Star-fish, urchin.*
2. Entozoa	*Fluke, hydatid, tape-worm.*
3. Acalephæ	*Actinia, medusa.*
4. Polypi	*Hydra, coral, madrepore, pennatula.*
5. Infusoria	*Brachionus, vibrio, proteus, monas.*

Theory of continuous gradation.

It has long been a favourite notion with speculative naturalists, that organized beings might be arranged in a continued series, every part of which, like the links of a chain, should be connected with that which preceded and that which followed it. Linnæus was even impressed with the idea that nature, in the formation of animals, had never passed abruptly from one kind of structure to another. But the idea of a chain, or continuous gradation of being, was cherished with enthusiastic ardour by Bonnet, who, assuming man as the standard of excellence, attempted to trace a regular series, descending from him to the unorganized materials of the mineral world. Many other writers have adopted this speculation; but none have carried it to a more extravagant length than Lamarck, who blends it with the wildest and most absurd hypothesis that was ever devised, to account for the diversities of animal structures. He conceives that there was originally no distinction of species, but that each has, in the course of ages, been derived from some other less perfect than itself, by a *spontaneous* improvement in the race. He believes that the animalcula of infusions gave birth, by successive transformations, to all other animals; aquatic animals acquiring feet and legs, fitting them for walking on the ground, and, after a time, being converted into wings, merely from the long continued operation of a desire to walk or to fly.

(70.) In support of the theory of continuous gradation many anomalous animals are produced as instances of links of connexion between different classes of animals. The bat has been regarded as one of these intermediate links between mammalia and birds. The cetaceous tribe, including the *whale, cachalot, dolphin,* and *narwhal,* though properly belonging to the class mammalia, make an apparently near approach to the tribe of fishes. The ornithorhyncus is allied both to quadrupeds and to birds. Many similar examples might be produced among the inferior classes of the animal kingdom. A little attention, however, will soon enable us to perceive that they occupy but small portions of the wide spaces intervening between different orders of animals. Even in the best arranged systems, such as that of Cuvier, we discover innumerable chasms wholly unoccupied, between adjacent orders; and in many instances animals, which are scarcely in any respect allied to each other, are placed in immediate sequence. This defect, as I have already observed, is unavoidable, because it is inherent in the very nature of the subject. Instead of a single continuous line, nature presents us with a multitude of partial series, with innumerable ramifications, and occasionally a few insulated circles. If metaphor must be employed, it would be better to say, that instead of being a chain, the natural distribution of animals offers the idea of a complicated network, where several parallel series present themselves, and are occasionally joined by transverse or oblique lines of connexion. The great divisions of Cuvier represent these principal parallel series. The last, however, or that of the *radiata*, appears to be the least perfect of these series, and might with advantage be farther divided. On the subject of natural classification Mr. Macleay[1] has advanced a hypothesis, which he supports with some ingenuity, namely, that the real types or models of structure may be represented by a circular or recurring arrangement; and he gives a number of instances in which this principle appears very happily to apply. But speculation on these subjects can lead to satisfactory conclusions only on the supposition that an extensive comparison of organs has been instituted throughout the whole of the animal kingdom.

3. Application to geology.

(71.) A scientific knowledge of the organization and functions of animals is valuable, not only in its application to zoology, but also in reference to many other sciences, such as geology, with which it might at first view appear to have but little connexion. By attending to the arrangement of mineral bodies as they occur in nature, we have sufficient proofs that the earth has undergone frequent and considerable changes prior to the existence of any living beings. But we find, besides, a great number of strata, which contain unequivocal remains of vegetable and animal bodies. A large proportion of these are shells, exuviæ of zoophytes, and other marine animals. We also find, in other strata, a multitude of fossil bones, and teeth of various quadrupeds and reptiles; and occasionally, but more rarely, of birds and fishes. Whole mountains and extensive districts appear to be composed entirely of these animal remains. It is by the aid of comparative anatomy and physiology alone that we are enabled to compare these relics of antiquity with similar facts of living or recent animals, to discover their differences or identity, and to deduce certain conclusions with regard to the nature, habits, and characters of the animals to which they had belonged; and by studying their relation with the strata in which they are found, to draw inferences with regard to the changes which must have taken place in those parts of the earth, inferences which are of the highest importance towards establishing a correct theory of those changes. The difficulties attending researches of this nature were of course exceedingly great; but they have been at length surmounted by the persevering zeal and industry of modern naturalists. In these arduous investigations Cuvier stands pre-eminent; and his labours have been rewarded with a number of highly interesting results. The great principle which he has assumed as the foundation of his researches, is that every organized individual constitutes a system of itself, of which all the parts are connected to each other by certain definite relations. In passing from each of these structures to that of other animals in the natural series, we find that all the changes of form which take place in any one organ are accompanied by corresponding alterations in the form of every other organ; so that by the careful application of certain rules, deduced from this observed reciprocal dependence of its functions, we are enabled to ascertain with considerable certainty the forms and habits of animals, of which only small fragments have been preserved. We have already given an instance of this mode of reasoning as applied to ruminant animals. By following this guide Cuvier ascertained and classed the fossil remains of nearly 100 different quadrupeds in the viviparous and oviparous classes. Of these above seventy were distinct species, hitherto unknown to naturalists.

---

[1] Macleay, *Horæ Entomologicæ*, or Essays on Annulose Animals, 1821.

It appears from these researches that the earth has sustained more numerous convulsions than had before been suspected, and that these must have been separated by considerable intervals of time; that the ocean has deposited various strata in regular succession; that the species of animals whose remains are found in these strata change with every variation in the nature of the deposit, and become more and more analogous with the living animals of the present day, in proportion as the deposits have been of more recent date. It appears from an examination of these fossil remains, that the sea must have retired at intervals from the districts it had formerly covered, and left dry land, affording habitation for large quadrupeds; and that after a certain unknown space of time, the sea has suddenly returned to the same spot, has destroyed all the terrestrial animals, and has formed subsequent deposits of shells and other marine productions.

These sudden irruptions and recessions of the ocean, which have occurred several times in the same district, must have been attended with extensive destruction of animal life. Whole races have perished irretrievably, and are known to us only by the durable memorials they have left behind of their own existence, and of the several epochs of antediluvian chronology.

(72.) The study of the fossil remains of animals has also extended our views of the animal kingdom; it has in many instances supplied chasms which had occurred in the natural series, and has enlarged our ideas of the extent of creative power. Another important conclusion which has resulted is, that the human race has been the last created; for nowhere do we find any vestiges of human bones. These researches tend also to throw light on the history of mankind, and to refute the pretensions to high antiquity which have been arrogated by certain nations, and particularly the Chinese, &c. which Voltaire and other modern philosophers had so zealously defended. All that science has brought to light, indeed, is in conformity with the testimony of the sacred writings, when rationally interpreted, and may even be adduced as illustration of their truth. Geology and comparative physiology concur with these writings in teaching us that man was the last act of creative power; that a great catastrophe took place on the surface of the globe a few thousand years ago, during which the sea covered for a time every part of the land; and that the subsequent diffusion of the population of the earth is of comparatively recent date. It is pleasing to see conclusions, derived from such different sources, converging to the same points, and affording each other that reciprocal confirmation which is the invariable concomitant and surest test of truth.

(73.) The enlarged views to which we are conducted by the study of comparative physiology afford us a glimpse of some of the plans or models of structure which appear to have been followed in the formation of the animal world. The analogies of form discernible in corresponding organs, throughout a very extensive series of tribes, have been lately traced and developed with extraordinary care by the modern naturalists of the French and German schools, and especially by Cuvier, Blainville, Savigny, Geoffroi St. Hilaire, Oken, Carus, and Milne Edwards. The conclusions they have drawn from their labours, though sometimes overstrained, are always ingenious, and in general satisfactory; and they strongly tend to prove, that several distinct types, or standards of figure, have been adhered to in all the multiplicity of forms with which it has pleased the Author of nature to diversify the animal creation.[1]

4. App
tion to
tural th
logy.

(74.) These inquiries, however, suggest still higher subjects of contemplation. They illustrate the connexion and relationship of every part with the rest of the system. They prove the unity of design with which the system has been planned and executed. They demonstrate the perfection with which all its parts are mutually adjusted, and the harmony which pervades the whole. The evidences of express design and contrivance are so distinct and palpable, and they so multiply and accumulate upon us as we advance, that they may almost be said to obtrude themselves on our notice; and we cannot avoid being impressed with the notion of its being intended that we should observe them. Whilst the purpose to be answered continues the same, the means are varied in every possible manner, as if designedly to display to us the exhaustless resources of inventive power, and the supreme intelligence with which that power is wielded. Nor is it possible to overlook the general object to which every thing so manifestly tends in the system of animal existence. Every element in every part of the habitable globe, teems with life, and that life is replete with enjoyment. Happiness is unquestionably the great object of animal existence. The benevolence which pervades the whole system of creation, is no less conspicuous than the power and intelligence from which it emanated. Revealed religion is thus in unison with the theology derived from the contemplation of nature, and the lights of modern science.

(75.) The facts derived from comparative physiology which more especially support the arguments of natural theology have been collected by authors who have written professedly on the subject. Derham's work, entitled *Physico-Theology*, has been deservedly held in estimation; but since the time it was published, which is now above a century, the sciences have been prodigiously extended. Dr. Paley, in his *Natural Theology*, has produced a great multitude of facts and observations in support of the same arguments, has applied them with singular felicity, and impressed them with the most fascinating perspicuity and eloquence. But his object being purely theological, he has not professed to adhere to any scientific order in stating them. The design of the Bridgewater Treatise, already referred to, is to supply this desideratum, by presenting the details of animal and vegetable physiology, arranged according to the functions to which they relate, or in other words, in reference to final causes. As theological arguments, the value of these facts cannot fail to be better appreciated when they are studied in all their bearings, and as forming a part of the science to which they belong. It is by the aid of genuine science alone, that we can avoid the dangerous error of building arguments, on so momentous a subject, upon equivocal or unstable foundations, and of injuring a cause already established upon incontrovertible grounds, by weak and inconclusive evidence.

(76.) It has been too hastily inferred, from the abuse which has too often been made of philosophical inquiries, that they are to be avoided as dangerous, and even pernicious; and that of the fountain of philosophy, as of the Pierian spring we should "drink deep," or abstain from tasting. Superficial knowledge has often been decried as mischievous, and extremely liable to abuse. The hackneyed maxim of Pope, that "a little knowledge is a dangerous thing," has furnished a ready text for those who declaim against all attempts to render science popular, and to include it as a branch of general education. Willing proselytes to this doctrine will always be found among those whom indolence or frivolity render averse to mental exertion, when bestowed on subjects not immediately connected with the common concerns of life, as well as among those who, already enjoying some of the advantages of knowledge, are desirous of securing to themselves the monopoly of those advantages. But their sophistry is soon detected when we examine into the real meaning of the expressions they employ. What is commonly denominated superficial knowledge, may certainly be useless, or even dangerous; but the mischief or danger arises, not because it is superficial, but because it is incorrect. It is error, under the guise of knowledge that alone deserves such reprobation. The value of information is to be estimated much more by its accuracy, than by its extent. Although it may be true that there is no royal road to science, it is equally true that many are the roads that lead astray; and that much fruitless labour may be spared by having that one pointed out which leads directly to the object we wish to attain. Though the distance we have to travel cannot be abridged, yet the path may be rendered smoother, and the velocity of our progress accelerated, by availing ourselves of such guidance as may be afforded by concise treatises, which, however superficial in appearance, or popular in their garb, are yet, as far as they go, perspicuous, accurate, and comprehensive.

---

[1] See the Bridgewater Treatise on Animal and Vegetable Physiology, where this subject is enlarged upon, and especially the chapter on "Unity of Design." Vol. ii. p. 625.

CHAPTER III.—ARRANGEMENT OF FUNCTIONS.

tempts an ar- gement func- ns.

(77.) The general review we have taken, in our introductory chapter, of the objects and mutual connexions of the functions of the animal economy will furnish us with the principles on which the methodical arrangement and classification of those functions should be established. Various attempts have been made by different systematic writers on physiology towards the accomplishment of that object; but they have generally been deficient in that logical precision, which alone can ensure entire comprehensiveness of every branch of the subject, and at the same time convey clear perceptions of the bearings of every part to one another. Some physiologists have limited their views to the human economy, or that of animals which most nearly resemble man; others have framed their systems so as to embrace the whole animal kingdom, and even all beings endowed with life. Some have been wholly governed by anatomical considerations, regarding mere structure as the basis of physiological distinctions; others, overlooking the unity of purpose in each function, and pursuing their subdivisions to an excessive degree of minuteness, have overloaded the subject by needless multiplication and superfluity of detail. Many have introduced confusion by a loose and vitious nomenclature, derived from partial or hypothetical views; which were often tinctured with mysticism, and which, by biassing their judgments, have betrayed them into a wide field of delusion and of error.

nal mis- en for ysical ses.

(78.) Another source, to which the greater part of the mistakes, pervading all the systems of physiological arrangement that have been hitherto framed, may be traced, is inattention to the essential distinction which exists between physical and final causes. The study of the phenomena of life differs from all the other branches of philosophical inquiry, by its involving considerations relating to both these kinds of causes; the latter of which introduces a totally new principle of arrangement, wholly inapplicable in those sciences which concern the physical properties of inert and inorganic matter. The rules of a strictly philosophical induction, which alone can guide our steps in the pursuit of these sciences, must be greatly modified, and in some measure superseded by those derived from another department of human knowledge; namely, psychology. The knowledge of those general facts, which, when once established, and the conditions on which they depend ascertained, constitute what are called the laws of nature, is obtained first, by comparing together phenomena and uniting in one class such as are of the same kind, and carefully separating them from others which are essentially different; and next, by endeavouring to remove all extraneous influences, so as to reduce each class of phenomena to its simplest conditions; an object to be attained by *experiments*, that is, by varying the circumstances under which they occur, and also by combining them in different ways, so as to enable us to verify our theories, by comparing their results with the actual observation of nature. But the attempt to apply the same process of induction to the physiology of organised beings, is attended with peculiar difficulty; for while the changes which occur in the inorganic world exhibit the operation of forces or agents characterized by their simplicity, their constancy, and their uniformity, the phenomena presented to our view by living beings, so prodigiously varied in their form, so extensively spread throughout every element, every clime, and every habitable region of the globe, and so infinitely diversified in their nature, and complicated in their connexions, are calculated to baffle the efforts of the most cautious reasoner, and elude the penetration of the most sagacious inquirer after truth. The resources of experimental research are here extremely narrowed, in consequence of the simultaneous and connected operation of a great number of powers, which prevent us from studying the influence which each would exert when isolated from the rest, and ascertaining the laws which are peculiar respectively to each. Hence it is that we have hitherto made but very imperfect approaches to the determination of those laws.

(79.) Some compensation is, however, afforded us, while struggling with the obstacles which impede our progress in the direct and thorny path of science, by the abundant resources accessible to us in the psychological considerations, which every where arise in this vast field of contemplation. All the phenomena of organic beings reveal to us so palpably the indications of *design*, that we cannot resist the impression thus created in our minds; nor can we avoid recognising the connexions which are so established between the objects and the changes they present, as being those of means employed for the accomplishment of certain ends. Thus, then, the relation of means to ends becomes a leading principle of association among the facts of physiology; giving a new aspect to the science, and creating an interest of a different and much higher kind, than could ever be inspired by the study of mere physical relations. So deep has been this impression, and so completely has the principle of final causes been interwoven with the pursuits of physiologists, that the study of the *functions of life*, that is, of the purposes to which the actions constituting life are subservient, has been almost universally regarded as the principal, if not the sole object of the science. It has, accordingly, been assumed as the basis of arrangement, in all systematic treatises of Physiology; and likewise in framing theories for explaining the phenomena of life, physiologists have generally been satisfied with pointing out their final, rather than their physical causes.

(80.) This natural proneness to substitute final for physical causes has been a frequent source of delusion, by insensibly leading to the belief that we have reached the physical law which regulates the phenomena we are viewing, when we have, in fact, done nothing more than traced their relation to the intelligent agency by which they have been each adjusted to their respective objects, and given that law a name with reference to that agency; thus, in our eagerness to grasp at hidden knowledge, mistaking the shadow for the substance.

Ancient divisions of the subject.

(81.) Frequent instances of this confusion of ideas occur in the writings of the older physiologists; but at all times the predominant tendency has been to refer the phenomena to their final causes; that is, to the purposes which they answer in the animal economy. The functions were arranged by the ancients into three classes, designated by the titles of *animal, vital*, and *natural;* the first comprising those powers of sensation and of voluntary motion which are more especially characteristic of animal, as contradistinguished from vegetable life; the second, those powers, the continued exercise of which are immediately necessary for the maintenance of life, such as respiration of the blood; and the third, those which are directly concerned in the continuance of its vital actions, but which are yet indispensable in preserving the organs in the conditions enabling them to perform their respective offices, by supplying the materials requisite for their nutrition, and for counteracting their tendency to decomposition; in this class were included digestion, secretion, and absorption. To these were added by many, a fourth class, the *generative*, comprehending all the functions which have for their object the continuance of the species by the reproduction of individuals similar to the parent animal. The principal objection to this arbitrary division of the functions is, that the line cannot be drawn with sufficient distinctness between what are called the vital and the natural functions, their connexion with the maintenance of life being one of degree only, and not of kind; as is evident from their being united together in the lowest tribes of the animal kingdom. This classification appears also to be defective, inasmuch as it omits all notice of those functions which have immediate reference to the mechanical condition of the frame; conditions which are the foundation of their physical capabilities of executing the operations assigned them in their respective places in the general system. It is also liable to the imputation of employing terms to designate the classes which are obviously incorrect, and bear not the meaning they are intended to convey. In one sense, and that which would first present itself to the mind, the term *animal* functions would comprehend all the others, for there are none in which powers peculiar to animal life are not called into play; and, on the other hand, the strictly animal functions are equally entitled to the appellation of *vital*, as being directly essential to the support of life; and no specific meaning can attach to the term *natural*, as applied to any description of functions.

Classification of Vicq D'Azyr.

(82.) Vicq D'Azyr proposes to establish a preliminary division of the functions into two great classes; the first, comprising those concerned in the preservation of the individual; and the second, those concerned in the preservation of the species. The former class he divides into two orders; the first having for their object the assimilation of food into the substance of the body, and designated as the interior assimilative and nutritive functions; and the second, establishing the relations of the individual to surrounding objects, and denominated the exterior or relative functions.

The first of these orders comprises six genera; namely, 1st, *digestion*, by which the nutritive particles are extracted from the food; 2d, *absorption*, by which this nutritive matter is conveyed into the blood; 3d, *circulation*, by which it is carried to all the organs; 4th, *respiration*, by which it is exposed to the influence of atmospheric air; 5th, *secretion*, by which it is made to undergo various modifications; 6th, *nutrition*, by which it is applied to the organs for the purposes of growth and nourishment.

The second order of the first class comprehends three genera; namely, 1st, the *sensations*, which give to the individual notice of the presence of surrounding objects; 2d, the *motions*, which bring him towards, or remove him from them; 3d, *voice* and *speech*, which enable him to communicate with his fellows without transporting his body to a different place.

The second class, or the generative functions, likewise comprise two orders; the first, including the functions of *conception* and *generation*, requiring the concourse of both sexes; the second, including *gestation, parturition*, and *lactation*, performed exclusively by the female. To these were subjoined by Vicq d'Azyr, as a kind of supplement to his system, the several facts relating to the progressive changes taking place during the advance of life from infancy to decrepitude, through the ages of growth, of maturity, and of decay, and to those which attend the absolute extinction of life, and the subsequent decomposition of the organs.

The arrangement of Vicq d'Azyr is entitled to much commendation, and has been followed in all its essential features by Dumas,[1] Richerand,[2] and other systematic authors on physiology, with the exception of Haller,[3] who adopted a classification of functions founded altogether on the anatomical relations of the organs by which they are performed.

Of Bich and Dumas.

(83.) Bichat,[4] whose original genius led him to disregard the opinions of his predecessors, and to strike out for himself new paths of inquiry, aimed at giving greater simplicity to physiological classification, by pursuing a more rigid analysis, and infusing a more philosophical spirit into the methods of research. With this view he distributed the functions into two classes, which he denominates respectively the *animal* and the *organic*; the former coinciding nearly with those already known by that title; and the latter comprehending both the vital and the natural functions of preceding writers. Impressed, however, with the necessity of drawing distinctions among the powers of life, he has perplexed his system by intermixing with those final causes, which he takes as the basis of his divisions, the results of a philosophical analysis of those powers. He is thus led to make continual efforts to establish a distinction between muscular contractibility, which is one of the simple and elementary powers of life, when that power is employed in subservience to the animal functions, and when it is subservient to the functions of organic life; a distinction which regards only the final, and not the physical causes of the phenomena. Dumas[5] has been guilty of a still more palpable error in deeming it necessary to add to his catalogue of principles, consisting of the acknowledged powers of sensibility and contractility, a third power, which he terms "*the force of vital resistance*;" thus associating a final cause in the same rank with causes that are strictly physical.

Of Cuvie Adelon, Bourdon, and Béclard.

(84.) To the animal and vital functions of Bichat, Cuvier has added, in his physiological arrangement, a third class, the *generative*, which cannot, indeed, be, with any propriety, included in any of the former. He still, however, falls into a similar mistake as that of Dumas, which we have just now pointed out; for he describes sensibility and muscular contractility not as primary principles, but both of them functions of the nerves. Adelon[6] distinguishes the following eleven actions as being the functions of life; namely, *sensibility, locomotion, language, digestion, absorption, respiration, circulation, calorification, secretion*, and *generation*. Bourdon[7] reduces them to seven, which are as follows: *caloricité, nutrivité, absorptivité, exhalativité, durabilité, reproductivité*, et *resistabilité;* thus presenting a strange jumble between physical principles of action, and actions referred to definite purposes. The same confusion may be remarked in the classification of the functions by Béclard,[8] who has arranged them into six classes, viz. *nutrition* in its most extended sense, *generation, muscular action, sensation, nervous action*, and the functions of the *intellect*. But it would be needless to multiply examples of this error, since it will be found to pervade almost every physiological system that has yet been framed, not excepting even that adopted by Dr. Bostock, in his valuable *Elementary System of Physiology*.

Bostock. (85.) Dr. Bostock regards contractility and sensibility as the two primary attributes of animal life, each equally characteristic of it, and peculiar to it, and each performed by its appropriate organs. " The functions," he remarks, " depend on the exercise of these powers, and although probably, in all cases, they are both of them exercised, yet generally one of them seems to be the principal agent, or the prime cause of the ensuing operation ; we may consequently divide them into the contractile and sensitive functions, or those which more directly belong to contractility and to sensibility, and which, of course, serve respectively for motion and sensation, and to these two classes must be added a third class of the intellectual functions." Among the contractile functions, the essence of which consists in motion, Dr. Bostock considers the circulation as being the first in point of importance, and the one which may be regarded as the most necessary to the direct support of life, and to the indirect maintenance of all the rest. Next in importance is respiration, which modifies the blood so as to adapt it to the maintenance of life. After these two functions, by the former of which the blood is carried to all the parts of the body, and by the latter of which it acquires its vital properties, Dr. Bostock places those of calorification, secretion, digestion, including assimilation and sanguification, and absorption, functions which contribute, he observes, to the continuance of the motion of the animal machine, and which preserve all its parts in their proper condition, without, however, being essential to the immediate support of life. In this class he places the function of generation, which, although one of the most inexplicable of all the operations that are performed by the animal powers, and acting in a specific manner of which we have no other example, may be considered as essentially consisting in secretion.

The sensitive functions are divided by Dr. Bostock into two classes ; first, those which originate in the action of the external agents on the nervous system ; and, secondly, those of a reverse kind, which depend on the reaction of the nervous system on these agents. In the first of these divisions are included what are called the external senses, the sight, hearing, taste, smell, and touch ; and in the same division must be placed the sensation of hunger, that of temperature, and some others, which have not been correctly discriminated from general feeling, but which possess specific characters. In the second class, those functions which depend on the reaction of the nervous system on external bodies, he places volition ; and to the same class he also refers instinct, association, sympathy, habit, and some other faculties of a similar kind, which appear to hold an intermediate rank between the corporeal actions and those of a purely intellectual nature. As the functions which compose the first of these classes may be all referred to a species of perception, so the latter may be considered as more or less analogous to volition ; in the former, the effect on the nervous system, whatever it may be, is propagated from the extremities to the centre ; in the latter, it proceeds in the opposite direction, from the centre to the extremities of the body.

The intellectual functions compose, in this arrangement, the third class. These, Dr. Bostock observes, are a less direct object of physiology than the two former, yet many of them are so closely connected with the physical changes of the body as to require being included in a complete view of the animal economy. Among those intellectual operations which possess a decided action on the corporeal frame, he places the *passions ;* and also refers to this class tha compound of mental and physical influence, from which results what are called *temperament* and *character*. These lead to the consideration of functions of a more purely intellectual kind, which, as they recede from the corporeal, and advance towards the mental part of our frame, are less within the province of the physiologist, and belong more to the metaphysician or the moralist.

(86.) Dr. Alison[1] has adopted a principle of arrangement, which, though differing in some of its applications, is essentially the same as that of Dr. Bostock, as it is derived from the analysis of the phenomena of life into certain powers ; or, if these phenomena be considered as the results of a single principle, which we may denominate *vitality*, the study of physiology will resolve itself into an inquiry into the conditions under which the various phenomena of life take place, that is, into the *laws of vitality*. These laws are ranked by Dr. Alison under three heads : 1. Those of *vital contractions*, by which the visible movements of living animals are chiefly effected : 2. Those of *vital affinities*, by which the chemical changes peculiar to living animals are determined, and their physical structure maintained : 3. Those of *nervous actions*, by which the physical changes in living animals are placed in connexion with mental phenomena, and subjected to the control of mental acts. The first and third of these divisions correspond to those of Dr. Bostock, which he has denominated the contractile and the sensitive functions. The second division of Dr. Alison is founded on the principle pointed out by the writer of the present article, in a treatise on Physiology which appeared many years ago in the last Supplement to this work, and to which he gave the designation of *the organic affinities*. Of Alison.

Dr. Alison considers that the movement of the fluids, in all the higher classes of animals, is in a great measure dependent on vital contractions in certain of their solids, and may accordingly be regarded as the first and most important consequence of the exercise of the vital power. This subject he divides into two parts ; first, the movement of the mass of blood in the heart, arteries, and veins, or the function of circulation ; and, secondly, the continual evolution of matters from, and absorption of matters into, the mass of blood ; or the functions of nutrition, exhalation, secretion, and absorption, to which the circulation is subservient, and on which all the other functions are dependent. The study of these nutritive functions naturally introduce the consideration of the properties of the different textures and secretions which are formed from the blood, and which are the materials combined in the construction of the organs themselves.

The nervous system has been endowed with peculiar properties or powers, in order that it may be the seat, and the instrument, of mental acts. These mental acts, and all the functions in which they bear a necessary share, constitute, according to Dr. Alison, the animal life, or animal functions. As in all animals the reception of food into the digestive organs, and in all vertebrated animals, and many of the inferior orders, in the adult, the reception of air into the respiratory organs is accomplished by movements which are excited through the intervention of sensations and of instincts and volitions ; he considers the commencement of the processes of respiration and digestion in them as belonging to the province of animal life, and as dependent on the nervous system. Dr. Alison, therefore, commences his account of the animal functions, with the consideration of respiration, animal heat, and digestion, which he refers to that class: proceeding afterwards to notice the physiology of the external senses, of the mental faculties, voluntary and instinctive motion, the involuntary action of the mind on the body, sleep and the analogous states of somnambulism, reverie, and other irregular actions of the nervous functions. The subjects of generation, and the peculiarities of age, sex, and temperament, occupy the concluding chapters of his work.

---

[1] *Outlines of Physiology and Pathology*, Edinburgh, 1833.

Of Mayo. (87.) The order in which Mr. Mayo has treated of the functions,[1] differs but little from that adopted by Dr. Alison.

Of Roget. (88.) The author of this article has given, in his *Bridgewater Treatise*,[2] an arrangement of the functions founded altogether on the basis of final causes: and corresponding therefore with the views, which have been explained in the preceding chapter, of the relative subordination of purposes which the functions are designed to answer in the economy; and not limited to human physiology, but embracing all the different forms and modifications which those functions present in the animal kingdom. Taking them in the order of their increasing complexity, he has distributed them into the four following classes; namely, first, *the mechanical functions*, which include the consideration of all the circumstances relating to the mechanism of the frame and of its different organs; the arrangements provided for procuring the proper cohesion, strength and mobility requisite for the different actions they have to perform; and also for the preservation of their connexions, support, security and other mechanical conditions adapted to the exercise of their respective functions. To this head are also referred the operation of the moving powers, derived principally from muscular contractility, by which the various parts of this system of machinery are set in motion.

Secondly, the *nutritive*, or *chemical functions*, corresponding to what has been formerly denominated the vital functions; and the object of which is the preservation of the organs in those states of chemical composition which enable them to sustain life, and to perform their destined offices in the economy. The functions by which, in the higher orders of animals, this object is accomplished, may be arranged under the following heads; each, however, admitting of further subdivision. 1. *Assimilation*, including the processes which prepare the food for *digestion*, *chymification*, which is the office of the stomach, and *chylification*, which is performed in the intestines. 2. *Lacteal absorption*, by which the chyle so prepared, is collected into the heart and blood-vessels. 3. *Circulation*, by which the blood, or nutrient fluid, is regularly diffused over the system. 4. *Respiration*, or the aeration of the blood. 5. *Secretion*, by which the properties of that fluid are modified. 6. *Excretion*, by which various chemical principles are separated from the blood, and discharged from the system. 7. *Absorption*, by which substances are conveyed from different parts back again into the general mass of circulating fluids. 8. *Nutrition*, by which the nutritive matter is applied to the growth or restoration of the various organs of the body, so as to maintain them in the state which enables them to discharge their proper functions. 9. For effecting all these various processes, the agency of a peculiar power, derived from the properties of the nervous system, is requisite. This may be termed the *nervous power*, in contradistinction to those actions of the same system, which have reference to mental phenomena, and which come under the next class of functions.

Thirdly, the *sensorial functions* comprehends all those corporeal changes in which the mind is concerned; and consequently include those of *sensation*, of *perception*, of *volition*, and all those intellectual functions which employ for their agency the physical organization of the body.

Fourthly, the *reproductive functions*, which have for their object the continuance of the species, and the multiplication of its numbers. This subject is naturally connected with the progressive developement of the organs, the growth of the body from infancy to manhood; and the stages of its decline, till all the vital phenomena cease by the death of the individual.

CHAPTER IV.—THE VITAL POWERS.

Physic laws. (89.) We have already remarked, that there are two ways in which the assemblage of phenomena presented to us by living beings may be studied. We may, in the first place, view these as mere physical phenomena, applying to them the same methods of induction which have been employed with so much success in other departments of natural science. The object of philosophical induction is the reference of the events occurring in nature to their proper causes. This is accomplished by comparing the phenomena together, observing in what they agree, and in what they differ, classing them in the order of their agreement; and distinguishing them according to their differences. The result of this process, when it has been carried as far as the extent of our mass of facts will allow, is the establishment of certain general relations between these facts, or conditions, under which they occur, and which we may consider as so many *laws of nature:* and any appearance we may afterwards meet with which corresponds in its character to any single law, or combination of these laws, is at once referred to them, and considered as a particular instance or exemplification of these laws. When we can succeed in tracing these coincidences with a previously established law or general fact, we are said to have discovered its cause. Philosophy, in this sense, then, comprehends the collection and comparison of phenomena, their classification, the establishment by careful induction of general laws; the verification of these laws by experiment; and lastly, the subsequent reference of particular phenomena to their appropriate laws.

(90.) In the sciences which relate to the laws of matter in its inorganic state, this inductive method of philosophising admits of being pursued to an indefinite extent, and with comparative facility. The phenomenon themselves, which are the subjects of induction, are of a simple and more definite character than those of animal or vegetable life; they are generally more under our control; and more easily subjected to the test of experiment. The endless variety of the forms of life, the extent and intricacy of the connexions between the different parts of the animal system, introduce a degree of complexity in the phenomena, incomparably greater than is ever met with in the combinations of inorganic matter. We shall accordingly find that the knowledge we have hitherto acquired of the physical laws which govern the vital phenomena, is as yet exceedingly imperfect.

Propert of inorg- ic matt (91.) In entering upon the philosophical study of the phenomena presented to us in the living body, and carefully arranging them according to the rules of induction, and without reference to the final causes that connect them, (a subject which forms a totally different branch of inquiry,) we easily recognize the operation of many of those powers and principles to which inorganic matter is also subjected. The living system, with all its complicated apparatus of solids and fluids, is obedient to the universal laws of gravitation, of cohesion, of elasticity, of capillary attraction, &c., as well as to the ordinary principles of mechanics, hydrostatics, hydraulics, and pneumatics, which result from combinations of these laws; and we may pursue the application of these laws to the mechanism of the body, as far as no other causes intervene, without danger of error.

Vital p perties. (92.) The laws of chemistry apply also, to a certain extent, to the changes which are going on in the living system; but in tracing the operation of these laws, we soon become sensible of the apparent interference of other principles which seem to control the ordinary chemical affinities which the same kinds of matter are found to exert when deprived of life. Here, then, we perceive a sensible deviation from the course of phenomena exhibited by inorganic matter; and we are forced to recognize the existence of new and unknown powers peculiar to, and characterizing the living state. We discern the operation of such powers in the processes of digestion, of sanguification, of nutrition, of secretion, of the growth and organization of the various structures that compose the fibres of the body. Powers of a similar kind are exhibited in the phenomena of vegetation: they seem, therefore, to attach to vitality in all its forms. In order to distinguish them from the ordinary chemical affinities to which they are so frequently opposed, we shall designate them by the name of *Organic Affinities*, although, as we shall afterwards attempt to shew, they probably do not differ in their kind, but only in the circumstances and conditions of action, from the ordinary inorganic affinities.

nities.

scular
tracti-

(93.) Another power which more peculiarly appertains to animal life is *Contractility*. This is especially a property of those fibres which compose the muscles. It is often denominated *Irritability*, a name originally given to it by Glisson, but which has justly been objected to by Dr. Bostock as a term employed in many different senses, according as it is applied in physiology, pathology, or ethics. Haller speaks of it frequently under the designation of the *Vis insita*. The term *Contractility*, adopted by Dr. Bostock,[1] and sanctioned by many other eminent physiologists, is in itself unobjectionable, and has the advantage of being a simple expression of the fact itself. It consists in the spontaneous shortening of muscular fibres, in consequence of the impression of certain agents termed *stimuli*, by a power residing in the fibres themselves, and which operates with a force greatly superior to any of the ordinary mechanical sources of motion.

rvous
ver.

(94.) The remarkable property which the nerves possess of conveying with electric celerity impressions made on one of their extremities, or even on any part of them, to the opposite extremity, and to other parts in the line of their course, the influence of which impressions are rendered apparent by certain effects, such as the contraction of the muscles, increased or modified action of the blood-vessels, absorbents, and organs of secretion, and the evolution of animal heat. All these effects may take place from impressions, or *irritations*, (by which term is meant impressions of a certain degree of intensity,) which do not excite sensation, or volition, or any other mental change; and they even occur after the destruction or removal of those parts of the nervous system which are connected with affections of the mind. A power of the same kind is also possessed by those nerves which are connected with the sensorium, on the parts in immediate connexion with the sentient principle.

(95.) It is by the exertion of this power that impressions made on those nervous filaments which are instrumental in sensation, and especially if made on their extremities which are distributed to the organs of the external senses, are instantly transmitted to the sensorium, in which they may be said to terminate, and the changes produced in which are attended by the mental affection termed *sensation*. In like manner, certain other changes in the sensorium, consequent on *volition*, which is a mental affection, are followed by the contraction of certain muscles, by means of some unknown influence communicated through the medium of certain other nervous filaments having their origin in the sensorium, and their termination in those muscles. The nature of the power by which these transmissions are effected in the course of each of these sets of nervous filaments, judging from the similarity of the circumstances under which it takes place, especially in the instantaneousness of the effect, is probably the same in every case; the only perceptible difference in the mode in which it is exerted consisting in the direction of the transmission. This remarkable power, which is totally distinct from any mental effect that may accompany its exertion, we shall distinguish by the name of the *nervous power*.

Sensorial
power.

(96.) A fourth power, perfectly distinct from any of the former, although it also belongs to a portion of the nervous system, is that from which the corporeal changes which take place in those parts immediately connected with sensation, volition, and the intellectual operations, proceed. To this specific property, which should be carefully distinguished from the mere faculty of transmission possessed by the fibres of the nerves, the name of *sensorial power* has been given. We are indebted to Dr. Wilson Philip for the establishment of this important distinction in the specific powers of the nervous system, and for having bestowed upon it the above appropriate designation. The same term had, indeed, been employed by physiologists in a different and much more extended sense, as including muscular irritability, which had been regarded as in some way or other analogous to nervous power. In the sense in which we shall use the term, it is meant to apply exclusively to those physiological changes occurring in certain parts of the nervous system, which produce or accompany changes or affections of the mind.

(97.) It is evident that the astonishing properties belonging to the refined organization of the brain, which constitute sensorial power, and which are, in a manner utterly incomprehensible to us, connected with the affections of the sentient and intelligent principle, present subjects of far higher interest than even the organic, muscular, or nervous powers, and are infinitely more remote from the ordinary attributes of matter.

Gradation
of powers.

(98.) Thus we may perceive that the system of the living body exhibits not only a multiplicity of new powers, which we no where meet with in unorganized matter, but also presents us with a gradation of powers ascending from those of a mechanical nature, but yet derived from highly artificial arrangement of particles, to those of a refined and elaborate chemistry silently at work in the secret laboratories of the body; rising again to principles of a still more elevated order, acting through the medium of the nerves; till we lose ourselves in the more lofty contemplation of those mysterious agencies, which confer on the central portions of the nervous system the power of exciting sensation; which render them instruments of thought and of volition, and which stamp on the being they compose the distinctive character of individuality.

(99.) Viewed with reference to their subserviency to final causes, it is to the sensorial powers, which confer the capacity of enjoyment, that the supreme rank in point of importance must be assigned. The faculties of sensation, of voluntary motion, and of enjoyment, are the only ultimate ends for which, as far as we can judge, the animal has been created and endowed with life. Those ultimate ends of its being are attained primarily by the sensorial powers; and to the maintenance of these are the muscular and the nervous powers subservient. Of these latter powers it is also evident that the muscular is placed in obedience to the nervous, in the same manner as the nervous is obedient to the sensorial power. Thus, the views now presented of the classification and distribution of the physical powers which operate in producing the phenomena of life, are in strict accordance and harmony with the results obtained from the consideration of final causes, which we have already presented in our preliminary chapter.

---

[1] *Elementary System of Physiology*, third edition, pp. 91, 92.

Vital principle.

(100.) If the analysis we have here offered of the vital powers, that is, of powers peculiar to the phenomena of life, and the distinctions we have endeavoured to establish between them be correct, we shall be enabled at once to detect the fallacy of those views of life, and of those definitions of the vital principle which are generally received; and which, we apprehend, have been laid down in violation of the just rules of philosophical induction. The truth is, disguise it how we may by a vain parade of words, that the real state of the science is not sufficiently advanced to authorise that degree of generalization which these definitions would imply. We are certainly not warranted, by the phenomena already known, in regarding life as the effect of any *single* power. The attempt of *Brown*, of *Hunter*, and of *Bichat* to reduce the science to this state of simplification, though highly ingenious, are yet premature; and have, it is to be feared, had rather the effect of retarding than of advancing the progress of real science.

Archæus.

(101.) Many of the older physiologists entertained the notion of a principle, endowed with qualities in some measure partaking of intelligence, and as if it were a spirit presiding over and governing the vital actions. Such was the idea attached by Van Halmont, and by Stahl, to the principle which they termed the *archæus*, or *anima*, and which they conceived regulated the operations of the different powers of the system; an assumption which, however naturally suggesting itself to the mind, while contemplating the harmonious adjustments that pervade every part of the animal economy, is in no respect a philosophical explanation of the phenomena, and is even utterly irreconcileable with some of these phenomena. In like manner, the *vis medicatrix naturæ*, which Hoffman and Cullen have so largely employed in their pathological theories, and which supplied them with ready solutions of every obscure morbid change that embarrassed them, was, in fact, nothing more than a branch of the same doctrine. Nor have the more sober theorists of modern times been sufficiently on their guard against this illusion. In the attributes which John Hunter ascribes to his *vital principle*, we may continually trace the same want of discrimination between that intelligence, by which the conditions of organization were originally adjusted to a variety of contingent circumstances, and those physical agents, by the instrumentality of which the intended objects are attained. When it is said, for example, in the language of this school, that the coagulation of the blood is occasioned by "the stimulus of necessity," it is clearly the final cause alone which is indicated, while the real physical cause is not assigned; and it is also evident that no advance is thereby made towards its discovery. This *principle of life*, with which organized beings are endowed, is represented as a new power, which modifies and controls the operation of those simpler physical laws, to which the same matter, in its unorganized state, is subjected; a power which imposes new cohesive and repulsive forces on the solid materials of the animal or vegetable structures, which imparts to the fluids a new property of coagulation, which alters the order of chemical affinities between their elements or primary compounds, retaining them, contrary to their natural tendencies, in a certain state of equilibrium, and resisting the agency of causes usually tending to destroy that state: and, lastly, which produces, in a degree corresponding with the wants of the system, either an evolution or an absorption of caloric. All these, it must be admitted, are purposes of manifest utility, being directly conducive to the welfare of the individual, and indeed essential to its continuance in the living state. In as far as they are means conducive to specific ends, the reference of all these phenomena to one class cannot be objected to. The fallacy lies in regarding it as a philosophical generalization of effects of a similar kind, resulting from the operation of a simple power in nature; for between many of these effects, considered as mere physical phenomena, there exists not the remotest similarity. But it is the fundamental principle of the method of induction, that similar effects alone are to be ascribed to the agency of the same physical cause. Judging, therefore, from the observed effects, which differ widely in their nature from each other, we ought to infer the operation of several distinct powers, the concurrence of which is requisite to produce the complex phenomena in question. We are, no doubt, unavoidably led to view these phenomena as conjoined, because we witness their existing combinations, and perceive that they are tending to the accomplishment of a specific purpose; namely, the preservation and welfare of the being to which they relate. But this unity of design is an attribute, not of matter, but of intellect, and does not necessarily imply the unity of the agent employed in their production.

(102.) We may take as an example, the phenomena of the circulation of the blood, which, when viewed with relation to that function, form together so beautiful and harmonious a system. These phenomena, taken abstractedly, are ultimately resolvable into such as result from a few general powers, as muscular contractility, membranous elasticity, the hydraulic properties of the blood, &c. The phenomena of digestion, in like manner, when subjected to analysis, are found to be results of the combined agencies of the muscular action of the stomach and intestines, of the chemical powers of the gastric juice, the bile, &c. of the organic powers of secretion, and so forth; all of which concur in the production of a definite object, namely, the conversion of the aliment into chyle. The combined processes subservient to this purpose, constitute, when viewed in their relation to final causes, the function of digestion.

Identity f vital w physica forces.

(103.) However the laws which regulate the vital phenomena may appear, on a superficial view, to differ from those by which the physical changes taking place in inorganic matter are governed, still a more profound investigation of their real character will shew that, when viewed abstractly from the consideration of final causes, there is really no essential difference between them, either as to their comprehensiveness, their uniformity of action, or the mode in which they are to be established by the generalization of particular facts.[1] The difficulty of effecting these inductive generalizations is undoubtedly incomparably greater in the former than in the latter; but this difficulty is similar to that which impedes our progress in all cases where the existing combinations which are the objects of study, are too numerous and too complicated to yield to our powers of analysis. We have examples of this difficulty in many branches of physical science; in meteorology, for example, where no one can doubt that the phenomena are the results of the ordinary physical powers, of the laws of which we are tolerably cognisant; but the operations of which, in effecting the daily and hourly changes of atmospheric phenomena, have hitherto baffled the most persevering and penetrating inquiries directed to this highly important branch of physics. There is, in like manner, no distinct evidence of the material particles, which compose the organized and living fabric, being actuated by any powers or principles different from those which are inherent in them, in their ordinary or inanimate state. They are, in both cases, obedient to certain definite physical laws, the operation of which is determined by the peculiar circumstances of their mode of combination, and the peculiar conditions under which they are brought into action.

---

[1] See an Essay by Mr. Carpenter on the difference of the Laws regulating Vital and Physical Phenomena, Edinburgh New Philosophical Journal, xxiv. 327.

(104.) It may, in like manner, be contended, that the affinities which hold together the elements of living bodies, and which govern the elaboration of organic products, are the same with those which preside over inorganic compounds; and that the designations of *organic* and *vital affinities* are expressive only of peculiarities attending the circumstances and conditions under which they are placed, but do not imply any real difference in the nature of the powers themselves. If our knowledge of these circumstances and conditions were complete, their identity would be at once revealed to us; but until that period, which must be very far distant, has arrived, we must be content with gathering a few indications, which occasionally break out from the clouds of mystery in which the subject is obscured, of the similarity of operation between these two apparently contending powers, the ordinary chemical, and the extraordinary vital affinities. Every fresh discovery in animal and vegetable chemistry, by shewing the mutual convertibility of many of the proximate principles of organic compounds, adds to the number of those indications. Hence it becomes every day more and more probable that the forces immediately concerned in the production of chemical changes in the body, are the same as those which are in constant operation in the inorganic world; and that we are not warranted in the assertion that the operations of vital chemistry are directed by distinct laws, and are the results of new agencies.

(105.) We are therefore led to the conclusion, that the vital properties are not, as it is commonly expressed, superadded to matter in the process of organization, but are the result of the material constitution, that is, of the peculiar combinations and arrangement of the ultimate molecules of the organized tissues, which call out and develope the properties previously existing in those molecules, but which cannot be effective unless these circumstances exist.

ality not mple ver.

(106.) However natural it may be to conceive the existence of a single and presiding principle of *vitality*, we should recollect that this, in the present state of our knowledge, is only a fiction of the mind, not warranted by the phenomena themselves, in which we perceive so much real diversity, and therefore inadmissible as the result of a philosophical induction. We find that vitality ceases in different textures, at different periods, prior to the total extinction of life; a phenomenon which appears scarcely compatible with the unity of any such power.

(107.) It is well known that attempts have in like manner, from time to time, been made to reduce the phenomena of the inorganic world, to a single primordial law; instead of being content to refer them to the operation of distinct laws, such as those of gravitation, cohesion, elasticity, light, heat, electricity, magnetism, and chemical affinity. The phenomena usually ascribed to these great powers of nature have, for instance, been considered as resolvable into one universal principle of *attraction*. By other philosophers, they have been regarded as the effects of a general and sole power of *repulsion*. None of these simplifications are as yet warranted by facts; and equally vain, in the present state of the science, is the endeavour to reduce all the vital phenomena to one single law. It is possible, or perhaps even probable, that future researches may be successful in establishing the identity of some of the powers we now conceive to be distinct, with other powers already known. Thus, in the physical sciences, the recent discoveries that have taken place in electro-magnetism, have satisfactorily established the identity of the magnetic and electric agencies. The same may possibly be accomplished in future times, with regard to heat and light, which are already connected together by so many analogies. But no such approximation can yet be attempted with any prospect of success, between the muscular, the nervous, the sensorial, and the organic powers. No speculative ingenuity can reduce them to a single physical power; nor can we establish any kind of association between them, but by the consideration of another and a totally different class of relations, namely, those they bear to the general object which they combine to produce. This, however, is to substitute final for physical causes; a mode of procedure which we have seen, is totally at variance with the principles of philosophical induction. It is physical causes only which are the legitimate objects of philosophical analysis, and the true bases of the physical sciences.

Order in which the functions will be considered.

(108.) We shall now proceed to give an account of each separate function; taking them in the order of their respective simplicity, with reference not only to their objects, but also to the powers which are concerned in their accomplishment.

We shall accordingly begin with the consideration of the *mechanical functions*, as being more simple in their character, and implying the operation of the simpler powers of organization; together with the peculiar faculty of muscular contractility, which is the great source of mechanical power provided for carrying on the greater movements of the machine. We shall, in the second place, review that class of functions which depend more especially on the operation of the *organic affinities*, and which have for their objects the nutrition and extension of the organs, and their maintenance in that state of chemical, as well as mechanical condition, which fit them for the performance of their respective offices. We shall then be properly prepared for the study of that higher class of functions, which appertain to *sensation*, and all the other faculties connected with mind; functions which imply, in addition to all the powers concerned in the preceding functions, others of a superior order, but which, although in the highest degree interesting and important, are incomparably the most obscure and complex of all. Our attention will, in the last place, be directed to the functions relating to *reproduction*, the study of which requires a previous knowledge of every other department of physiology.

CHAP. V.—THE MECHANICAL FUNCTIONS.

Sect. I.—*On Organization in general.*

Idea of organization.

(110.) If we analyze the ideas attached to the term *organization*, we find that it implies, as its essential condition, a specific arrangement of parts, adapted to some particular purpose, and composing by their assemblage, an individual system endowed with life. It seems impossible, therefore, to attach the idea of organization to a mere fluid, because the mechanical condition of the particles of a fluid is such as to preclude the capability of any permanent arrangement. It appears to be essential to every organized structure, that there shall be solid parts provided for containing those which are fluid. All animal bodies accordingly, are composed of solids and fluids; the former being more permanent in their nature and arrangement, and constituting the basis by which the general form of the body is determined; and the latter, being lodged in appropriate cavities formed by the solids, but capable by their mobility of undergoing more rapid changes of place, and of chemical composition.

(111.) It may in general be said, that the solids bear but a small proportion to the fluids, which enter into the composition of the body. It is difficult, however, to determine the exact proportion which they bear to one another; in the first place, because this proportion is not fixed, and admits of variation in different ages, circumstances, and conditions of the system; and secondly, because it is scarcely possible to effect the complete separation of these two constituent portions; partly from the ready conversion of the solids into fluids, and *vice versa*, and partly from the tenacity of their mutual adhesion. Some estimate of this proportion has been attempted to be formed, by carefully drying the dead body in a stove, or oven; and the result of some experiments has been, that in an adult man, the weight of the fluids is to that of the solids, as six to one, or, according to other experiments, as nine to one. From the examination of an adult Egyptian mummy, which may be supposed to contain nothing but the dry fibres of the body, a still lower proportion has been assigned to the solid part; since this mummy weighed only seven pounds and a half.[1]

Is there an elementary material?

(112.) The possibility of reducing all the organic textures of the human body to one elementary material, which might be regarded as the basis of the whole, was long a favourite subject of speculation among anatomists: and Haller has devoted to it the first section of his great work on Physiology.[2] He conceives that all the solid parts of the frame are ultimately composed of fibres; the animal fibre being the simplest form of organized matter, and being to the physiologist, what the line is to the geometrician, that from which all other figures are produced. This simple fibre, he observes, is invisible, even with the assistance of the microscope; it is only by the union of the primary fibres, that visible fibres are constituted; and from the assemblage and lateral adhesion of these, again, thin plates of animal substance are formed, while the grosser substance of the organs themselves, is composed of a complicated contexture of these plates and fibres. This supposed basis, or essential constituent, of all animal textures, has been by some termed the *animal parenchyma*, and by others, has been designated by the general name of *animal membrane*.

Theory of universal vascularity.

(113.) Besides this spongy or areolated texture, which composes by far the greater bulk of the organs of the body, Haller has also admitted two other constituent parts, namely the *muscular*, and the *nervous substances*. These views have since been generally adopted by physiologists, with some slight modifications. Many have thought it necessary to introduce, in addition to the preceding, an element which they consider as of a tubular form, constituting vessels fitted to contain fluids. This was the favourite doctrine of Boerhaave, who supposed that the simple fibres, or the smallest into which they can be conceived to be divisible, formed by their lateral adhesion, a membrane of the first order, which, when coiled up into a tube, would constitute a vessel of the first order. These vessels, again, when interwoven together, composed a new order of membranes, by the duplication of which a second order of vessels was formed. Successive series of membranes and vessels were thus constructed, until they acquired a magnitude sufficient to be visible to the eye. According to this hypothesis, therefore, all the parts of the body might ultimately be resolved into a congeries of vessels, arranged in these ascending orders. This hypothesis, which evidently rested on the most visionary basis, has been ably refuted by Albinus, and by Haller. It has, however, left some traces in the opinions expressed by many subsequent anatomists, who still cherished the idea of the universal vascularity of the animal fabric, and of this vascularity being essential to organization. The skilful injections of Ruysch, who succeeded in introducing coloured fluids into vessels, the contents of which are naturally transparent, had long ago shown that there exists an order of vessels too minute to be otherwise detected. Dr. William Hunter has, even in later times, adopted the opinion that every living part is necessarily vascular; and that where there is no circulation, there can be no life. Mascagni was also a strenuous advocate of the hypothesis of the universal vascularity of the animal textures; but he conceived that every part is made up of a congeries of minute lymphatic vessels. We shall have occasion afterwards to point out the fallacy of these views.

Other mentar structur

(114.) Although the analysis of animal tissues, into the three primitive elements we have pointed out, namely, into the membranous, the muscular, and the nervous fibres, be founded on the most prominent and well marked features of distinction which they exhibit, yet there are perhaps other kinds of texture also, which possess sufficiently characteristic properties to entitle them to rank as elementary tissues: these are the *albugineous fibre* of Chaussier, and the *epidermoid substance;* and to these we might also add, in order to make the analysis complete, the *cartilaginous* and the *osseous structures*.

Ultima forms o tissues.

(115.) But this analysis of animal textures, has, by some later anatomists, been carried, in another point of view, still farther. With relation to the forms assumed by the elementary tissues, they have been referred to three kinds, the *fibrous*, the *lamellar*, and the *granular*, or *globular*. The two former are exemplified in the structure of the cellular substance, which composes the greatest portion of the animal fabric; the fibrous is characteristic of the muscular and ligamentous structures; the fibrous, united with the granular, is exhibited in the texture of the glands, and in the medullary substance of the nervous system; and the globular is most perfectly shown in the composition of the chyle, the blood, and several of the secretions.

Micros pical o vation. Theory Meckel Edward

(116.) Anatomists have sought for still more general results, by means of microscopical investigations. When very high magnifying powers are employed, both the muscular fibre, and the nervous or medullary matter, appear to be resolvable into a mass of globular particles, analogous to those which compose the opaque portion of the blood. Meckel has founded upon these observations the following system: He conceives that every animal structure is ultimately resolvable into two kinds of substance, the one formed into minute, but solid spherular masses, or globules; and the other, being an homogeneous, but amorphous matter, either uniting together these globules in the way of a cement interposed between them, or constituting by itself, what has been termed the cellular substance, membrane, and the various structures derived from membrane. Dr. Edwards, on the other hand, has carried this notion to the utmost possible length; for he represents the cellular and membranous substances, as being themselves composed of globules; so that, according to his views, the whole structure of an animal body will consist of globules.

Observ tions of Hodgki and Lis

But the later, and more careful investigations of Dr. Hodgkin and Mr. Lister,[3] appear to have established, that the globular appearance of the different organized textures, when viewed with microscopes of high magnifying power, is altogether an optical deception. A similar conclusion, indeed, was, many years ago, deduced by Dr. Monro, from his microscopical researches, detailed in his work on the Nervous System.

SECT. II.—*Combinations of Textures.*

System compou textures

(117.) Such being the results of the general analysis of animal textures, into a few primary elements, we are next to consider the combinations of these textures which are actually presented to us by nature, in the various organs of the body; and in order to possess the most comprehensive views on the subject, it will be proper to study these organs as forming systems of which the several parts are related to each other by similarity of composition and of properties. The most elaborate arrangement founded on this principle is that of Bichat, who distinguishes the constituent textures of the body into twenty-one different kinds.[4] But it may be objected to his classification, that it is founded on distinctions of function, as well as on those of structure. We

Béclard

therefore prefer following on this subject, the arrangement of Béclard, which proceeds on one uniform principle, namely, that of mechanical conformation. Taking this principle as our guide, we shall find that the systems of organs may be easily reduced to eleven different classes; namely, 1, the *Cellular;* 2, the *Adipous;* 3, the *Membranous;* 4, the *Dermoid;* 5, the *Ligamentous;* 6, the *Cartilaginous;* 7, the *Osseous;* 8, the *Muscular;* 9, the *Medullary* or *Nervous;* 10, the *Vascular;* and, 11, the *Glandular* systems of structures. The properties of these several tissues will come under our review in connexion with the functions to which they are more immediately subservient. The three first of these, however, claim our immediate attention, as being the simplest, and most generally diffused over the body.

1. *The Cellular Texture.*

cellu-
texture.

(118.) This is the simplest form in which the animal substance presents itself to our observation; and it appears to be not only the real basis of the structure of all the other organs, but also the general medium which unites their several parts together, as well as the bond of connexion between adjacent organs. It is accordingly, of all the simpler textures, that which is the most extensively diffused over the body; not only pervading the substance of the organs, but also filling up all the intervening spaces, and preserving them in their proper relative situations. Haller found it to consist of an irregular assemblage of plates and fibres, crossing one another in all manner of directions; so that when stretched or expanded by the insinuation of any fluid between the plates, the whole presents a cellular structure. These cells, which are produced by the separation of the plates from each other, are of no regular shape, but communicate freely with one another throughout the whole extent of the substance in which they are met with.

inuity
of cells.

(119.) As there is a continuity of the cellular substance in every part of the body, where it exists in this form, there must, in like manner, be a continuity in the cavities of these cells; and the consequence of this structure is, that any fluid, such as air, or water, which may happen to be introduced into any one part, will readily find its way into adjoining parts, and will thus gradually be diffused over the whole body. If the fluid be water, as happens in dropsies, it will, by its gravity, tend to accumulate in the most depending parts of the body, as the ankles, while a person is standing or sitting; and it will leave these parts, and be more generally distributed, after he has remained for some time in a horizontal posture.

The cellular texture may easily be inflated by air; and this may happen in consequence of injury, even during life; in which case the air gradually insinuates itself into every part of the frame, puffing up the skin to an extraordinary degree, so as totally to obliterate the features of the face, and disfigure the whole body. If measures be not taken to let the air escape, the patient is at length destroyed by suffocation. A remarkable instance of this disease, which is termed *Emphysema,* is given by Dr. William Hunter, in an essay on the properties of cellular texture, contained in the second volume of the *Medical Observations and Inquiries,*[1] and which also deserves particular notice, as presenting the best account of this branch of general anatomy.

Ce ar
ser y.

(120.) The cells, or rather intervals between the plates and fibres of this substance, contain in the natural and healthy state, a quantity of aqueous fluid, which has been termed the *cellular serosity,* and which serves the purpose of lubricating the surfaces of the plates, and thus, by diminishing friction, of facilitating their relative motions on each other. To this circumstance we may also trace many of the mechanical properties of the cellular texture; such as its perfect flexibility, and its great extensibility in various directions; while it exerts, at the same time, considerable powers of cohesion. The combination of these two latter properties is the source of another, which it possesses in a very eminent degree, that of *Elasticity,* or the power of recovering its original form, when the disturbing force, whether producing compression or extension, has ceased to act. It is evident that by possessing all these properties, the cellular texture is eminently qualified to fulfil the important offices assigned to it, of serving as the elastic scaffolding or canvass for sustaining all the other parts, and retaining them in their proper situations; and whilst it is the universal mechanical cement, or medium of connexion between them, it is at the same time admirably adapted to facilitate their relative movements and mutual actions, which are required for the performance of their respective functions.

M nical
pro ties.

Elasticity.

Cellular
contractility.

(121.) Another property, besides elasticity, has also been ascribed to the cellular substance and other textures derived immediately from it. It consists in a peculiar kind of contractility, attended by a sudden corregation and curling up of its substance. As this property has been supposed to bear some relation to muscular contractility, we shall defer its consideration till we come to treat of that property.

2. *Adipose Texture.*

Fat.

(122.) This texture contains the oily secretion which is known by the name of *fat.* The adipose matter, or fat, is lodged in particular portions of the cellular texture, appropriated to this office. It consists of very minute grains or globules, distinguishable only by the aid of the microscope. Each of these globules is contained in a separate investment, or sac, constructed of an exceedingly fine and delicate membrane, formed out of the constituent plates of the cellular substance, and having no external opening. The size of these vesicles is stated to be from the eight-hundredth to the six-hundredth part of an inch in diameter. They are collected together in small rounded masses, united by vessels, and presenting an appearance under the microscope, not unlike that of a bunch of grapes. They are lodged in the cells of the cellular substance in various situations throughout the body, and contribute to fill up the hollows which occur in different places between the bones and muscles, and other organs. They are very abundant immediately under the skin; and in some parts are evidently interposed as cushions for the protection of organs exposed to injury from pressure or other mechanical violence.

Contained
in separate
cells.

It is evident that the cells in the cellular substance which are occupied by the fat, are different from those which are the seat of dropsical accumulations of fluid; and that they do not, like the latter, communicate with one another; for it is found that each portion of fat always remains stationary in the same cell in which it was originally lodged.

Its properties.

(123.) The fat varies considerably in its consistence in different parts of the body, according to the purpose it is intended to serve. At the usual temperature of the living body, however, it is retained very nearly in a state of fluidity. The quantity accumulated in the body is very different at different periods of life; and varies also according to the state of health, and the peculiar habit and constitution of the individual. It is whiter in its colour, and more firm in its consistence, during the earlier periods of life, and becomes more soft, and acquires a yellow tinge as age advances.

(124.) The fat of animals has been resolved by *Chevreul,* who undertook an elaborate analysis of this substance, into two proximate principles, to which he gives the names of *stearin* and *elaïn.* The former, derived from the Greek word στεαρ, signifying tallow, is of a much more solid consistence than the latter in ordinary temperatures, and does not melt under a heat of from 110° to 120° of Fahrenheit. It is obtained from fat by digesting it in alcohol, in the form of white crystalline needles, which are deposited as the fluid cools. It is a white brittle substance, void of taste or odour, and resembling wax in its appearance. If, after the stearin has been deposited, heat be applied to the remaining solution, so as to drive off the alcohol, there remains an oily matter, which continues fluid at 59° of Fahrenheit, and is called, by *Chevreul*, *elaïn*, from the Greek term for oil, ἐλαιον.

---

[1] Page 26, et seq.

The consistence of the fat of different animals, and in different parts of the same animal, admits of considerable diversity, according to the proportions in which these two ingredients are contained; the abundance of stearin is the principal cause of the hardness of tallow or suet, whilst an increased proportion of elain characterises the composition of marrow, which is one of the most fluid kinds of fat.

Marrow.

(125.) The marrow which occupies the central cavities of the cylindrical bones, and which also exists in small quantities in the canals that pervade the substance of the denser portions of the bones, is perfectly analogous in its composition and structure to the fat in other parts of the body. The oily particles are contained in membranous vesicle, which are themselves connected together, and retained in their places by a fine net-work of plates and fibres, corresponding to the general cellular structure of other parts, but of a peculiarly delicate contexture.

3. *Membranous Structures.*

Membrane.

(127.) When the texture of cellular substance becomes consolidated by the intimate adhesion of the plates and fibres of which it is originally composed, which, of course, produces the complete obliteration of its cells, it constitutes the different varieties of *membranous structures*. These structures are of different degrees of thickness, and compose masses of different degrees of density. When expanded into a continuous sheet or plate, it forms what is more properly termed a *membrane*. These membranes, when sufficiently thin, are semi-transparent, and have a smooth and uniform surface. Haller found that all membranes are resolvable, by long maceration in water, into a flocculent spongy substance, in which the original cells of the cellular texture from which they were formed, could be rendered apparent by inflating them with air.

Their impermeability to fluids.

(128.) Membranes retain almost all the mechanical properties belonging to the cellular substance from which they are derived; for they are equally flexible and elastic, although possessing superior strength and firmness. But in one respect they exhibit a marked difference, while the simple cellular texture, as we have seen, allows of the general communication of fluids introduced into its cells, from one part to another; membranes are for the most part impermeable to fluids, and are in consequence employed with the express design of preventing their diffusion.

(129.) The property possessed by membranes of contracting in their dimensions by the evaporation of the water they contain, and which is united with the animal material by a very weak affinity, constitutes what may be termed the *hygrometric property*.

All the membranes are capable of being dried by the continued application of a moderate heat, and may be kept in this dry state for a great length of time without undergoing any change. But if a dry membrane be immersed in water, it absorbs a considerable quantity, recovers its softness and flexibility, and expands in all its dimensions. These effects are greater when the action of warmth is combined with that of moisture. A membrane will absorb moisture even from the atmosphere, and again part with it, according to its different states of humidity. Philosophers have availed themselves of this property in the construction of an hygrometer, or instrument for indicating these varying states of the atmosphere with respect to dryness or humidity. Any long slip of dried membrane, suspended in the air, and stretched by a moderate weight, may be made to act on a moveable index by any mechanical contrivance rendering the variations in its length visible on a large scale, and will serve the purpose of an hygrometer. The membrane will be found to lengthen by exposure to a humid atmosphere, from which it imbibes moisture, and again to contract by the evaporation of this moisture in a drier air.

A piece of catgut, which is prepared from the membrane of a sheep, will answer the same purpose. We find, accordingly, that the state of the weather has a considerable effect upon the tone of a musical instrument made of catgut. A violin, or harp, may be in perfect tune in one situation, and yet become quite out of tune when placed in an atmosphere of greater humidity, as in that of a room filled with company.

The principle of which these facts are illustrations, is to a certain extent applicable to the animal body. The doctrine of the animal fibres being braced or relaxed, which was formerly a more fashionable language than it is at present, may perhaps have been carried too far, but it has certainly a foundation in truth. Warmth and moisture have a powerful influence on the body, and their effect is partly mechanical; and this operation, which is primarily exerted on the skin, renders them efficacious in the relief of inflammatory action, by diminishing the tension of the inflamed parts. This effect is not merely temporary, but may become the permanent habit of the system. Thus, we find that the inhabitants of elevated countries where the air is peculiarly dry, are more hardy, and possess more of the *vis tonica* in their frames, than those who dwell in a humid climate, or in low and swampy plains. The Swiss and other inhabitants of mountainous tracts, may in this respect be contrasted with the Dutch and Flemish, who have in general a constitutional laxity of fibre; and similar differences have been observed in the lower animals among varieties of the same race.

(130.) All these properties of membrane, taken together, adapt them for being employed in various useful ways in the animal economy. Membranes in general are employed to establish relations not only between adjacent, but also between distant parts; they strengthen their connexions, and, whilst in some they allow of relative motions in certain directions, and to a certain extent, in others they restrain them and limit their degrees. Almost every organ is furnished with a firm covering of membrane, which gives it protection and support. For all these purposes, a looser and more yielding cellular tissue would not have possessed adequate strength.

Vessel &c.

(131.) As the cellular substance is the basis of membrane, so membrane, in different modifications, constitutes the essential portion of many other parts of the body; such as all those recipient organs, having the form of sacs or pouches, like the stomach, and especially those which are provided for the retention of fluids, as the gall-bladder, and urinary bladder. Membranes are also formed into tubes of various kinds, destined to transmit their fluid contents to various parts. These tubes, known under the name of *vessels*, *canals*, or *ducts*, are also frequently furnished with a valvular apparatus, likewise composed of membrane, allowing of the passage of the fluid only in one direction.

(132.) The structure and properties of every description of membranes have been minutely investigated by Bichat, who, in his *Anatomie Générale*, has given us an elaborate classification of the animal textures. He establishes two general divisions of membranes, namely, the simple and the compound. Of the former he makes three classes; first, the mucous membranes, the surface of which is defended by a mucous secretion; secondly, the serous membranes, characterised by the serous nature of the fluid with which their surface is constantly moistened; and thirdly, the fibrous membranes, which are distinguished by their peculiar structure, as being composed of dense and inelastic fibres. The compound membranes are formed by the intermixture of two or more of the simpler membranes, and exhibit a combination of the characters of each.

S us
m ranes
ar flect-
ed as to
fo closed
sa

(133.) *Serous membranes* are universally met with whereever there are internal cavities in the body, which are closed on every side, that is, have no communication, by any channel, with the external air; such cavities being always lined by serous membranes. This is exemplified in the cavities of the chest, which are three in number; namely, one on each side, containing the right and left lung, and the intermediate cavity, occupied by the heart. The membranes lining the former are called the *pleuræ;* and the membrane lining the latter, the *pericardium.* The great cavity of the abdomen, in which are situated the organs of digestion and chylification, is lined by the *peritoneum,* which is also a serous membrane. The same, also, applies to the cavities in the interior of the brain, which are called *ventricles,* and also the external surface of the organ, which are lined by the *dura mater,* the *arachnoid coat,* and *pia mater.* The serous membranes, after lining their respective cavities, are extended still farther, by being reflected back upon the organs inclosed in their cavities, so as to furnish them with an external covering. If it were possible, therefore, to dissect these membranes from off the parts which they invest, they would have the form of a sac without an opening, the organ invested by one of their folds, being altogether external to the cavity of that sac; just as happens when a double night-cap is worn, of which the part immediately covering the head is analogous to that portion of the serous membrane which adheres to, and invests the organ; whilst the external portion of the cap represents the lining of the cavity in which that organ is said to be contained.

Th have
tw rfa-
ces

(134.) Hence it will readily be understood, that the serous membranes never open, or allow of any perforation, for the passage of blood vessels, nerves, or ducts, to or from the enclosed organs; but that they are always reflected over those parts, forming a sheath round them, and accompanying them in their course. It also follows, as a necessary consequence, that their free surfaces completely isolate the parts between which they intervene. The great viscera, suspended in the bags formed by their serous coverings, can have no communication with the adjacent parts, except at the points where their vessels enter; in all other situations there is no continuity of parts, although there may be contiguity.

Li of
sur s.

(135.) In every serous membrane we may distinguish two surfaces having very different characters: the external surface, or that by which they adhere to the surrounding organs, and the internal surface, which is in immediate contact with another portion of the same membrane, but without adhering to it. This interior surface is remarkable for its perfect smoothness and polish; and it is continually preserved in a state of moisture by a serous fluid, which exudes from it. This fluid has been termed the *liquid of surfaces,* and consists almost entirely of water, with a very minute proportion of albuminous matter. Its presence is evidently of the greatest use in facilitating the motions of the parts contained within the cavities, with relation to their sides, by diminishing friction, preserving the smoothness of the surfaces applied to each other, and preventing their mutual adhesion. When the internal surface of these membranes is exposed to the air in living animals, or immediately after death, this fluid exhales in the form of vapour, to which formerly great attention was paid, and which was dignified with the name of *halitus.* In consequence of disease, this fluid of surfaces sometimes accumulates in one of these cavities, and thereby produces a dropsy of that respective cavity: a fact which proves the power of serous membranes to retain these fluids, and not, as in the case of the cellular substance, to allow of their diffusion into the adjoining organs.

(136.) The serous membranes constitute the simplest form of condensed cellular substance; they are not divisible into any regular layers; although cellular portions may be removed from the outer surface by which they are attached to the surrounding parts. In the natural state they are exceedingly thin, and transparent; but become thicker and opaque by disease. Although perfectly flexible, they possess considerable strength; they are exceedingly extensible; but they are not in the same proportion elastic: for after they have been stretched, they give but feeble indications of a power of retraction.

4. *The Osseous Fabric.*

Properties of the bones.

(137.) For the purpose of thoroughly understanding the whole mechanism and operations of any complicated engine, or system of machinery, the best and most natural course is to commence with the study of the solid frame-work, which gives stability to the whole fabric, and affords fixed bearings from which the powers, regulating the movements of its different parts, exert their respective powers. This purpose of procuring mechanical rigidity and support, is the appropriate function of the osseous system, or *skeleton;* which is composed of a connected series of solid structures, called *bones,* deriving their mechanical properties from their peculiar chemical composition, and almost crystalline hardness, and which constitute one of the most important of the constituent textures of the body. Our first object of attention, therefore, in considering the mechanical functions, is the study of this system of structures.

(138.) The bones, then, are to be viewed as the densest and most solid parts of the animal frame; constituting the basis of support to the softer textures, affording protection to all the vital organs, and furnishing those powerful levers which are essential to the advantageous action of the muscles concerned in locomotion, and in the various movements of the limbs. With reference to their form, they have usually been divided into three classes: the *long cylindrical bones;* the *broad and flat bones;* and the *short or square bones,* which include those of a more irregular form, and not referable to either of the other two heads. To the first class belong the principal bones of the upper and lower limbs, which are adapted more especially to the purposes of motion. Under the second may be ranked the bones of the skull, which serve for the protection of the brain; and the third include the vertebræ, the bones of the face, and the small bones which concur in the formation of the wrist and the ankle. There are, besides, other bones, such as the ribs and the bones of the pelvis, of a more anomalous description, which are rather distinguished by their irregularity than by any definite character.

Structure of bones.

(139.) On examining the mechanical structure of bones, we find that their external surface is generally their hardest part, and that it consists of a solid plate, or layer of bony matter, of different thickness in different bones, and in different parts of the same bone. In the cylindrical bones this firm and compact substance extends only to a certain depth, and within this the structure is spongy and cellular. To the latter part the name of *cancelli* has been given. In the middle of the long bones the central parts are occupied by the marrow; but as we continue our examination, by taking different sections across the bone, in proportion as we approach the extremities, we find the dense external substance diminishing in thickness, while the proportion of the spongy part increases, and encroaches upon the space in the centre occupied by the marrow, which at length disappears, so that at the very extremity of the bone, nearly the whole area of the section is filled by the cancelli, while the outer covering of solid bone is merely a thin superficial plate. In the flat bones, having, of course, an upper and under surface, the plates of bone forming each of these surfaces, are termed the two *tables*, and the cellular portion which is found between them is called the *diplöe*. In many of the more irregularly shaped bones, neither cancelli nor diplöe are found, the whole substance being compact. Dr. Bostock observes, that the transition from the compact to the spongy part of a bone is not marked by any decided limit; but they pass into each other by insensible degrees, so as to shew that there is no essential difference between them.[1]

(140.) Bones present the appearance of fibres on their surface. This is seen particularly in all bones that have been long exposed to the weather, or that have been long boiled. In the cylindrical bones most of these fibres are longitudinal; but in the flat bones they generally run in a radiated direction. In the short bones their course is much more irregular and difficult to trace. In the compact part of the section of a bone, the appearance of plates is not very distinguishable; but certain cavities are discovered which, for the most part, run in a longitudinal direction, and nearly parallel to one another. They are of various lengths; and their diameters are exceedingly small. They have transverse or oblique canals, which establish communications between them; and some of which also open into the larger cancelli in the middle of the bone. These cavities have been called the canals of Havers,[2] who first discovered them. Their existence, however, was for a long time considered as dubious; but it has been lately verified by Mr. Howship,[3] who, with the help of the solar microscope, obtained distinct views of them, and was enabled to trace their course. He ascertained the diameter of these canals to be about the 400th of an inch; and farther discovered that they are lined with an extremely fine vascular membrane, and that they are filled with marrow.

(141.) The intimate structure of bone was first minutely investigated by Malpighi, who discovered that its basis consists of an animal membrane having an areolated, or cellular form. Duhamel[4] next ascertained that this membranous matter was frequently disposed in plates or laminæ; and he described these plates as forming concentric rings, analogous to those which compose the trunk of a tree; but there is no other foundation than mere fancy for this analogy. We owe to Herissant[5] the important fact, that the chief properties of bone are derived from the presence of an earthy ingredient, which is deposited in the animal basis, or parenchyma of the bone.

Analysis of bone.

(142.) The analysis of a bone into its two constituent parts is easily effected by the agency either of acids or of heat. By macerating a full grown bone for a sufficient time in diluted muriatic acid, the earthy portion of the bone, amounting to nearly one-third of its weight, is dissolved by the acid; the animal portion only remaining. This animal basis retains the bulk and shape of the original bone, but is soft, flexible, and elastic; possessing, in a word, all the properties of membraneous parts, and corresponding in its chemical character to condensed albumen.[6] A portion of this solid animal substance affords gelatine by long boiling in water, especially under the pressure, admitting of a high temperature, to which it may be subjected in Papin's digester. On the other hand, by subjecting a bone to the action of fire, the animal part alone will be consumed, and the earth left untouched, preserving, as before, the form of the bone, but having lost the material which united the particles, presenting a fragile mass which easily crumbles into powder. This earthy basis, when chemically examined, is found to consist principally of phosphate of lime, which composes eighty-two hundredths of its weight; and to contain also, according to Berzelius, minute portions of fluate and carbonate of lime, together with the phosphates of magnesia and of soda.

Dr. G. O. Rees, who has lately made exact analysis of different bones taken from the same individual, in a state of perfect dryness, and quite free from fat, periosteum, or cartilage, deduces from his researches the following conclusions:[7]

1. The long bones of the extremities contain more earthy matter than those of the trunk.

2. The bones of the upper extremity contain somewhat more earthy matter than the corresponding bones of the lower extremity; thus the humerus more than the femur, and the radius and ulna more than the tibia and fibula; this difference is, however small, being about one half per cent.

3. The humerus contains more earthy matter than the radius and ulna, and the femur more than the tibia and fibula.

4. The tibia and fibula contain, as nearly as possible, the same proportions of animal and earthy matter, and the radius and ulna may also be considered alike in constitution.

5. The vertebræ, ribs, and clavicle, are nearly identical as regards the proportion of earthy matter; the ileum contains somewhat more of the earth, the scapula and sternum somewhat less: the sternum contains more earthy matter than the scapula.

6. The bones of the head contain considerably more earthy matter than the bones of the trunk, as observed by Dr. J. Davy; but the humerus and other long bones are very nearly as rich in earths.

7. The metatarsal bones may probably be ranked with those of the trunk in proportional constitution.

8. The cancellated structure (at least in the rib) contains less earthy matter than the more solid parts of the bone; this difference, however, is not considerable.

9. The bones of the trunk of the fœtal skeleton are as rich in the proportion of earthy matter as those of the adult; at least the difference is too small to be material.

10. The bones of the fœtal extremities, on the other hand, are deficient in earthy matter, which is a fact simply explicable from the circumstance that such an excess of earths as appears necessary to very great strength of bone is not needed at birth, and therefore only appears in after life.

The existence of a general law, regulating the proportion of earthy deposit in the different bones, (which is shown by the curious agreement of relative proportions observed between the fœtal and adult skeletons,) adds one more to the many proofs of the regularity and perfection of design which nature evinces in her operations.

(143.) It appears evident, then, from these and other facts, that the basis of the osseous structure is essentially the same as that of membraneous parts, being composed of fibrous laminæ or plates, which are connected together so as to form, by their intersection, a series of cells analogous to those of the cellular texture. In the interstices of these plates, or in the cells themselves, the particles of phosphate of lime are deposited; the particles being held in union by the interposed membrane, which performs the office of a cement. Hence there is no necessity for admitting the hypothetical explanation of Gagliardi,[8] who maintained that the bony plates are held together by small processes, like nails, which, rising from the inner plates, pierce through the adjoining ones, and are fixed into the more external plates. Of these processes, or *claviculi*, as he called them, he described four different kinds, the perpendicular, the oblique, the headed, and the crooked. But no subsequent anatomist has been able to verify these observations; and the account given by Gagliardi remains on record as a curious instance of the extent to which an observer of mere appearances is liable to deceive himself by the influence of too vivid an imagination. Monro states, that in bones fitly prepared, he could only see numerous irregular processes rising out from the plates. Duhamel, trusting to a fancied analogy between the process of ossification, and the growth of trees, imagined that a bone is composed of a series of regular concentric laminæ. But this hypothesis has been refuted by Scarpa,[1] who investigated, with great care, both the mechanical structure of bone and the mode of its formation; and concludes that the ultimate texture of bone is not lamellated but reticular. Raspail has indulged in speculations of a still more questionable nature respecting the ultimate osseous texture, which he endeavours to assimilate with that vesicular form, which he views as the essential character both of animal and of vegetable organization. Dr. Benson observes[2] that all writers, before the time of Scarpa, considered the structure of bone as laminated, or fibrous and laminated; whilst, according to all later authorities, it should be regarded as cellular. In the works of the former, however, we may notice intimations of a reticular texture; and in those of the latter, on the other hand, we meet with the expressions of a *tendency* or *disposition* to a laminated arrangement. "If, with these opinions before us," he continues, "we come to examine for ourselves, we shall have no hesitation in agreeing with Scarpa that it is really cellular. At the same time, it must be confessed, that the sides of the cells are, in the compact tissue, so pressed together, that the appearance of laminæ is often very striking; and, again, that the sides of the cells have, in most places, the appearance of fibres; when the earthy portion is removed by an acid, we can tear out with a pin the membranous fibres, and almost demonstrate the fibres. But a closer examination will shew that we have torn the cells, and destroyed the true texture. The laminated disposition supposed to be shewn by exfoliation, the weather, burning, &c., may all be proved to be deception; and there can seldom, indeed, be exhibited a plate, however small, of equal thickness throughout, which has been removed by any of these agents. There is, however, an approach to the laminated arrangement, and every cell is formed of particles which approach to the form of fibres. The longitudinal canals of Havers, Leuwenhoeck, and Howship, probably result from the flattened cells, and may be deceptive appearances in the old bone, or the channels for blood vessels, &c."

osteum

(144.) Bones are invested on every part of their surface, excepting in those parts where they are plated with cartilage, with a firm plate of membrane, termed the *periosteum*, which conveys blood vessels to the bone, and establishes mechanical connexions between it and surrounding parts. This membrane belongs to the class of fibrous textures, being composed of numerous inelastic fibres of great density and strength, passing in various directions, and composing a kind of ligamentous tissue, interlacing with the fibres of the ligaments which encircle the joints.

row.

The inner surface of the periosteum is connected with the bone by the vessels passing from the one to the other, and also by numerous prolongations which dip down into the osseous substance. The blood-vessels of this membrane are numerous, and easily rendered apparent by means of injections, especially in young subjects. Besides the more obvious uses of the periosteum, in affording protection to the surface of bones from injurious impressions they might receive from the action of surrounding parts, and interposing a membranous layer for the defence of the latter, Bichat ascribes to it the more important office of affording fixed centres of support to the general system of fibres, in its mechanical relations to the rest of the frame. The periosteum which covers the bones of the skull has received the name of the *pericranium*.

(145.) The internal cavities of the bones are, as is well known, occupied by an oily secretion, termed the *marrow*, contained in a delicate structure, composed of minute vesicles which are filled with the fluid oil, and which are connected by fine threads and plates of fine cellular tissue. Monro describes the vesicles as perfectly distinct, having no communication with one another, and as presenting, under the microscope, the appearance of a cluster of pearls.

Many have been the conjectural uses assigned to the marrow by the older physiologists; it was at one time very generally imagined that it served, by its mechanical properties, to temper the brittle quality of the earthy materials which form the chief constituent portion of the bone; a purpose, however, which it is impossible it could fulfil, as, instead of being mixed up and blended with the phosphate of lime, or diffused generally through the substratum of the bone, it is lodged in separate cavities, and thereby prevented from any union with bony matter, or intermixture with its substance. The marrow is, in general possessed of little sensibility, except in a few points, where it is traversed by the nervous filaments supplying the bone itself. It is regarded by physiologists of the present day rather as constituting a part of the general store of nutritious matter, which is kept in reserve for particular occasions of exigency, than as having any mechanical relation with the dense texture within which it is lodged. The circumstance of its being wholly absent in the bones of birds is a clear proof that there is no mutual dependence between the functions of the latter and the presence of the marrow.

Internal periosteum.

(146.) All the internal cavities of bones occupied by the marrow are lined with a vascular membrane, which follows all the windings of the canals and of the cancelli, and has been called the *internal periosteum*. It may easily be rendered visible by sawing a long bone longitudinally, and plunging it in boiling water, by which treatment the membrane is made to detach itself from the bone, and contract upon the marrow which is within it, and to which it is closely attached. It has then the appearance of a fine cobweb.

5. *Cartilage.*

Properties of cartilage.

(147.) The structure which ranks next to bone in respect to its density is *cartilage*, a term which expresses a firm and dense substance, apparently homogeneous in its texture, semipellucid, and of a milk-white or pearly colour. Substances of this description are found to enter into the composition of several parts of the body. The surface of a cartilage is perfectly uniform, and presents no visible eminences or pores; nor can any cavities or inequalities of any kind be perceived in its internal texture. When it is cut into with a sharp knife, the section exhibits an uniform appearance, like that of a piece of glue. Yet, after exposure for a certain time, the surface thus cut begins to contract, and a serous fluid is perceived slowly to exude from it, proceeding from certain invisible pores, which are in all probability minute capillary vessels, of which the diameters are too small to admit the coloured globules of the blood. That a delicate system of circulating passages exist in cartilages, is shewn by various diseased conditions, in which sometimes granulations have been seen to arise from their surfaces, and at other times extensive absorption of their substance has taken place; and although insensible, on ordinary occasions, to wounds inflicted by cutting instruments, yet in others, when sudden pressure is made on them under peculiar circumstances, extreme pain arises, giving warning of serious injury impending.

Cartilaginous structures appear to be composed of albumen alone, with scarcely any intermixture of gelatin. Dr.

---

[1] *De Perit. Structura Ossium.*

[2] *Cyclopædia of Anatomy and Physiology*, vol. i. p. 433.

John Davy found that they contain a small proportion of phosphate of lime, amounting to about the two hundredth part of their weight. Mr. Hatchett, however, does not regard this substance as an essential ingredient in their composition.

The mechanical property which particularly distinguishes cartilage is elasticity, a quality which it possesses in a greater degree than any other animal structure, and which adapts it to many useful purposes in the economy. Hence it forms the basis of many parts where, contrary to the purposes answered by the bones, pliancy and resilience as well as firmness are required; and hence cartilage is employed when a certain shape is to be preserved, together with a capability of yielding to an external force. The flexibility of cartilage, however, does not extend beyond certain limits; if these be exceeded, fracture takes place. Great density bestowed upon an animal structure, indeed, appears to be in all cases attended with a proportionate degree of brittleness. These mechanical properties of cartilages, as well as their intimate structure, although nearly homogeneous in all, are subject to modification in different kinds of cartilage. Cartilages are covered with a fine membrane, termed the *perichondrium*, analogous in its structure and office to the periosteum, which we have already had occasion to point out among the fibrous membranes, as investing the bones.

Cartilages, temporary and permanent.

(148.) Cartilages are distinguished into those which are *temporary* and those which are *permanent structures*. The former are only met with in the earlier periods of life, during the growth of the body, and are gradually removed to make way for the deposition of bone. When about to undergo this change, small canals have been detected in the substance of these temporary cartilages. The permanent cartilages are those which retain the cartilaginous structure throughout every period of life. They have been distinguished into three or four different kinds, such as the membraniform, the interosseal, the articular, and the interarticular cartilages.

Membraniform.

(149.) The *membraniform cartilages* are included by Bichat in the class of fibro-cartilaginous structures hereafter to be described. They furnish a basis of support to the softer parts, and in some measure supply the place of bone, giving a determinate shape and firmness to parts where bone would have been inconvenient. They possess greater tenacity and less brittleness than the other kinds of cartilage. By their elasticity they admit of considerable variation of figure, yielding to external pressure, and recovering their proper shape as soon as the pressure is removed. Of this kind are the cartilages of the nose and ear, and also those of the larynx and trachea. These cartilages are extremely thin, and are invested with a very thick and firm perichondrium, to which they are connected by means of a number of fibres traversing their substance, and rendering their surfaces rough and porous. Long maceration enables us to detect these fibres, and to resolve the whole into a cellular and albuminous substance.

Interosseal.

(150.) The *interosseal cartilages* pass from one bone to another, adhering firmly by their extremities to each. They answer the same purpose as would be attained by an increase of extent in one or both of the bones, with the further advantage of allowing of obscure degrees of motion, and deadening the effects of jars incident to percussion. The cartilages of the ribs are of this class. They are covered with perichondrium. When they have been steeped in water for a great many months, they are divisible into laminæ, of an oval shape, which are united by fibres passing obliquely between them.

Articular.

(151.) The *articular*, or *diarthrodial cartilages*, are those plates of cartilaginous substance which adhere firmly, and almost inseparably, to the surfaces of those bones which are opposed to each other in the joints, or over which tendons and ligaments slide. In some joints the whole of the surface of the bone within the capsular ligament is covered with cartilage; in others, only the parts of bones which move upon each other; the remaining part being covered with ligament. This latter disposition is met with in the joint of the hip. This kind of cartilage, like the others, appears perfectly smooth on its surface, and also when a section is made through its substance; but by a sufficiently long maceration, to allow of a commencement of putrefaction, its fibrous structure may be detected. The elastic resilience of these cartilages has a powerful tendency to lessen the shocks incident to sudden and violent actions.

Interarti cular.

(152.) Cartilages of a similar kind are found in the cavities of certain joints, and have hence been called *interarticular cartilages.* They have no immediate connexion with the bones forming the joint, but are attached only to the inside of the capsular ligament. They are thus rendered somewhat moveable, and being interposed between the bones, allow them a greater latitude of motion, while they at the same time contribute to adapt their surfaces more perfectly to each other. By long maceration in water, a laminated structure is more distinctly perceived in this kind of cartilage than in any of the others.

6. *Fibro-Cartilaginous Structures.*

(153.) Many structures exist in the human body which appear to be of an intermediate nature between ligament and cartilage, in which a fibrous texture is united to a cartilaginous basis, and which combines the characteristic properties of both these textures. They are distinguished from the purely ligamentous parts by their high degree of elasticity, and from cartilage by their fibrous texture. Accordingly we find them employed when this combination of properties is requisite for the functions of the parts. They form additions to interarticular ligaments, and eke out the borders of cavities adapted to the reception of the rounded heads of bones.

Interver bral sub stances.

(154.) The principal instances of large masses of fibro-cartilaginous structures occur in those which unite the bodies of the vertebræ and of the bones of the pelvis. These *intervertebral substances*, as they are termed, impart great elasticity to the spine; and diminish the effects of concussion. When the body has been long in the erect position, the weight of the head and upper parts of the trunk occasions the compression of these intervertebral substances, and the height of the person is diminished. By continuance for an equal time in a horizontal posture, this superincumbent pressure being removed, they recover their original dimensions. Hence a person is taller when he rises in a morning than after sustaining the fatigues of the day; and the difference of stature often amounts to a whole inch.

7. *Ligamentous Structures.*

Ligame tous sys tem.

(155.) Structures possessing inferior degrees of solidity, but still exhibiting structures of considerable density, are met with in the interior of the body, and serve various mechanical purposes of cohesion and support. Many of these may be regarded as mere modifications of membrane; but yet the peculiarities of structure and of properties exhibited by ligamentous textures point them out as requiring to be classed separately. Bichat, who has viewed them as composing a system of structures, has given to it the title of *the fibrous system;* a name which is liable to the objection of not being sufficiently distinctive; since, as we shall afterwards find, many other parts, and especially the muscles, are no less fibrous than the tendons and the ligaments. As a general designation of this class of fibres, we have therefore preferred the term of *ligamentous system*, which sufficiently expresses the general mechanical purpose which they are designed to serve in the animal economy.

(156.) This system includes a great number of structures, which, although very similar in their nature and office, have received different names, such as *ligaments, tendons, fasciæ, aponeuroses, capsules,* &c. Fibres of a similar kind to those which constitute these parts, also enter into the composition of other organs, imparting to them different degrees of mechanical strength.

(157.) Various as are the forms and dispositions assumed by ligamentous fibres, they present us with two principal varieties, according as they are expanded into thin and broad plates, or ligamentous membranes, or collected into thick and elongated cords. The first division includes fibrous membranes, fibrous capsules, tendinous sheaths, and aponeuroses.

rous mbranes.

(158). *The fibrous membranes* resemble ordinary membranes, but have, superadded to the structure of the latter, numerous denser fibres, which give them greater strength, and fit them for affording mechanical support to various organs. Thus the periosteum of the bones is a membrane of this description. The internal periosteum of the skull or *dura mater* has a similar structure. The external coat of the globe of the eye, or *sclerotica;* the investing membranes of many of the glands, as the kidneys, belong to the class of fibrous membranes; to which also we may perhaps refer some of the coats of the larger blood-vessels, and of the excretory ducts of glands. Besides enveloping organs, these fibrous membranes often extend into their interior, forming partitions, or even cells, which contribute to their firmness and support.

I ous c ules.

(159.) *The fibrous capsules* present the form of sacs, which surround certain joints, especially those of the shoulder and hip, and preserve the connexion between the bones which form these joints. These capsules, again, are lined internally by serous or synovial membranes, supplying the fluid which lubricates the surfaces of the parts playing upon each other.

S ths of te ons.

(160.) *The tendinous sheaths* are formed by fibrous membranes of a cylindrical shape, which surround the tendons in those parts where they pass over bones, and are particularly subjected to friction, or liable to occasional displacement during the action of the muscles which move the joint. Some of these include only one tendon in their respective cavities, as those of the fingers and toes: others receive several tendons, as those belonging to the muscles of the wrist and ankle joints.

A eu- ro

(161.) *Aponeuroses* consist of extended sheets of fibrous texture, principally belonging to the organs of locomotion; and disposed in some instances so as to form coverings of parts; while in others they constitute points of attachment to muscles. Thus they may be distinguished into aponeuroses for enveloping, and aponeuroses for insertion. The former, which are generally termed fasciæ, either surround the muscles of the limb, forming a general sheath for it, as in the fore-arm and thigh; or else they invest and confine some particular muscles. The aponeuroses for insertion either form broad or narrow surfaces, or consist of separate fibres, giving attachment to particular portions of muscles, or form arches, which both admit of their connexion with muscular fibres, and at the same time allow of the passage of vessels.

(162.) The second division composes the proper ligaments and tendons, all of which have more or less the form of cords.

Lig ents.

The *ligaments* connect together the articular surfaces of bones, and oppose a very considerable resistance to any force tending to their displacement. The fibres which enter into their composition, generally preserve a direction nearly parallel; but frequently they are extended in various ways, forming an intertexture calculated to resist extension in different directions; and from their mere flattened form, bringing these ligaments nearer to the description of fibrous membranes.

Tendons.

(163.) The *tendons* are generally more simple in their structure, consisting of elongated cords; but in some instances they are more complicated, being divided into several smaller cords.

Bichat's arrangement.

(164.) Bichat[1] has exhibited, in the following table, a general view of the preceding classification of what he calls the *fibrous system.*

- Fibrous organs,
  - In the membranous form.
    - Fibrous membranes.
    - Fibrous capsules.
    - Fibrous sheaths,
      - Partial.
      - General.
    - Aponeuroses.
      - For envelopment.
        - Partial.
        - General.
      - For insertion
        - In a broad surface.
        - In an arch.
        - In separate fibres.
  - In the form of cords.
    - Ligaments.
      - With regular fasciculi.
      - With irregular fasciculi.
    - Tendons.
      - Simple.
      - Complicated.

Albugineous fibre.

(165.) The structure of all these parts, as their name imports, is essentially fibrous; the individual fibres which compose them being exceedingly slender filaments of a very dense, firm, and inelastic substance; sometimes parallel to each other, as in the tendons and ligaments, and sometimes variously interwoven, as in the fibrous membranes. In some portions of the denser structures hereafter to be noticed, the fibres are so closely united as to present an almost homogeneous appearance; but in all the parts hitherto considered, the bundles of fibres admit of being separated by maceration; and are resolvable into lengthened filaments of extreme tenuity. It has not been perfectly ascertained what is the diameter of the fibres when this subdivision has been carried to its utmost limit; but they appear in this ultimate state of division to be as fine as the filaments spun by the silk worm. These ultimate fibres are distinguished by their flexibility, their extreme tenacity, and their brilliant whiteness. They are probably in no case tubular, but solid throughout, although Mascagni, extending to them his general system of organic textures, regards them as formed of lymphatic vessels. Chaussier,[2] with great appearance of truth, considers them as a peculiar and primary organic tissue, to which he has given the name of the *albugineous fibre,* in order to distinguish it from the mere simple cellular or membranous fibre, which constitutes the basis of the general substance of the body.

(166.) The fibres which enter into the composition of these ligamentous textures, are united by a cellular tissue of extreme fineness and tenuity, which is rendered evident after maceration when the ligamentous fibres are drawn asunder. Their arrangement at the surface of these structures is such as to produce that glistening and satin-like lustre which results from a surface of high polish and density; an appearance which is very characteristic of the fibrous structures. This smoothness and resplendent white colour is possessed in the greatest degree by tendons, which have in general a greater extent of motion than the ligaments, and therefore require a higher degree of polish.

Sect. III.—*Mechanical Connexions.*

1. *Articulation.*

Variety in the modes of connexion.

(167.) Having noticed the properties of those elementary textures that furnish those cohesive and resisting forces which are necessary for the mechanical purposes of the animal fabric, we have next to review those combinations of structure which have been adopted for establishing the connexions between the various parts of the frame, and which adapt them to those objects. These modes of connexion admit of great variety, according to the different mechanical relations which must take place between them; and more particularly with reference to the degrees of mobility which are to result from their union. In many cases the parts placed in juxtaposition require to be fixed in their places by the firmest bonds which can secure their relative immobility: in others, the freest motion must be allowed; while in various other instances, we find almost every intermediate degree of flexion allowed, and every kind of connecting mechanism employed. But from the deep implanting of the teeth in the jaws, like nails firmly fixed in wood, and the mutual locking in of the bones of the skull by indented sutures, like the dove-tailed junctions of carpentry, to the freely rotating joints of the limbs, as in those of the shoulder or the hip, we may trace various modes of articulation which are calculated to limit the extent and to regulate the kind of movements, in subordination to particular ends. There is certainly no part of the human fabric, wonderfully and fearfully as the whole of it has been made, which exhibits more palpable evidences of express mechanical contrivance and adaptation to specific purposes, than the construction of the joints, and of the whole of their auxiliary apparatus. It is well observed by Paley,[1] that every joint is a mechanical curiosity, and a proof of contriving wisdom. They are, indeed, as Cicero has truly expressed it, "mirabiles commissuras, et ad stabilitatem aptas, et ad artus finiendos accommodatas, et ad motum, et ad omnem corporis actionem."[2]

---

[1] See his *Anatomie Générale,* tom. iii. p. 142.

[2] *Dictionnaire des Sciences Médicales.* Organization.

Joints.

(168.) There are two circumstances which determine the kind of relative motion of which a joint, by which term is more particularly meant the connexions of adjacent bones, is capable. The first of these comprises the form of the contiguous surfaces of the bones themselves which are brought to play on each other, and their mode of apposition; the second relates to the structure and mechanical conditions of the interjacent flexible parts, such as the ligaments, the cartilages, and the membranes, which impart different degrees of elasticity or springiness, and variously modify the motions which result. With respect to the first, the principal diversities arise from the various extent of range allowed with regard to the planes of motion; and these varieties are naturally distributed under two heads; the one being a semi-rotatory motion within a considerable extent of a spherical surface, as exemplified in what are called the ball and socket joints; the other, in which the angular motion is restricted to a single plane, as is the case with what are termed the hinge-joints. It is not necessary here to advert to the further distinctions to which a minute examination of all the different modifications of these kinds of mechanism, which are exhibited in the solid structures of the body, would lead us; which the older physiologists pursued with great diligence, and which they were fond of dignifying with a formidable array of technical terms; a sufficient account of these now obsolete denominations having been already given under the head of ANATOMY in this work. It will be sufficient for our present purpose to observe, in general, that the long bones of the limbs have their extremities expanded so as to form broad surfaces where they are in apposition with the contiguous bones, between which a joint is formed. In the ball and socket joint, it is the moveable bone which has the rounded head, and the fixed bone, or that nearest to the trunk of the body, which contains the corresponding cavity or socket. Such at least is the case in man; but some animals present us with examples of a contrary arrangement; that is, of the concave surface of the moveable, turning on a convex projection of the fixed bone. Bones of a flat or irregular shape are, in general, much more limited in their motions, when they form joints, than those of a lengthened cylindrical form.

(169.) In proportion to the extent of motion allowed in the joint, we find provisions adopted for diminishing friction, and guarding against injury. In all the articulations the ends of the bones which enter into their formation, are invested with a smooth and polished plate of cartilage; a substance which, by its modified hardness, and great elasticity, is especially adapted to both these purposes. Its limited degree of organization, also, gives it many advantages in withstanding the influence of pressure, especially if suddenly made, and frequently repeated. In some joints this investing layer of cartilage is of equal thickness throughout, so that it appears as a crust, regularly moulded over the articular surface of the bone which it covers, and exactly preserving its figure; but, in other cases, it is found to be thicker at the middle than at the marginal parts; thereby increasing the convexity of the projecting portion, or diminishing the concavity of those which recede; both of which appear to be provisions for ensuring, as the case may be, the uniformity of contact of the adjacent parts composing the joint. These superficial articular cartilages, or "cartilages of incrustation," as they have been termed, appear to be composed of a multitude of slender fibres, strongly adhering together, and all of them being perpendicular to the tangential planes of the surface of the bone they invest, like the pile of velvet, and disposed, therefore, in a manner very similar to that of the fibres of the enamel of the teeth, which is superimposed in nearly the same way on the bony part of the tooth. The most complete investigation of this structure will be found in a paper of Dr. William Hunter's, published in the *Philosophical Transactions*.[3] It results from this conformation, that the fibres, on the application of pressure, yield to a certain degree, and bend in waves; just as happens to velvet when it is compressed; and they again resume their perpendicular positions on the removal of the compressing force.

Synovi capsule bursæ m cosæ, alar lig ments.

(170.) The whole of the interior surface of each joint is lined with a smooth and glistening membrane of great tenuity, forming a cavity closed on every side, and supplying a peculiar secretion, termed the *synovia*, obviously intended for the lubrication of all the contiguous surfaces. Similar *synovial membranes*, as they are called, forming, in like manner, closed sacs, are met with, surrounding the sheaths of the tendons, and interposed between other parts, the motions of which would expose them to considerable friction. In the former case, when employed in the articulations, they are termed *capsules* of the joints; in the latter, they have received the inappropriate name of *Bursæ Mucosæ*. The synovia is a transparent and viscid fluid, slippery to the feel, and capable of being drawn out into strings by the fingers. It has been imagined that the secretion is principally derived from certain fringe-like processes, chiefly visible in the knee and hip-joints, and constituting what have been called the *alar ligaments*. These membranous appendages, which project into the cavity of the joint, and appear to be formed by folds of the synovial membrane, containing some cellular substance, and small pellets of adipose matter, present an appearance very similar to that of the epiploic duplicatures of the peritoneum, and especially of the appendices epiploicæ of the colon.

(171.) The motions which a joint is capable of performing are often modified and extended by the interposition of detached plates of cartilage, connected only by ligament with the synovial capsule, and capable of shifting their position, so as to enlarge the range and modify the mode of action. Those which we have already described under the title of *interarticular cartilages*, are met with chiefly in those joints where the motion is frequent and considerable, and where the ends of the bones are subjected to great pressures; as in the junction of the lower jaw with the temporal bone, and in the knee-joint. The *semilunar* cartilages, in this latter example, increase the depth of the articular cavity, and ensure, in all the motions of the joint, a perfect adaptation of the surfaces to one another.

---

[1] *Natural Theology*.

[2] *De Natura Deorum*, l. ii. c. 35.

[3] For 1743, vol. 42, p. 544.

aments.

(172.) The bones are retained in connexion, their junction strengthened, and their relative movements farther regulated, by the ligaments which invest the joint. Of these there are two kinds, the *capsular*, and the *fascicular ;* the former investing the joint on all sides in the case of the ball and socket articulation; and the latter passing from bone to bone in different directions, limiting the motion more or less to a particular plane. When, in the hinge-joint, they are placed externally on the two sides, they form what are called *lateral ligaments ;* but in the case of the knee, additional securities are provided, by short and round ligaments, crossing one another in the interior of the joint; these are the *crucial ligaments*. Besides these, we often find other ligamentous bands, passing more obliquely, and dispersed in different directions, which assist in strengthening the joint, preventing the displacement of the bones, and thus completing the mechanical apparatus of each articulation. The muscles which surround the joint also contribute very powerfully in retaining the bones in their proper places, and preventing the sudden dislocations which might otherwise occur during the strains incident to rapid and violent actions.

2. *Package of Organs.*

kage of organs.

(173.) The great mechanical objects of adhesion and support being provided for by the organic systems we have now considered, our attention may next be directed to purposes of a subordinate and special nature, and which relate to local adaptations, comprehending what Paley has aptly termed the *package* of the organs. Art and contrivance have been as manifestly displayed in fulfilling these more limited objects, as in the more extended designs of the general fabric. When we consider the vast multiplicity of parts, which it requires the study of years of patient instruction and dissection to be thoroughly acquainted with, which are closely arranged and stowed in the narrow space allotted for them in the body, we cannot but be struck with the care that has been taken in their disposal in the most convenient manner, and with the greatest economy of room. The brain consists of a prodigious number of fibres, gathered together in curious folds, or convolutions, in order that they may occupy the smallest possible bulk, and be contained within the circumscribed cavity of the skull, which is to afford them protection. Within how small a compass are lodged all the delicate parts which compose the complex organ of hearing, and which are encased in a hollow space, scooped out of the most solid parts of those bones. Equal care has been bestowed in the lodgment and package of the viscera which occupy the other cavities of the body, namely, the thorax and abdomen. Those which are of greatest importance to life, and whose delicate texture admit most easily of being injured, are always placed in situations of greatest security, and effectual care is taken to provide additional protection by means of bones, cartilages, or other denser mechanical fabrics. All the organs are tied down and secured in their places by membranes, so adjusted in regard to breadth and flexibility, as to allow of those motions which their functions require ; or, in other cases, to restrain their displacement, by tightly binding them in their situations. All the important viscera are invested with coverings proper to themselves, composing capsules, which are generally of great density and strength, and calculated to give them effectual protection against pressure or other mechanical causes of injury. The muscles, which are in strongest and most frequent action, are firmly braced and tied down by sheets of fibrous tissue, inserted into the neighbouring bones, and preventing them from starting from their places when urged into sudden and violent contractions. Lastly, all the spaces intervening between the muscles, blood-vessels, nerves, and bones, are filled up with a quantity of cellular and adipose substances, sufficient to leave no vacuity. Hence arises that rounded and flowing outline which has been given to the body, and which forms one of the constituent elements of its beauty.

(174.) The provision of a general envelope to the whole of this complex system of organs, may be regarded as another consideration which appertains to the subject now before us, namely, the package of the body ; but its importance is such as to entitle it to be treated of under a separate section.

Tone, or tonicity.

(175.) This combination of structures, individually possessing different degrees of rigidity, but cemented together by a highly elastic medium, and bound down by a general envelope of considerable strength, produces a result, which, being of considerable importance with reference to the mechanical condition of the fabric, is deserving of special notice. It is matter of observation that the sum of the cohesive forces among the particles composing the mass of animal tissues, is balanced, in the living body, only by the resistance arising from the rigidity or incompressibility of the parts opposed to them ; or, in other words, the force of elasticity in the cellular and membranous textures is not in a state of neutrality, but the equilibrium is maintained only by the mechanical circumstances of situation. Thus it happens that, when these circumstances are altered, and the equilibrium disturbed, elasticity comes into play and produces a shrinking of the whole mass. The result is that, in the natural state, every part is kept on the stretch ; but retracts as soon as its elasticity is allowed to act by the removal of the extending cause. This will happen whenever the contents of hollow organs are withdrawn, whenever the parts themselves are divided transversely by a cutting instrument, and also when, by a change of position, their extremities are brought nearer together, and the mass assumes a more rounded figure. This property, the result of a high degree of unbalanced elasticity, has long been known, though described under various names. The term by which it has most frequently been designated is that of *tone* or *tonicity ;* but Bichat, who has given a good description of its effects, denominated it "contractilité de tissu" and "contractilité par défaut d'extension," whilst he regards tonicity as another and distinct property not of a mechanical, but of a vital nature. The observations we have formerly made on the vital properties, will show that we regard the distinction which he here makes as being founded on very questionable grounds.

SECT. IV. *The Integuments.*

1. *The External Integuments.*

Integument in general.

(176.) The skin, which gives covering to the whole body, together with its various prolongations and parts connected with it, and constituting altogether the *integuments*, are complex structures. They consist, in the first place, of ordinary cellular tissue ; secondly, of the same substance in a more condensed and membranous form ; and, thirdly, of a stratum of adipose substance ; but they also present us with a kind of structure which differs totally from any of those we have hitherto had occasion to notice. For the clear understanding of these distinctions, it will be necessary, first to explain in greater detail the composition of the external integuments, or the skin.

Structure of the skin.

The parts of which skin consists are arranged in layers ;

and in giving an account of these we shall take them in an order the reverse of that in which they are usually considered; beginning with the innermost layers, and proceeding successively to the more external.

Cutis vera, or corion.

(177.) That portion of the integuments which is called *the true skin*, is in most parts of the body separated from the subjacent muscles or bones, by a stratum of fat, or rather of adipose substance; that is, as we have already seen, of a cellular and vesicular structure, containing the minute globules of the fat. In other parts, the attachment of the skin is effected merely by interposed common cellular substance, of more or less thickness and density in different places. The succeeding layer is that which forms by far the largest portion of the integuments, and has been denominated *the corion*, or the *true skin*. Its ultimate structure is described by Haller as being analogous to that of membranous parts; that is, composed of a dense intertexture of short fibres and of plates, artificially interwoven together, and united by the close adhesion of their surfaces. It may in this view, therefore, be considered as merely a denser tissue of the common cellular substance, which is, in fact, the basis of most animal structures. This density increases gradually as we trace the texture from the inner to the outer parts; while at its interior surface it passes gradually into the looser cellular texture which is beneath it. Bichat gives a similar description of the essential structure of the corion, but states that, in addition to this, there are found a great number of dense fibres, of a whiter colour than the rest, interspersed throughout its substance, which pass in all possible directions, so as of themselves to compose a close net-work, and leave certain interstices or *areolæ*. This reticulated texture, with the interposed vacuities, may be discovered by long-continued maceration, which loosens the adhesion of the fibres. Small masses of fat are found occupying the intervals between them. Thus the dense fibres of the corion may be regarded as the chief support or skeleton, as it were, of the whole fabric, giving it its requisite form, consistence, and other mechanical properties.

Corpus papillare, and papillæ.

(178.) The external portion of the corion is more finely organized than the rest. It has been considered as forming a distinct layer of the skin, named by Bichat, from the large proportion of minute blood-vessels it contains, the vascular net-work; and by other anatomists, *corpus papillare*, from its presenting on its outer surface, when viewed with the microscope, an immense number of little eminences or conical projections, which have been termed *papillæ*. These papillæ were discovered by Malpighi, and have been since described and delineated by Ruysch, Albinus, and many other anatomists. Cheselden and others, however, have doubted their existence, at least as a necessary appendage of the corion; for papillæ are perfectly visible to the naked eye on the upper surface of the tongue, where they are presented on a very large scale. They are also easily perceived, with a magnifying glass, at the tips of the fingers, as well as in other organs endowed with a peculiar sensibility to impressions of touch. But in those parts of the body which have not the same sensibility, and are seldom employed as the vehicles of touch, they are so minute as scarcely to admit of detection; and their existence has been inferred rather from analogy than from distinct and positive observation.

Rete mucosum.

(179.) The external surface of the corion, or of the corpus papillare, is covered with a thin layer of a soft substance, which has been termed the *Rete Mucosum*. It was first observed by Malpighi, in the skin of the negro, and is hence often called after him the *Rete Malpighianum*. The structure, and even existence of this membrane have given occasion to much controversy. Malpighi had announced it as being a stratum of soft matter, disposed in the form of lines which crossed one another in various directions. Blumenbach and other anatomists describe it as merely a thin layer of pulpy matter, without any distinct reticulated structure. Bichat, on the other hand, denies altogether its existence as a proper membrane, and supposes that what Malpighi saw and described is merely a collection of very delicate vessels, which, after having passed through the corion, form a network on its surface. In this opinion he is supported by other anatomists of high authority, as Chaussier and Rudolphi. Mr. Cruickshank,[1] on the contrary, who has bestowed great pains on the examination of this subject, entertains no doubt of the existence of the rete mucosum, both in the external skin, and also even in some of its productions in the interior of the body. Dr. Gordon admits of the presence of the rete mucosum in the skin of the negro, where it is easily demonstrated; but asserts that it cannot be found in that of the European. On the whole, the positive evidence in favour of the real existence of this membrane appears to preponderate; and at any rate, it seems admitted on all hands, that the colouring matter of the skin, which is black in the negro, and has different tints in the other varieties of the human race, is situated in that part which has been assigned as the seat of the rete mucosum. By some it has been stated that the rete mucosum extends in a uniform layer over the whole surface of the true skin; by others that it is perforated in various parts by the papillæ of the corion, and exists only in the interstices of these papillæ.

Cuticle o
epidermi

(180.) The outermost layer of the skin is the *cuticle* or *epidermis*, which gives a uniform covering to every part of its surface, adhering closely to it, and being accurately applied to all its inequalities. It adheres with considerable tenacity to the subjacent skin, through the medium of the rete mucosum, and its attachment is perhaps also secured by fibres passing from the one to the other. In the dead skin a separation is easily effected by maceration in water, and by a state of incipient putrefaction. In the living body the cuticle is detached by the operation of a blister, or by scalding water, which produce an effusion of serous fluid on the outer surface of the corion. As the cuticle is impervious to this fluid, it is raised, and gives rise to a permanent vesicle.

(181.) When the cuticle is carefully separated from the corion, after its connexion has been loosened by putrefaction, a multitude of very slender transparent filaments are seen, stretching between these two layers, which are torn asunder when farther extended. Dr. William Hunter believed these filaments to be the terminations of those vessels which exhale the perspiration, and nearly the same views have been entertained with regard to their nature by Bichat and by Chaussier. Cruickshank, on the contrary, considered them to be processes from the cuticle, and not vessels.

(182.) Many erroneous notions have at different times prevailed with respect to the intimate structure of the epidermis. Leeuwenhoeck conceived that it is composed of a number of laminæ, or scales, which he represented as having an imbricated arrangement, that is, overlapping each other successively, like the scales of a fish. But it is now generally admitted that this was a deceptive appearance. The division of layers, which it may seem to admit of in parts where it is of unusual thickness, is merely an artificial separation, not warranted by any natural distinction of textures. Although some have pretended to discover in it a congeries of vessels, especially lymphatics, yet the most accurate and unbiassed observers declare that they cannot perceive in the epidermis, a specific texture of any kind or any regular arrangement of its parts. Dr. Gordon gives it as his decided opinion that it is "truly inorganized, and non-vascular."

---

[1] *On Insensible Perspiration.*

es.

(183.) Leewenhoeck imagined also that he could discern a number of perforations, or pores, as he termed them, in the cuticle. But later and more scrupulous inquirers have looked in vain for these supposed pores; and it is now generally admitted that none such exist. Indeed, one of the most characteristic properties of the cuticle is its impermeability to fluids, under ordinary circumstances. The latest inquiries into this subject are those of Mr. Chevalier, who describes the cuticle as composed of an infinite number of small *velamina*, regularly arranged, so as to form a bibulous and exquisitely hygrometrical covering.[1] The mode in which the occasional transmission of fluids through this substance takes place in cutaneous absorption, and perspiration, will be the subject of future discussion. The only real distinguishable pores in the cuticle are those which give passage to the hairs, and to the sebaceous follicles hereafter to be noticed.

Thus, then, there is presented to us in this layer of the integument, a kind of structure differing essentially from either the cellular or membranous tissues which have already been described. The epidermis is an animal texture, nearly homogeneous in its substance, possessing but a moderate degree of extensibility, and approaching to the nature of an inorganic substance, inasmuch as it exhibits no appearance of vascularity, and a total absence of nerves, or other medium of connexion with the living system. Bichat even considers its vitality as exceedingly obscure; he doubts whether it can be said to possess life; but is inclined to regard it as a semi-organized, or rather inorganic body, placed by nature at the point of communication between external dead matter and the living skin, and serving as a gradation between them.

Na

(184.) The nails and the hair are to be classed as structures very similar to the epidermis, of which, indeed, they are often regarded as mere appendages. The nails, in particular, have so intimate an adhesion to the epidermis, that both are generally detached together, by maceration. They consist of hard, transparent, and semi-elastic plates, formed of a substance analogous to the horns of animals. They adhere to the subjacent corion, (which is in those parts furnished with a great abundance of minute blood-vessels, and of which the papillæ are arranged in longitudinal and parallel rows, very close to one another,) in a manner similar to that in which the epidermis adheres to the corion in other parts. The internal surface of the nail is soft, pulpy, and marked with longitudinal grooves corresponding to the lines which they cover and enclose; and by this mutual adaptation the connexion between them is extremely intimate. The innermost edge of the nail is received into a groove formed of a duplicature of skin fitted for its reception. The epidermis belonging to this portion of skin is folded back upon it, and on arriving at the root of the nail, quits the corion, is reflected over the external surface of the nail, and becomes identified with its substance.

The nails, in all their mechanical properties, correspond to the cuticle, and may be regarded as the same substance in a greater state of condensation.

Ha

The hair consists of slender filaments, which appear to be formed of nearly the same substance as the nails, and may be considered, in a mechanical point of view, as still more condensed forms of cuticle. Each hair is provided at its root, with an expanded portion, or bulb, from which its extension proceeds, and which, by the intervention of its vessels, connects it with the corion, in which it is imbedded, just as the roots of a vegetable attach it to the soil. The strength of hair is exceedingly great, compared with its small diameter, as has been frequently ascertained by trying the weights which it can support without tearing. There is no substance, indeed, which would be better adapted for making ropes than human hair, provided it could be procured of sufficient length. It scarcely possesses any extensibility, and is consequently inelastic. If exposed to moisture, it imbibes a certain quantity of water; and this absorption is accompanied with an increase in the length of the hair. From its having this property, it has been employed by De Saussure as a hygrometer, or instrument for indicating the degree of moisture or dryness of the atmosphere. In order to adapt it to this purpose, however, it requires to be freed from a quantity of oily matter, which it naturally contains, by maceration in an alkaline solution. The colouring matter of the hair is supposed to correspond in its nature, as it does in its appearance, to that which is contained in the rete mucosum of the skin.

Thus we find that there is a very considerable similarity between the hair, the nails, and the cuticle, with regard both to structure, composition, and mechanical properties; and that they may be regarded, when once their formation has been completed, as equally devoid of vascularity, and as possessed of the lowest degrees of organization and vitality; if, indeed, these latter properties can at all be attributed to them.

2. *Of the Internal Integuments, or the Mucous Membranes.*

Mucous membranes.

(185.) The structure which characterises the external integuments, is continued in various places into the internal parts; and is found, with certain modifications, in all those membranes which line the internal surfaces of cavities or channels having an external opening. This is the case with the whole track of the alimentary canal; including the mouth, pharynx, œsophagus, stomach, and intestines. It is exemplified, also, in all the passages of the air in respiration, as the nostrils, larynx, trachea or wind-pipe, bronchia or air tubes, and the air vesicles of the lungs. All those passages which open externally, such as those of the ears, urethra, and vagina, are likewise defended by a lining of mucous membrane.

(186.) Bichat has considered the mucuous membranes as forming a distinct system of structure. Analogous in many respects to the serous membranes, they present, in others, the most marked differences. They agree in their office of affording protection to the organs to which they are attached; and their structure, in as far as it is chiefly resolvable into condensed cellular tissue, is very similar. But as they have to serve the additional office of defending the parts which they invest against the irritating qualities of the substances that may come in contact with them, and which may be either the external air or the food, or extraneous bodies, received from without; or else secretions formed by the internal organs, which are to be conducted to the surface, it was necessary that the fluid which covered them should have properties adapted to this object.

Mucous secretions.

(187.) We find, accordingly, that instead of the watery liquid which exudes from serous membranes, the mucous membranes prepare a secretion containing a large proportion of mucus. Hence a more complicated structure is required in the mucous than in the serous membranes. They are divisible into several layers; that which connects them with the parts surrounding the passage or cavity which they line, is of a denser structure; while the one which forms the inner surface of the cavity is softer, and somewhat pulpy in its consistence. Its surface is beset, in many parts, with numerous minute processes, or *villi*, as they are termed. Villi.

---

[1] *Lectures on the General Structure of the Human Body*, p. 133.

These have been supposed to bear some analogy to the papillæ of the corion; and the general correspondence of the structure of the mucous membrane and of the external integuments has been farther pursued in the examination of the fine pellicle which gives an universal covering to the pulpy portion, and which has been assimilated to the cuticle. There can be no doubt that the cuticle belonging to the skin is continued over the membranes which line many of the passages above enumerated, and may be traced for a considerable way in those passages. As we advance farther, this cuticular covering becomes gradually thinner, till it ceases to be perceptible.

Crypts, or follicles.

(188.) But the circumstance which more especially characterises the mucous membranes, is the presence of a number of small cavities, *crypts* or *follicles* as they are called; which have more or less of a spheroidal shape, and which open upon the surface of the membrane by a distinct orifice, or duct of communication. These minute sacs or follicles are themselves lined with an extremely fine cuticular membrane, derived from the general covering of the surface on which they are met with. They are found filled with mucus, and are therefore considered as the sources whence that secretion is principally derived.

(189.) Follicles of a similar structure are found in the various parts of the skin; but the substance which they produce, and which they effuse upon the surface of the skin, is more of an oily, than of a mucous nature. It has been termed *sebaceous matter;* and the small cavities which prepare this matter, are known by the name of the *sebaceous glands* or *follicles.*

Sebaceous secretion.

(190.) Thus it appears, that although the offices of the external integuments of the internal mucous membranes are sufficiently distinct, yet a general analogy exists between them in many points of their structure, sufficient to justify their being arranged under the same order, in a general classification of animal structures.

SECT. IV.—*Muscular Action.*

(191.) Having now considered the system which constitutes the passive instruments of the fabric, it is time that we direct our attention to the active powers which are the sources of motion, and the springs of animation and of energy in the living body.

(192.) As in an extensive system of machinery, economy is best consulted by the employment of a single moving power, such as a fall of water, the impulse of the wind, the current of a river, or the force of steam, so, in the animal economy, nature has provided the muscular power, and applied it in every instance where great mechanical power was required to accomplish the intended object. But before inquiring into the nature of this new animal power, it will be necessary to consider the properties of those organs, the muscles, in which this power appears to reside.

1. *Structure of Muscles.*

Structure of muscles.

(193.) *Muscles* are organs composed of certain fibres, endowed with a peculiar power of contracting in their length, under certain circumstances. These fibres are generally disposed in a parallel direction, and variously united together by intervening cellular substance. The muscular system forms a large proportion of the weight, and certainly the greater part of the bulk of the human body.

Fasciculi of fibres.

(194.) On examining the structure of a muscle, we find the minuter fibres are every where surrounded by a fine cellular texture, which connect them together into bundles, which have been called *fasciculi.* These bundles are connected to each other by coarse cellular membrane, so as to form fasciculi of larger size: these, again, are united together into still larger fasciculi by a still more loose cellular tissue. This system of package is continued until we arrive at large cylindrical bands of fibres, which have been termed *lacerti*, and which, being applied laterally to each other, and covered by a general investment of membrane, compose the entire muscle. The fasciculi, as well as the cellular membrane, are coarser in some muscles than in others. Thus they are thicker in the large muscles of the limbs, than in the delicate muscles appropriated to the eye, and other organs of sense. The structure which has now been described is easily discovered in a portion of muscle which has been cut transversely, and then boiled for some time, or macerated in alcohol.

Ultimat structur Observ- tions of Leewen eck.

(195.) Physiologists have not contented themselves with these general views of the structure of muscles, but have been solicitous to ascertain the nature and dispositions of the ultimate fibres to which muscles owe their characteristic properties. The microscope has been resorted to for this purpose; but the success of those observers who have trusted to this instrument in establishing any certain facts, has by no means corresponded with the diligence and zeal with which they have engaged in the inquiry. We find in this, as in many other subjects where the appearances resulting from the employment of very high magnifying powers are the objects of research, that the greatest discordance prevails among the accounts given by different observers. Leewenhoeck, who was one of the first who applied the microscope to the investigation of the intimate structure of organized bodies, but who was too often led away from the truth by the ardour of his imagination, describes the ultimate muscular fibres, or those which admit of no further mechanical division without a separation of their substance, as being almost inconceivably minute. He states them to be many thousand times smaller than a fibre which would only be just visible to the naked eye. He represents them as cylindrical in their shape, and parallel to each other, but pursuing a serpentine course. He remarks that they are of the same figure in all animals, although differing considerably in their diameter in different animals, and that without any relation to the size of the animal. He observed, for example, that the fibril of the frog was larger than that of the ox.

Of Muy

(196.) Muys, a Dutch anatomist, who was engaged for a period of twenty-five years in the most laborious researches on this subject, arrived at a very different result from Leewenhoeck; for he concludes that the real ultimate fibrils of muscles are in all cases, even when the comparison was extended to animals, exactly of the same size.

Of Pro chaska.

(197.) Among the more modern anatomists, Prochaska[1] has bestowed the greatest care in the examination of this subject; and his account has every appearance of being entitled to our confidence. He states expressly that the muscular fibrils are not all of the same diameter, but differ in different animals, and even in different parts of the same animal. Each individual fibril, however, when carefully separated from all extraneous matter, is of uniform thickness throughout its whole extent, and perfectly continuous, even in the longest muscles, from one end to the other. He confidently asserts that they are solid; and instead of being cylindrical, that they have a prismatic, or polyhedral shape, generally flattened, or thicker on one side than on the other; a transverse section of the muscle thus presenting the appearance of basaltic columns in miniature. Their diameter is stated to be about the fiftieth part of that of the globules of the blood. Their surface was found to present a number of depressions or wrinkles; a circumstance which gives them a serpentine appearance. These transverse lines he attributes to the numerous blood-vessels, nerves, and membranous bands which cross the fibrils at different points.

Of Ho Swamm dam,

(198.) According to Hooke and Swammerdam, the musowper, uart, relli, and ntana.

---

[1] *De Carne Musculari.*

cular fibrils are composed of a series of globules. Other physiologists, such as Cowper and Stuart,[1] whose observations appear to have been influenced by preconceived theories, imagined that they were cellular. Borelli,[2] who was also biassed by his favourite hypothesis, believed them to be composed of a series of rhomboidal vesicles. The Abbé Fontana[3] in general agrees with Prochaska in his representation of muscular fibrils. He remarks that they are furnished with transverse bands at regular intervals, and that they may always be distinguished by their parallel disposition from the fibres of membrane, which are more or less contorted.

Carlisle.

Sir Anthony Carlisle[4] states that a muscular fibre duly prepared, by washing away all adhering extraneous substances, and viewed by a powerful microscope, appears to be a solid cylinder, the covering of which is a reticulated membrane, and the contained part, a dry pulpy substance, irregularly granulated, and of little cohesive power when dead.

Bauer, wards,

(199.) Mr. Bauer,[5] who is one of the latest authorities on this subject, represents the ultimate muscular fibrils, as composed of a row of globules, exactly corresponding in size to those of the blood when deprived of their colouring matter; that is, about the five-thousandth part of an inch. By long maceration in water, he finds that the mutual cohesion of these globules is loosened, and the fibre is consequently broken down and resolved into a mass of globules. The general results of Mr. Bauer's observations were confirmed by various observers in France, such as Dr. Edwards, and by Messrs Prévost and Dumas, Béclard and Dutrochet.

Hodg. Lister, Skey.

(200.) On the other hand, the more recent, and apparently accurate researches of Dr. Hodgkin and Mr. Lister,[6] and subsequently those of Mr. Skey,[7] have clearly shewn that the supposed globular structure of the muscular fibre is a mere optical deception, arising from deficient defining power in the microscope employed; and that the fibre is continuous throughout its whole length, and sometimes marked by transverse striæ, which occur at intervals much smaller than the diameter of the fibre itself. They have also pointed out this circumstance as constituting a remarkable distinction between the muscles of voluntary and those of involuntary motion, with regard to this striated structure; for it is only the fibres of the former which are characterized by innumerable very minute, but clear and fine parallel lines, or striæ, which cross the fibre transversely. Mr. Skey concludes from his researches, that these fibres in man have an average diameter of one four-hundredth of an inch, and that they are surrounded by transverse circular striæ varying in thickness, and in the number contained in a given space. He describes these striæ as constituted by actual elevations on the surface of the fibre, with intermediate depressions, considerably narrower than the diameter of a globule of blood. Each of these muscular fibres, of which the diameter is one four-hundredth of an inch, is divisible into bands or fibrillæ, each of which is again subdivisible into one hundred tubular filaments, arranged parallel to one another in a longitudinal direction, around the axis of the tubular fibre which they compose, and which contains in its centre a soluble gluten. The partial separation of the fibrillæ gives rise to the appearance of broken or interrupted circular striæ, which are occasionally seen. The diameter of each filament is one sixteen-thousandth of an inch, or about a third part of that of a globule of the blood. On the other hand, the muscles of involuntary motion, (or as Bichat would term them, of *organic life)* are composed, not of fibres similar to those above described, but of filaments only; these filaments being interwoven with each other in irregularly disposed lines of various thickness, having for the most part a longitudinal direction, but forming a kind of untraceable net-work. They are readily distinguishable from tendinous fibres, by the filaments of the latter being uniform in their size, and pursuing individually one unvarying course, in lines parallel to one another. The fibres of the heart appear to possess a somewhat compound character of texture. The muscles of the pharynx exhibit the character of the muscles of voluntary motion; whilst those of the œsophagus, the stomach, the intestines, and the arterial system, possess that of the muscles of involuntary motion. The determination of the exact nature of the muscular fibres of the iris, presented considerable difficulties, which Mr. Skey was not able satisfactorily to overcome.

2. *Muscular Contractility.*

(201.) The proper muscular fibre is so completely surrounded by cellular membrane, and is of so small a diameter, that it is scarcely possible to determine with accuracy its physical properties, independently of those of the tissue in which it is imbedded. The contractile power with which it is endowed, can be studied only as its effects are exhibited by collections of fibres, such as those which constitute the muscles; although in these it must obviously be combined with the elastic power of the cellular texture entering into its composition.

Muscular action.

(202.) It will soon be evident, however, that the property by which the muscular fibre is eminently characterized, is that of suddenly contracting in its length, and thus of bringing the two ends of the muscle, and the parts to which those ends are attached, nearer to each other. This contraction is produced with astonishing quickness and force, overcoming considerable resistances, and raising enormous weights. It is generally the effect of the will of the animal to move the parts to which the muscle is attached; but it may also be excited by other causes. The agent which thus produces muscular contraction is called a *stimulus.*

Stimuli.

(203.) Under the appellation of stimuli, are included many things which seem scarcely to have any property in common, except that of acting upon the muscular fibres, either directly, or through the medium of the nerves which supply them. The contact of many bodies will produce this effect by mere mechanical impulse, independently of any other quality they may possess. Whatever occasions a mechanical injury to the texture of the muscle or nerve, or an actual breach of substance, such as the puncture, division, or laceration of the fibres, will immediately excite muscular contraction. This effect also results from the application of any substance exerting a chemical action on the part; a class of stimuli which comprehends a great variety of agents, such as acids, alkalies, and most of the salts which they form by their mutual combinations, as also the earthy and metallic salts, alcohol, the volatile oils; and above all, oxygen, either in the form of gas, or when contained in substances that part with it readily. Even water itself seems to have some corrugating power when it is applied directly to the muscular fibre; its action, however, is much increased by minute quantities of salt which it may hold in solution. Thus it is found that hard water promotes the contraction of the muscles of fish that have been crimped more than fresh water; and a similar difference of effect is often observed in boiling meat in soft or in hard water.

(204.) But besides these, there are several of the vegetable and animal products which, when applied to the body, produce muscular contraction by an agency which cannot clearly be traced to any chemical property they possess. This class of stimuli includes a variety of substances which are denominated *acrid*, and others which are called *narcotics*, because when largely applied they destroy altogether the power of contraction, and soon extinguish life. As an example of this latter class, we may take opium and hydrocyanic acid.

[7] *Philosophical Transactions* for 1837, p. 371.

(205.) Some particular muscles have a disposition to be acted on more especially by particular kinds of stimuli. Each stimulus applied to the body generally, appears to exert a particular influence upon certain parts of the system which are predisposed to be affected by it, while on other parts it appears to be wholly inert. Thus emetic substances act principally on the stomach, even when applied to a different part of the system; and cathartic substances act specifically on the intestines. The muscular fibres of the heart are more particularly excited to contraction by the influx of blood into the cavities of that organ; and, in like manner, every system of muscular fibres concerned in carrying on the vital functions, has a specific disposition to be affected by its appropriate stimulus.

(206.) All the muscles which move the joints of the limbs, and the several parts of which the skeleton is composed, together with several muscles attached to the softer parts, such as the eye, tongue, and throat, are excited to contract by the stimulus of the will, and are therefore called *voluntary muscles.* They compose a class by themselves, as distinguished from those muscles which are not under the control of volition, and which are therefore involuntary muscles, such as the heart, stomach, intestines, and blood-vessels. The nature of this distinction, and of the different laws under which each class of muscles act, will be afterwards pointed out, when we come to treat of the physiology of the nervous system.

Relaxation

(207.) The natural state of a muscle, or that in which it exists when not acted upon by any external cause, is relaxation. When contracted, its surface, from being smooth, becomes furrowed, its middle portion swells out, and grows exceedingly hard and firm, while the extremities are drawn nearer to each other, so that the muscle is now both thicker and shorter than it was before.

Change of specific gravity.

(208.) It has been frequently made a question whether the increase of thickness exactly compensates for the diminution of length. This point might be determined by ascertaining whether the specific gravity of a muscle undergoes any alteration during this change. Glisson had inferred from some experiments which he had made on this subject, that the bulk of a muscle is, on the whole, diminished when it is in a state of contraction. Sir Gilbert Blane,[1] on the contrary, inferred from experiments which he made on fishes confined in a glass vessel with a very slender neck, that the absolute bulk, and of course the specific gravity, of their muscles remains the same whether they are contracted or relaxed; for the level of the water in the narrow stem of the vessel was observed to be unaffected by the muscular exertions made by the fish. Mr. Mayo, by an experiment of this kind on the heart of a dog, found the bulk of that organ unchanged during its contraction or relaxation.[2]

Exhaustion

(209.) The long-continued, or frequent application of a stimulus to a muscle, tends to impair its power of contracting, or, in other words, to exhaust its irritability. This liability to exhaustion is exemplified by all the muscles that are under the controul of the will. We cannot continue to exert the same muscle, or set of muscles, with the same degree of power beyond a certain time, however strong may be the motive to continue that action, and whatever mental effort we may make to persevere. If, for example, we extend the arm in a horizontal line, with a weight held in the hand, we shall find, in the course of a few minutes, that the source of fatigue becomes intolerably acute; and the arm at length drops from mere exhaustion, in spite of every voluntary effort.

Elongatio

(210.) The contraction of a muscle ceasing on the removal of the stimulus that produced it, relaxation succeeds, and the muscle becomes again elongated; not, however, in consequence of any inherent power of elongation, but from the operation of causes which are extraneous to it. The elasticity of surrounding parts is often sufficient to produce this effect; but in most cases the elongation of the relaxed muscle is the consequence of the action of other muscles, which produce motion in a contrary direction. Almost every muscle has another corresponding muscle, or set of muscles, which are antagonists to it. If the one, for instance, binds a joint, the antagonist muscle unbinds or extends it; and by this action must elongate the former muscle.

(211.) The swelling of the muscles of the limbs, when they are in strong action, is matter of familiar observation. It is this circumstance, above all others, which renders a knowledge of anatomy so essentially necessary to the painter and the sculptor. In every attitude and in every movement of the body some particular set of muscles are in action, and consequently swelled and prominent, while others are relaxed and less conspicuous; and unless these differences were accurately noted and faithfully expressed, it would be impossible to give a correct representation of the living figure.

Variatio in the di position the fibres

(212.) Although the fibres which compose the smaller portions of a muscle are arranged in parallel directions, yet the disposition of the mass of fibres, relatively to the whole muscle, varies considerably according to the action which the muscle is intended to perform. We find them, in some cases, radiating from, or converging to a particular point; and sometimes we even find that the different portions of a muscle having this structure can act independently of the rest. The temporal muscle is an instance of a muscle of which the fibres converge from the circumference to a central point, where they are inserted into the coronoid process of the lower jaw. In other cases the fibres composing the muscle pass in a circular direction so as to close upon some organ which they surround, or to compress the bodies they enclose. Thus the eye and the mouth are closed each by a circular or orbicular muscle. In other parts, muscles of this description are called *sphincters.* Some parts, as the iris, are provided with both radiating and circular fibres, the one used for dilating, and the other for contracting the central aperture. We meet with a circular arrangement of muscular fibres in the coats of the various pipes and canals of the body, such as the blood-vessels generally, and also the alimentary passages; and together with these circular fibres are also often found bands of longitudinal fibres, which shorten the tube, while the former tends to contract its diameter, and press upon its contents. The several hollow receptacles for fluids, such as the heart and the stomach, present us with a still greater complication in the arrangement of their muscular fibres, in which we may sometimes trace layers of fibres having a spiral course.

Sphincte

Tendon

(213.) But it very frequently happens that the action of a muscle is wanted when its presence would be exceedingly inconvenient. The common medium of connexion employed by mechanicians, when the object to be moved is at too great a distance to admit of the direct application of the power, is that of a rope or strap. In the animal machine the same purpose is effected by means of tendons, which are long strings attached at one end to the muscle, and at the other to the bone, or part to be moved. If the muscles by which the fingers are bent and extended, for instance, had been placed in the palm or back of the hand, they would have enlarged that part to an awkward and clumsy thickness, which would not only have destroyed the beauty and proportion of the organ, but have impeded many of its uses as an instrument. They are therefore disposed at the arm, even as high up as the elbow, and their tendons pass along the joints of the wrist, to be affixed to the joints of the fingers they are intended to move.

---

[1] *Phil. Trans.* for 1805, p. 22, 23.

[2] *Anatomical and Physical Commentaries*, p. 12.

(214.) The employment of tendons also reduces the space which would have been necessary for the direct insertion of the muscular fibres in a bone, so that the same bone may be acted upon in a great variety of ways, by means of the tendons attached to it proceeding from a great number of muscles.

nniform
scle.

(215.) Another advantage resulting from the employment of tendons is, that by their intervention a great number of fibres are made to act in concert, and their united power is concentrated upon one particular point. In this respect, also, they resemble a rope, at which a great number of men are pulling at the same moment, by which means their combined strength is brought into action. These tendons are variously disposed with respect to the muscular fibres to which they are attached. It is but in a few muscles that the fibres are arranged in a perfectly longitudinal direction. We often find them covered on both sides with a tendinous investment, the muscular fibres proceeding obliquely from the one to the other. This arrangement forms what is called a penniform muscle, which may be either single or double. The structure is frequently even more complex than this, a number of tendinous layers being interposed among the fleshy fibres. By means of tendons a different direction may also be given to the moving power, without altering its position. There are many instances of this employment of tendons, in which they are made to pass through a loop, which serves as a pulley, an expedient which is adopted in one of the oblique muscles of the eye.

(216.) We have already seen, that wherever friction takes place by the motion of tendons over bones, or other hard parts, a bursa mucosa is interposed, which obviates in a great measure the injurious effects that would otherwise result from the rubbing of the parts.

chanical
tations

(217.) But although it be true that the force with which muscles contract is very great, yet the extent to which they are capable of exerting that force is in general very limited, and would be insufficient for most of the purposes their contraction is intended to serve, unless it were very considerably enlarged by mechanical expedients. In the practice of mechanics we find a variety of contrivances had recourse to for attaining this object; namely, the production of a great extent of motion, by a power acting through very limited space. But most of these devices would not answer in the human body, from the inconvenience which would attend their application. We find that nature has solved this problem in the simplest possible manner. In the first place, the tendons are inserted into the bones they are designed to move, very near to the centres of motion, so that a small extent of contraction in the muscle will produce a great range of motion at the other extremity of the limb. The principle is here obviously that of what mechanicians have termed a lever of the third class, namely, that in which the power is applied at some point intermediate between the fulcrum and the weight to be raised, or resistance to be overcome. Secondly, the direction of the power so applied, with reference to the line connecting the point of application and the centre of motion, or what is termed the radius of rotation, is oblique; that is, it forms with it an acute angle. Here again we may perceive another cause of the increase of motion, obtained by a smaller extent of contraction above that which would have resulted if the power had been applied at right angles to the radius of rotation, which is obviously the most advantageous mode of employing that power, when the object is to economise it, by giving it the greatest mechanical advantage. It must happen, indeed, by such a disposition of the force, that a large portion of it is lost, being spent on a fixed obstacle, namely, on the bone of the joint, against which the pressure is exerted; but the quickness and velocity of the motion that results are undoubtedly increased. Thirdly, the muscular fibres are themselves obliquely disposed with respect to the tendons, so that the same cause operates in a similar manner here also. Lastly, pairs of muscles are placed so as to form an obtuse angle with one another, and are made to contract at the same time. Their actions, therefore, will partly concur, and partly oppose one another. They will conspire to produce a movement in the parts to which their extremities are attached, in a direction intermediate to that of the muscles themselves; for it is a fundamental law of dynamics, that when a body is urged by two forces inclined to each other at any angle, it will move as if it were urged by a force in the direction of the diagonal of a parallelogram, having for its sides lines corresponding in their direction and their lengths to the directions and relative intensities of the two component forces.

Loss of
force.

(218.) In all these cases it is evident that there must be a great loss of force; but when the muscular power is concerned, we almost always find that strength is sacrificed to convenience, and that construction adopted which unites in the whole the most advantages. We must allow, that the muscular power is turned to the best account when it is made to perform in the completest and quickest manner the intended motion. We find, in following the mechanism not only of the joints of the limbs, but of the whole system of organs, both internal and external, that the mode in which this force is applied is diversified in every possible way. Its combinations are varied, and its action modified beyond calculation, though the original power be still essentially the same, and observes the same laws in its action.

Source of
muscular
power.

(219.) The source of that enormous mechanical power which seems to be an inherent property of the muscular power, has long been sought for by physiologists; but it has always continued to elude their most patient and laborious researches. It was at one period a favourite subject of speculation to devise hypotheses as to mechanical arrangements of particles capable of producing results similar to those of muscular contraction. Borelli[1] conceived that each muscular fibre might be composed of a series of minute bladders, or vesicles, of a rhomboidal figure. Stuart supposed that these vesicles were round. But on either hypothesis they were conceived to be empty, while the muscle remained in its natural state of relaxation. On the sudden introduction of a fluid of some kind into these vesicles, their sides would be separated, they would become distended, and assuming a more spherical form, would consequently be shortened in their longitudinal diameter; and as this shortening would take place simultaneously in all the vesicles, the whole muscle would be contracted in its length, and at the same time proportionally dilated in its breadth. The contrivance had certainly the merit of ingenuity, inasmuch as it explained the swelling of the muscle as well as its shortening, in the act of contraction. But it evidently will not bear the test of serious examination. No such structure as is implied in the hypothesis has ever been rendered visible to the eye, however dexterously the microscope may have been applied to the muscular fibre; nor can we find any power sufficient to propel so large a quantity of fluid as would be required for the distension of the vesicles; an effect also which, in order that the theory may correspond with the phenomena, must be produced almost instantaneously The resistance that would be opposed to the entry of a fluid so propelled would be incalculable, and incomparably greater than that exerted by the muscle itself, which latter force, it may be observed, it is the professed object of this theory to explain. The hypothesis itself, therefore, on which the theory is built, involves a greater difficulty than the simple fact. Such, indeed, was a very common mistake in the speculations of the earlier philosophers, who were ever prone to theorize without having any legitimate basis for the formation of a theory; their foundations being often more in need of support than the superstructure they attempted to raise upon it. It reminds us of the Indian fable of the world being carried on the back of an elephant, whilst the elephant was supposed to require a tortoise for its own support.

---

[1] *De Motu Animalium.*

(220.) The hypothesis that the fibres of muscles have a spiral shape, and pass in a contorted line from one end of the muscle to the other, like the turns of a corkscrew, a form which readily admits of elongation or contraction, according as it is more or less contorted, is quite as unsatisfactory as the former; and equally open to the fundamental objection, that it leaves the original source of motion still unexplained. Muscular power, indeed, does not appear, from what we hitherto know of its laws, to bear any close analogy to any of the other great principles in nature, which we recognize as original sources of mechanic force; and until such analogy can be traced, all our endeavours to explain the phenomena of muscular contraction must be fruitless.

(221.) It was a favourite notion with the physiologists of the seventeenth century, that an effervescence was excited in the interior of the muscle, by some chemical operation; such as a mixture of acid and alkali. Willis and others ascribed muscular contraction to a fermentation occasioned by the union of the particles of the muscle, with a supposed nervous fluid, or ethereal spirit contained in the blood.

(222.) But in fact, the only power in nature to which irritability can be compared in the quickness and suddenness of its variations, as well as in its dependence on peculiar qualities of matter, is electricity, and more particularly that form of electricity which constitutes galvanism. Attempts have accordingly been often made, since the phenomena of galvanism have engaged so much attention in the philosophic world, to explain muscular contraction by means of this principle; and endless have been the fanciful hypotheses invented for this purpose. Each muscular fibre was at one time considered as performing the office of a separate Leyden jar, charged with opposite electricities on its exterior and interior; whilst the filament of nerve which penetrated into its substance was the conducting wire, that occasioned the discharge of the jar. After the discovery of the voltaic pile, it was immediately conceived that an arrangement corresponding to the plates of the pile, existed among the particles of nerve and muscle, thus composing a galvanic apparatus, ready to discharge itself when the proper communications were effected. The latest hypothesis of this kind, is that of Prévost and Dumas, who conceived that the muscular fibre was thrown, during its contraction, into serpentine flexures, in consequence of the attractions of electrical currents, passing in similar directions through minute filaments of nerves, the directions of which were at right angles to the axis of the fibres. But in the present state of the science, all these analogies are far too vague and remote to serve as the foundation of any solid theory.

(223.) It has been the fashion among some physiologists to consider muscular contraction as only a particular mode of attraction, and as included in the general law of attraction which subsists among all the particles of matter; but this is a generalization totally unwarranted by the phenomena. Others have maintained that contractility is to be ascribed to the attraction of life, and to be merely a modification of vitality. Thus, Girtanner imagined that this property resided even in the living fluids, and was co-extensive with organized nature. This, however, is equivalent to the assertion, that the phenomena requires no explanation at all; for it certainly leaves the question just where it was before. We already knew that the effect of muscular power indicated a peculiarity to the nature of that power, for they appeared different from any other. To say that it is a peculiar modification of the power of life, gives us therefore no new information, unless it be meant that it is similar in its nature to the other powers which the living organs exhibit; but it would, in that case, convey an erroneous idea, because, the phenomena themselves being different, cannot, according to the rules of legitimate induction, be ascribed to the same physical cause. We have already pointed out the fallacy of this mode of reasoning, in which final causes are confounded with physical causes, and substituted for them as philosophical explanations of phenomena.

Cohesiv force, an tonicity.

(224.) There is, unquestionably, a greater degree of cohesion in the particles which compose the fibres of muscles in their living, than in their dead state. This cohesive power, in consequence of the connexions of the muscle in the body, is equivalent to a constant tendency to contraction. Hence, the fibres of muscles are in a constant state of tension, like an elastic substance kept upon the stretch. This property, evidently derived from contractility, has been denominated *tonicity*, a term which has also, as we have seen, been applied to the peculiar state of tension of cellular and membranous structures, derived from a particular condition of their elasticity. (See § 175.) It produces the state of *tone* in a muscle; or that in which it is disposed to contract to a greater degree, than its connexions with the neighbouring parts will allow. This explains why, on cutting a muscle across, the cut edges retract to a considerable extent, leaving a wide gap at the place of section: when, by a sudden effort, the tendo achilles is ruptured, the muscles in the calf of the leg to which that tendon had been attached, being released from this stretching force, retract to a great extent, and form a large and hard swelling high up in the leg.

Tremulo action of muscles.

(225.) On minutely examining the phenomena of muscular contraction, it will be found, even in those instances in which the contractile power appears to be exerted with undiminished vigour for a certain time, that each individual fibre undergoes, during the interval, a succession of changes of condition, contracting and relaxing alternately. It is only a certain number of the fibres that are in action at the same moment; their power is soon exhausted; and until recruited by repose, other sets of fibres are thrown into contraction, so as to supply their place. They thus relieve one another in succession, until by frequent action the exhaustion becomes more general, and the restoration less complete. In this state, the whole muscle is fatigued, its contractions become irregular and unsteady in proportion as they are more feeble, and the whole action is tremulous, and incompetent to the production of the desired effect. These tremulous movements are very obvious when the muscles are weakened from any cause, as well as when exhausted by excessive action. Dr. Wollaston[1] with his usual acuteness, detected, by a very simple experiment, the minute oscillations consequent upon these continual and rapid alternations of contraction and relaxation in the fibre. When the finger is inserted in the ear with a moderate degree of force, and the pressure is continued with as much steadiness as possible, a peculiar vibratory sound is heard, similar to that of a carriage rolling on the pavement. This must evidently proceed from a corresponding vibratory action of the muscular fibres. It appears, therefore, as Dr. Wollaston remarks, that the voluntary effect in this case, although it may seem to us to be perfectly continuous, consists in reality, of a great number of vibrations repeated at extremely short intervals.

---

[1] *Philosophical Transactions* for 1810, p. 2.

(226.) There is a peculiar kind of contractility possessed by membranous structures, which has often been supposed to bear an analogy to muscular contractility, or even to be some modification of this property. It is called into action by the application of a certain degree of heat, and also by some powerful chemical agent, such as the concentrated mineral acids; and the effect produced is a sudden corrugation, or curling up of the membranous part. This phenomenon was noticed by Haller, and was termed by Bichat *racornissement.* Alcohol, and many of the neutral salts produce, but more slowly, effects which are similar in kind, though much inferior in degree; but in this case the corrugation continues to increase, if the agent continues applied, which does not happen when the more powerful agents, as the acids, or boiling water are employed; for the continued operation of these latter agents is to dissolve and disorganize the animal substance. Bichat took considerable pains to investigate these phenomena, and has pointed out[1] several circumstances by which this property may be distinguished from mere membranous elasticity. From muscular contractility, indeed, it differs much more considerably, and depends, therefore, in all probability, on principles totally different from that remarkable animal property.

Sect. V.—*Functions of the Osseous Fabric, or Skeleton.*

uctions he eleton.

(227.) The general basis for the mechanical support of all the softer organs of the body, both in their states of quiescence and of motion, is the osseous fabric, or *skeleton;* composing a connected frame-work of solid and unyielding structures, fitted for the threefold purposes of giving protection to the more important organs which perform the vital functions, of sustaining the weight of the several portions into which the body may be conceived to be divided, and of furnishing fixed points of attachment to the muscles or moving powers, and thus supplying them with the mechanical advantages of levers in the execution of the more powerful movements of the frame, and especially in the progressive motion of the whole body from place to place.

(228.) The organs more especially defended from external injury by a bony covering, are the *brain,* the principal organs of the *senses,* and the organs of *circulation and respiration.*

1. *The Cranium.*

ctions e sk.

(229.) The bones of the skull are contrived with singular artifice and skill to afford protection to the brain, an organ, as we have seen, of peculiarly soft and delicate texture, and of which the functions are so refined as to require for their accomplishment the most perfect freedom from external pressure, and even from any harsh vibration or concussion of its parts. It is evidently with this view that the bony covering of the brain, or skull-cap, as it has been called, is constructed in the form of a vault or dome, as being the best calculated to resist external pressure, on the well-known mechanical principle of the arch. But pressure applied vertically to an arch necessarily gives rise to an outward horizontal thrust at the two ends of the arch. In architecture, various expedients are resorted to for opposing this force. In a bridge it is resisted by the solid abutments where the arch takes its rise on each side. In the higher arches of ornamental architecture it is counteracted by the weight of a buttress placed over the origin of the arch, and in harmony with the design of the whole. For the support of the roof of a building, which has to rest upon perpendicular walls, either these walls must be built of a strength equal to withstand this horizontal pressure, or, what is generally resorted to, a tie-beam must be attached to the base of the roof, which tie-beam will resist by its cohesive strength the force which tends to stretch it, derived from the outward pressure of the roof.

(230.) In the architecture of the skull we find the exemplification of these methods, and their strict conformity with the refined principles of mechanics. The two parietal bones on the sides, the frontal bone before, and the occipital bone behind, may be considered as the four great stones which compose the convex part of the dome. If we first consider the parietal bones, viewing them as constituting a single arch, we find that their lower edges are bevelled off at an acute angle, so as to be overlapped on each side by the upper edge of the temporal bone, which continues the curvature as far as the basis of the skull. Thus the two parietal bones are effectually wedged in between the two temporal bones, and any pressure applied on the top of the head, which would of course tend to thrust their lower sides outwards, is resisted by the temporal bones. But these temporal bones are themselves locked into the irregularly-shaped sphenoidal bone, which, as we have seen, forms the central piece of the basis of the skull, being in actual contact with every one of the bones which compose it, as well as the face, in which the organs of all the senses, except that of touch, is contained. The os sphenoides thus performs the office of a great tie-beam to the lower part of the arched roof of the skull: and the same principles will be found to hold good when the section of the skull is taken in the longitudinal direction; the os frontis before, and the os occipitis behind, which sustain their share of any pressure made on the upper parts of the head, being so locked in, by the bending inwards of their lower processes, with the sphenoid bone, as effectually to prevent their starting outwardly.

(231.) Another circumstance in the architecture of the skull is particularly deserving of notice, as it exhibits the most marked instance of provident design. It relates to the structure of the bones themselves, which is that best calculated to resist fracture on the one hand, and on the other to prevent the transmission of vibrating concussions to the brain. It is manifestly with this view that it is composed of two plates of bone, the external one fibrous, tough, and not easily broken; the inner one more dense and rigid, offering the most poweful resistance to simple direct pressure; yet, on that very account, more fragile in its nature, and partaking therefore in the quality of brittleness, which belongs to all the harder bodies, such as glass or flint. It was on account of its possessing this property that it was named the *tabula vitrea* by anatomists. But while it is evident that such an accident would have been of frequent occurence if that part of the bone had been directly exposed to every casual blow, this evil has been carefully guarded against by the interposition of a spongy intertexture of bony fibres, the *cancellated structure,* as it is termed, which forms a thick layer between the two laminæ of bone, or as they have been called, the outer and the inner *tables* of the skull. This intervening layer operates as a cushion, arresting the progress of the vibrations from the external to the internal plate of bone, and preventing fracture.

(232.) Even when the impetus is so great as to penetrate through this resisting medium, still the force with which it impinges on the subjacent parts must be very considerably moderated, and the danger of injury to the brain diminished. It is with a similar design of giving protection that a soldier's helmet is lined with leather or covered with hair; a provision which we even find in the head-piece of the Roman soldiers, in whose equipment utility alone was consulted, and nothing was admitted that served the purpose of mere ornament. Wherever the bones of the skull are more particularly exposed to blows, we find a greater thickness of bone provided for the sake of additional power of resistance.

---

[1] *Anatomie Générale.*

(233.) The *sutures*, or joinings of these bones, are also admirably contrived to stop the transmission of vibrations arising from percussion from extending to any distance round the skull. These sutures, externally, where the tough and fibrous plates of bone are united, present a serrated line; the fibres at the edges of each being mutually inserted between those of the contiguous bone. But this dove-tailed joining is not met with in the inner table; there the edges of the bone are smooth and placed in simple contact. This is evidently done in order to prevent the chipping off of the minute parts of a brittle structure, had they been interlaced together as the fibres of the outer table are. But still the interruptions afforded by the suture tends in a great degree to check the progress of fracture.

2. *The Face.*

Protection given to the organs of the senses.

(234) The organs of the principal senses, the eye, the ear, the nostrils, and the mouth, are protected by the bones of the face, which likewise form part of the skull. The eyes are exceedingly well defended by the superciliary ridge of the frontal bone above, and also by the orbital plate which supports the anterior lobes of the brain; anteriorly they are protected by the projection of the nasal bones, and outwardly by the arched process which divides them from the temples: while the prominent cheek bones below guard them from injury in that quarter. No part of the body has so effectual a protection from bone as the internal organ of hearing: nor is there any part of the osseous system so hard as the portion of the temporal bone in which this organ is lodged. The nasal cavities, in like manner, which are occupied by the membranes receiving impressions from odorous effluvia, are formed in deep recesses of bone. The organ of taste is also protected by the jaws, though less completely, because the same parts are required to enjoy extensive power of motion.

3. *The Thorax.*

Framework of the chest.

(235.) The heart and lungs, which are lodged in the cavity of the thorax, are defended before and behind by the spine and sternum; and laterally by the ribs, which form bony arches, the shape best calculated for resisting pressure applied externally. They are formed of separate pieces, with intervals between, in order to admit of motion: for the cavity of the chest requires to be alternately enlarged and contracted in the performance of respiration, which is a function of primary importance in the animal economy.

4. *The Spine.*

Functions of the spine.

(236.) The support of the trunk and upper parts of the body, including the head, is entrusted to a column of bones, the assemblage of which constitutes the spine. The spine is that part of the skeleton of all animals composing the four superior classes, namely, the mammalia, birds, fishes, and reptiles, which is most constantly found, and which exhibits the greatest uniformity of structure. The individual bones which compose the spine are so intimately united and so firmly secured by ligaments on every side, that they appear in the living body as one continued bone, and the whole assemblage is known, in ordinary language, by the name of the *back-bone.* The purposes answered by this complex fabric are numerous and important. It is the great central beam of the fabric, and furnishes the basis of support to all other bones of the skeleton. It serves, in particular, to unite the bones of the limbs with the trunk, so that they form with the latter one connected frame-work. It is the axis of their principal motions, the common fulcrum round which they all revolve. It has an intimate mechanical relation with all the parts of the body. It affords attachment to the great muscles which move the trunk and the principal joints of the extremities. It contains and gives protection to that important organ, the spinal cord, from which, as we have seen, almost all the nerves of the body take their origin, and which is unquestionably, next to the brain, the most essential organ in the economy. Whilst the spinal column performs these offices, it is at the same time capable of considerable flexion, both laterally and longitudinally; and admits also of some degree of twisting motion, in a plane perpendicular to its axis.

(237.) No where has art been more conspicuously displayed than in the construction of an apparatus adapted to fulfil such opposite and apparently imcompatible functions. To secure the firmness and strength which are required in the basis of support to the whole body, in the key-stone, as it were, of its various arches, whilst it is at the same time rendered capable of so great a variety of motions, objects which seem utterly at variance with its also affording protection to a tender and delicate organ, in which the least pressure would be attended with fatal consequences, must be allowed to be a most difficult problem of mechanism. And yet these various, complicated, and apparently inconsistent offices, we find executed by one and the same instrument. Flexibility is obtained by subdividing it into a great number of small portions, each of which is separately allowed but a small degree of bending upon the next; and thus a considerable motion is obtained in the whole column, with but a very inconsiderable one at each joint. Each bone, as was described in the account of its anatomy, is connected with its neighbour by a broad basis of attachment; and the slight relative motions of which they are susceptible are chiefly entrusted to the lateral articulations. Whilst these broad bones give the whole chain its requisite firmness and stability, they are so constructed as to afford a passage, without any diminution of their strength, to the substance of the spinal marrow. For this purpose each of the bodies is hollowed out so as to form a continued groove all down the back; and over this groove a broad arch is thrown from each side, converting it into a complete canal. In order to preserve the continuity of this canal, and prevent the vertebræ from shifting upon one another so as to press upon the spinal cord within, during the various movements of the body, further securities are provided. They are severally connected together by their projecting processes, which lock into one another, and are still more firmly secured by the ligaments that bind them down on every side. Thus, the bodies of the vertebræ are guarded against the danger of accidental slipping, but they are defended also from displacement by any force short of what would break the bone.

(238.) But besides all these provisions the vertebral column is protected from injury arising from violent jolts or jars, by having interposed between each adjoining vertebræ, the peculiar springy substance known by the name of the *intervertebral cartilage or ligament;* for it in reality partakes of the nature of both these textures. It is a substance quite peculiar to this part of the frame. Its compressibility and the elastic force with which it recovers its shape when relieved from the compressing power, must greatly lessen the quantity of motion required of each bone during the flexion of the column, as well as soften all the concussions incident to violent motion. No chasm is left by their separation when the spine is bent; and the unity of the whole column, and of the channel in its centre, is preserved unbroken. A passage is at the same time allowed between each contiguous vertebræ for the nerves which issue in pairs from the spinal cord, to distribute their branches and filaments to every part of the body.

(239.) The natural curvatures in the line of the vertebral column also contribute materially to the elasticity of the whole framework. On receiving any shock in the direction of its length, the impulse, instead of being propagated the whole length of its line, is diverted from its course and taken off by the flexures of the column; and the maintenance of its natural position is effected more by the power of the muscles attached to the spine, than by its inherent elasticity.

5. *The Pelvis.*

nework
e pel-

(240.) The broad expansion of bone which extends on each side of the pelvis, and the extremities of which form the hips, are evidently designed as a basis of support for the viscera of the abdomen. The lower portion of the bones of the pelvis is at the same time rendered light by being formed into several arches; strengthened at the points where it is exposed to the greatest pressure, and at the same time affording room for the articulations of the thigh bones.

6. *The Limbs in General.*

nework
e limbs.

(241.) The third office of the skeleton is to furnish levers for accomplishing the progression and other movements of the body, which require great force, great extent, and great precision of motion. These objects are attained by the limbs, which, as is well known, are divided into separate portions, obviously for the purpose of increasing the facility of adaptation to a great variety of movements and of actions which the individual may be called upon to perform.

(242.) The principal bones of the extremities have the shape of lengthened cylinders, and compose a system of levers adapted to the regular and accurate application of the moving force, and for the execution of rapid, extensive, and powerful movements. The circumstance of their hollow and cancellated structure is a palpable instance of provident adaptation to the office for which they are framed. It may be mathematically demonstrated, that if the quantity of materials assigned for the construction of the bone be given, there is no mode in which those materials could have been more advantageously disposed for resisting a transverse force, that is, a force tending to break it across, than the form of a tube, or hollow cylinder, which is that actually given to them by nature. If, for instance, the same quantity of matter had been collected into a solid cylinder of the same length, it would have been subject to fracture by a much smaller force than that which it bears without injury in its actual tubular form. This remark was long ago made by the elder Dr. Monro,[1] who observes that the resistance opposed by a body of cylindrical shape to a force applied transversely is in the direct ratio of its diameter; hence the same number of fibres disposed round the circumference of a circle in such a way as that their sections would present the appearance of a ring, will resist with greater force than if they had been united at the centre, so that their section would present a circle of much smaller diameter than the ring. The hollow cylindrical bones are accordingly found in those situations where the power of resisting external force is principally wanted, while it is at the same time an object of importance not to add unnecessarily to the weight. A simple experiment will illustrate in a very striking manner this proposition. Let a cylindrical glass rod and a glass tube be taken of the same length and also of the same weight, so that they may both contain the same quantity of materials. If each be then supported at their two ends, on a frame adapted to the purpose, it will be found that the same weight which, when hung from the rod, will break it asunder, will, when transferred to the tube, be sustained without even bending it in any sensible degree. Dr. Porterfield has given an elaborate mathematical demonstration of the general proposition.[2]

(243.) There are few subjects in physiology which present so many interesting points of inquiry, or afford more abundant proofs of intelligence and design than the mechanical properties of the osseous fabric. From the account we formerly gave of the composition of bone, it appears that it is constructed of two principal materials, an earthy basis, which is the phosphate of lime, and an animal or membranous substance, which possesses considerable tenacity. To the first of these ingredients the bones owe their solidity and hardness. No inorganic matter, not even the metals, has so great a cohesive power, with a given weight of materials, as the earthy bodies; and this is probably the reason why the phosphate of lime has been selected as the substance employed to give the necessary solidity and hardness to bones. But these qualities, if carried to excess, would be accompanied with brittleness. To guard against this evil, the cohesion of the inorganic earth is tempered by the interposition of an elastic organic material; this is the cellular tissue, within the cells of which the bony matter is deposited, and which acts the part of a cement, binding them more strongly together, and at the same time obviating the excessive brittleness which a substance of more uniform hardness would have possessed. Thus, by the admirable blending of these two elements, two qualities which, in masses of homogenous and unorganized matter are scarcely compatible with one another, are happily united.

Articulations.

(244.) The manner in which the cylindrical bones are connected together is also highly deserving of attention. There are, indeed, few parts of the mechanism of animals more peculiarly fitted to excite our admiration than the structure of the joints. Every provision seems to have been made for facilitating their motion, and every precaution taken to enable them to act with safety. Their ends are enlarged for the purpose of affording a broader surface of junction, and for procuring greater firmness and security of connexion. The rough and hard substance of bones would have been particularly exposed to injury if they had been allowed to grate upon one another without some intervening smooth surface. In all the joints, at the places where the ends of the bone would have suffered from this cause, we find them tipped with a white, smooth, and elastic cartilage. Dr. Paley[3] has very aptly compared this expedient to the plating of a metallic instrument with a different metal. Detached portions of cartilage, are, as we have seen, frequently placed between the bones, which thus, instead of working upon each other, work upon the intermediate cartilages. This is analogous to the contrivance practised by mechanics, who interpose a loose ring where the friction of the joints of any of their machines is great, and who particularly resort to it where some strong and heavy work is to be done. It is precisely under similar circumstances that the same contrivance is employed in the human body; and the analogy is a striking evidence of that art and foresight which are manifested in the plan of its conformation. The lubricating quality of the synovia is also an exquisite provision designed to diminish friction.

(245.) The ligaments which bind the ends of the bones together, and restrain the direction of their motions, are admirably calculated to perform the offices assigned to them. Like the bones, they unite qualities which are rarely met with in conjunction. They have all the properties we can desire in a rope; namely, perfect flexibility, with great power of resisting extension. It is hardly imaginable how great a force is required to stretch, or rather to break asunder a ligament, for it will not yield in any sensible degree until the force is increased so as at once to tear it to pieces. Yet with all this toughness, it is so flexible as to oppose no impediment to the suppleness of the joint. "Every joint," says Dr. Paley, "is strictly a mechanical instrument, and as manifestly contrived, and as accurately defined as any that can be produced out of a cabinet maker's shop. Their durability is no less astonishing. A limb shall swing upon its hinge, or play in its socket, many hundred times in an hour, for sixty years together, without diminution of its agility."[1]

7. *The Lower Extremities.*

Mechanism of the lower extremities.

(246.) The three portions into which the lower extremities are divided, namely the *thigh*, *leg*, and *foot*, being united by joints, and moveable upon one another, are calculated to serve the double purpose of firm columns of support to the body while standing, and of facilitating and regulating its movements while advancing. It might, on a superficial view of the subject, be supposed that, in standing in the erect posture, the weight of the body would be more firmly and effectually supported had the whole limb consisted of a single straight column. But independently of the greater strain to which such a structure would be exposed, in consequence of the great length of bone required, it would, in fact, have had less stability than it now possesses. A marble statue of a man resting merely on the feet in a natural attitude, would be overthrown by a small impulse; and even in the living body, it is an infallible consequence of the laws of mechanics, that if ever the perpendicular line drawn from the centre of gravity happen to pass beyond the base of support, the body must inevitably fall in spite of every muscular exertion that can be made. The only way to prevent such an accident is to bring back the centre of gravity nearer to a point above the centre of the base before it has actually passed it; and this we instinctively do when we feel ourselves in danger of falling to one side, by extending the arm horizontally on the opposite side.

Act of standing.

(247.) But the limb being divided into joints, these joints would give way under the weight of the body, were they not prevented from bending by the constant action of the muscles. The continual muscular effort required in standing is nearly as great an expenditure of muscular power as the act of walking. Soldiers on parade remaining in the same attitude, experience even more fatigue than they would suffer by a march during an equal time, because the same muscles are constantly in action. The posture of a soldier under arms, with his thighs and legs in the same straight line, is one which requires a painful effort to preserve. The moment the word of command is given him to "stand at ease," the muscles on one side immediately relax, the right knee is slightly bent, the tension of the ankle-joint is relieved, and the body, sinking upon the left hip, has its height diminished by above an inch and a-half. The weight of the trunk is sustained more directly by the column of bones of the left limb, which support that weight at a greater mechanical advantage than before; for the oblique direction of the neck of the thigh bone, with regard to the bones of the pelvis, which is very great in the perfectly erect position, is now diminished. But the great source of relief is that a different set of muscles is called into play on every change of posture; those which were before fatigued have time to recruit their energies, and become prepared afterwards to afford in their turn the same relief to others by resuming their exertions.

(248.) Strictly speaking, it is quite impossible for even the strongest man to remain for even a very short interval of time in precisely the same position. The fatigue of the muscles which are in action soon become sensible, and relief is instinctively given to them by varying the points of support. Thus we may observe that in standing, the weight of the body is naturally thrown alternately from one foot to the other. The action of standing must be considered as a series of perpetual, but obscure movements, by which the centre of gravity is continually shifted from one part of the base to the other; the tendency to fall in any one direction being perpetually counteracted by small and insensible movements in the contrary direction. Long habit has rendered us unconscious of these exertions, and inattentive to the sensations which prompt them. But a child, when acquiring the art of walking, is sensible of all these difficulties, and does not learn to walk but by reiterated lessons, and by the experience of many falls. It is by a practice of the same kind, and continued during a longer period, that the rope-dancer learns to support himself on a narrower or more unstable base than that which nature has provided. This he effects, not by keeping his centre of gravity precisely in the mathematical perpendicular to the rope, but by continually shifting it from side to side; never allowing it to fall above a certain very minute distance, and immediately correcting the vacillation by a movement which gives it an impulse in the contrary direction.

(249.) The flexures of the joints of the lower extremities, it may be observed, take place alternately in opposite directions. Thus, the thigh is bent forwards upon the pelvis; the leg is bent backwards upon the thigh; and the foot, again, is bent forwards upon the leg. This arrangement is obviously the one best adapted to convenience, both as regards the folding the parts when bent, and the commodious disposition of the muscles, which perform the opposite motions of flexion and extension. As the weight of the body occasions the flexion of the joints, so it is that flexion which the muscles are chiefly required to counteract; and this is the duty of the extensor muscles. We accordingly find, that in each joint, the latter are much larger, and more powerful than the flexors. They are enabled also to act with greater mechanical advantage, in consequence of their being inserted into projecting processes of the bones, evidently provided with this express intention. This is the purpose of the trochanter of the thigh bone, and the projecting bone of the heel. The same object is accomplished, in a still more artificial manner, in the knee-joint, by an additional bone, the *patella*, or knee-pan, into which the great extensor muscles situated in the fore part of the thigh are inserted, and which renders their action much more efficient, both by diminishing its obliquity, and by removing it farther from the centre of rotation. It acts, therefore, as a pulley, which is a species of lever; and it is so contrived, that while the knee is bent, and the muscles at rest, as when we are sitting, this bone sinks down, concealed in a hollow of the knee. When the extensor muscles begin to act, they draw out the patella from this hollow; and in proportion as they contract, and their strength diminishes, the patella gradually rising, gives greater mechanical advantage to their action, which is greatest of all when, by their complete contraction, their power is most expended.

(250.) The structure of the feet is also admirably contrived, as a secure basis for the support of the whole superincumbent weight of the body, and of all the additional burdens which the body may be made to sustain. The arrangement of the bones is in as strict conformity to the principles of the arch as those of the skull. The bones of the tarsus constitute what may be called a double arch; that is, an arch in two different planes, at right angles to one another. There is, in the first place, one great longitudinal arch, springing from the point of the heel to the ball of the great toe: and there is, in the second place, a transverse arch formed among the tarsal bones themselves, one within another. Near the heel this arch is composed of the astragulus, os calcis, and naviculare; and farther on, by the cuneiform or wedge-like bones, the name of which expresses their office, analogous to that of the stones at the crown of an arch of masonry. The elasticity, as well as security, resulting from all these arches, imparts that ease and spring so remarkable in the step, and obviates the injurious jar that would be otherwise inevitably communicated to the body by leaps, by falls, or other accidents.

---

[1] *Natural Theology.*

on of ing.

(251.) In walking, the first action consists in fixing one foot firmly on the ground, by transferring to it the whole weight of the body; the other foot being then at liberty to move, is with the leg carried forwards. This projection of the limb is necessarily attended with a corresponding advance of the centre of gravity, which proceeds to move forwards till it arrives beyond the basis of the foot on which the body is resting. Whenever this happens, the body, being unsupported, begins to fall, and would continue to fall, were not the other foot in advance, and ready to receive it, and stop its further descent. This is the reason why we experience so disagreeable a jar, if in walking inattentively, the foot we had advanced happens to arrive at a lower level on the ground than had been expected; as when, for instance, we meet with a descending step for which we were not prepared. The body on these occasions, falling through greater space than usual, acquires a certain velocity of descent, and this unusual velocity being suddenly checked, commuicates a shock to the whole system.

(252.) While the weight of the body is thus transferred alternately from one foot to the other, the centre of gravity of the body, while it is continually carried forwards, is at the same time alternately raised and lowered, so as to describe at each step a small arch; and its whole motion may be represented by a waving line, having lateral as well as longitudinal inflexions, and composed of a succession of short curves. In taking long steps, we are obliged to raise the centre of gravity through a longer arch, and therefore to a greater height. This is consequently more fatiguing than a shorter step. If, however, we go into the contrary extreme, and take too short steps, the advantage obtained in lessening the height of the arches described by the centre of gravity, is more than compensated by the greater quickness required in the motions necessary for keeping up the same rate of walking.

(253.) The lateral undulation of the body during walking is never performed with precise equality on both sides; and the amount of the accumulated deviations would be considerable, did we not avail ourselves of the assistance of the sense of sight in counteracting it. This will appear from the well-known fact, that it is impossible for a person who is blindfolded to continue to walk in a straight line for any considerable distance. Even on a perfectly level plain, we unavoidably incline to the right or to the left; and the want of consciousness that we are doing so, prevents us from rectifying the error; so that while we imagine we have undeviatingly pursued a straight course, we may perhaps, when the bandage is removed from our eyes, find ourselves near the very spot from whence we had commenced our circumambulatory excursion.

8. *The Upper Extremities.*

Mechanism of upper extremities.

(254.) The upper extremity, though exempt from the office of supporting any part of the weight of the trunk, and intended for a variety of very different uses, presents us with exactly the same number of divisions as the lower extremities; excepting that in the skeleton, if we compare the scapula to the bones of the pelvis, there is an additional bone provided in the clavicle, or collar bone, by means of which the bones of the arm are articulated with those of the trunk. The extremity of the clavicle, indeed, by which it joins the sternum, is the pivot on which all the great motions of the arm are performed. The interposition of the scapula is evidently for the purpose of giving a more extended surface for the attachment of the strong muscles destined to act upon the arm and upper part of the trunk, and which also lend their aid in performing the movements necessary for respiration. It also contributes its share in the defence of the back part of the chest.

(255.) The joint of the shoulder is of the ball and socket kind, and admits, therefore, of the greatest latitude of motion. That of the elbow is a simple hinge-joint, and restricted consequently to mere flexion and extension. A rotatory motion was here unnecessary; for the free rolling of the arm at the shoulder answers every purpose that can be desired, and the elbow-joint is rendered more secure by this limitation of its motion; for it will always be found, that whenever a hinge-joint is sufficient for the purposes required, it is employed in preference to that of the ball and socket, which, from its very extensive range of motion, must necessarily be looser in its structure. and more liable to dislocation.

The hand.

(256.) In the wrist, which is the great centre of all the motions of the hand, a construction was called for which might allow of the utmost latitude of motion. The following were the three kinds of movement required; first, simple flexion and extension; secondly, lateral flexions; and, thirdly, twisting, or rotation of the hand, as when it is employed in turning a screw. If all these different motions had been entrusted to a simple ball and socket joint, they could not have been well performed without great strains and hazard of dislocation. This danger is admirably obviated by distributing the motions among several articulations. No part of the bony system is more complex than the wrist, which consists of eight small bones crowded into a very narrow space, and lashed together by many strong ligaments, that form bands crossing one another in every possible direction. While they are together fitted to the bones of the fore-arm in the manner of a hinge-joint, their mutual connexions allow at the same time of considerable lateral flexion.

(257.) But still the rotatory or twisting motion of the hand, which is perhaps the most useful of all, is not provided for by this mechanism. For the accomplishment of this object there is employed a contrivance to which the rest of the system presents nothing similar. The wrist is connected not so much with the principal bone of the fore-arm, as with a subsidiary bone of equal length with it, and placed in a parallel position, termed the *radius;* and its peculiar mode of junction is such as to enable it to describe round the former a complete semicircle. In these rolling motions the radius carries along with it the hand, which thus turns in perfect security; for it is difficult to conceive how a force could well be applied, so as to separate bones having so long a lever of resistance. Thus, while the wrist is exempt from the weakness incident to circular joints, it possesses all the properties which we find in the most moveable.

(258.) The manner in which the fingers are disposed in the hand, like radii from a common centre, is such as to allow them very free play, and to extend their sphere of action. But the chief perfection of the hand, as a mechanical instrument of prehension, consists in the structure of the thumb, which is furnished with muscles of so great a strength, compared with those of the fingers, as to enable it to oppose and balance their united power. Hence the hand is capable of grasping a spherical body, and of keeping firm hold of a variety of objects, which it would otherwise have required the concurrence of both hands to retain.

(259.) The passage of the tendons, by which the fingers are bent, is particularly deserving of notice, and has often been appealed to as a signal instance of express contrivance. As the uses of the hand require the bending of each joint of the fingers independently of the others, it was necessary that separate muscles and separate tendons should be provided for each. The muscles are most advantageously placed high up in the arm, and convenience requires that those muscles which bend the last joints should lie beneath those that bend the middle joints. Had the tendons proceeding from the latter been directly inserted into the middle of the second bone of the finger, they would have been exactly in the way of the tendons which are underneath, and which are proceeding to a more distant insertion. They are therefore split into two branches, each being inserted into the side of the bone; and the lower tendon is thus allowed to pass on securely between them. This structure has also this further advantage, that it procures a more ready flexion of the last joint than of the other joints; a provision, the purpose of which is manifest, since it tends effectually to prevent the escape of the object we wish to lay hold of. "There is nothing," says Dr. Paley, "in a silk or cotton mill, in the belts, straps, or ropes, by which motion is communicated from one part of the machine to the other, that is more artificial, or more evidently so than this perforation." "Let a person observe his own hand while he is writing, the number of muscles that are brought to bear upon the pen, how the joint and adjusted operation of several tendons is concerned in every stroke, yet that five hundred such strokes are drawn in a minute. Not a letter can be turned without two or three tendinous contractions, definite both as to the choice of the tendon, and as to the space through which it moves. Yet how correctly does the work proceed; how faithful have the muscles been to their duty; how true to the order which endeavour or habit has inculcated. Let us watch the hand while playing upon a musical instrument. All the changes produced, though extremely rapid, are exactly measured, even when most minute; and display on the part of the muscles an obedience of action alike wonderful for its quickness and its correctness."

Uses of the hand.

(260.) To specify all the instances of express contrivance in the mechanical conformation of the hand would fill a volume. As an organ of touch it is admirably formed. No instrument is better adapted to the practice of the mechanical arts; none could be better fitted for examining the properties of bodies, and the laws of the material world, of which none of the other senses, unassisted by that of touch, could impart to us any accurate knowledge. So great are the advantages which the possession of this organ has conferred upon the human race, that many philosophers, prone to paradox, have ascribed to this circumstance alone the whole of the intellectual superiority which he enjoys over the brute creation.

CHAP. VI.—ASSIMILATION.

Sect. I.—*Chemical Constitution of Organized Matter.*

1. *Necessity of Aliment.*

Necessity for nutriment.

(251.) A constant supply of nutritive matter is necessary for the continuance of life, a necessity arising from a variety of causes. In the first place, the substance of which the body is formed is exposed to various sources of waste and dissipation, and is continually verging to a state in which the organs become unfit for the performance of their functions. The chemical affinities by which the elements of organized substances are retained in that peculiar mode of combination which constitutes their living state, are, as we shall presently see, very nicely balanced, and would be unable to preserve them in that condition were not some means provided for counteracting their natural tendency to decomposition. By the active exercise of their respective functions all the organs, but more especially the muscular and nervous systems, experience a deterioration of their component parts, and suffer decay and waste. Fresh materials are required for supplying this continual expenditure. A certain degree of temperature must also be kept up, otherwise the muscles would lose their faculty of contracting, and the nerves their power of conveying impressions to and from the sensorium. Materials are therefore necessary to be employed as fuel for keeping up the vital warmth. The daily consumption of combustible materials, apparently used for this purpose in the animal economy, is, we shall afterwards find, very large, and forms a considerable proportion of the food received into the body.

(262.) All that we have now said refers to the body in its adult or mature state, when it has attained its full dimensions, and when all that is required is its preservation in that state. But during all that period of life when the body is increasing in its size, it is evident that its growth can only take place in consequence of the addition of new particles to those already composing the substance of the body; and some parts, such as the hair and nails, continue to grow even to the latest period of life. At every age some part is liable to be injured or destroyed, and a provision is in most cases made for the reparation of that which has been injured, or even for the replacement of that which had been destroyed. These objects can be effected only by the supply of new materials derived from external sources.

The changes effected by the long series of assimilatory processes being essentially chemical, it becomes necessary to institute a particular inquiry into the chemical constitution of organized substances in their successive stages of mutation, from the most simple to the more complex conditions in which they are found to exist in the composition of an animal body.

2. *Chemical conditions of organized matter.*

Chemical conditions of organized matter.

(263.) The parts, which by their assemblage constitute an organized body, when compared with unorganized matter, exhibit in their chemical, as well as in their mechanical characters, the most well marked and striking contrast. Complexity, variety, and difficulty of analysis, are the leading features as much in the former, as in the latter of these subjects of consideration. Combinations equally artificial, equally the result of design, and of refined elaboration, are exhibited both in the mechanism of organic structures, and also in the chemical constitution of organic substances. Compared with the latter, all the bodies which are presented to us in the mineral kingdom, are extremely simple; and their study presents no difficulties of an insurmountable nature. The number of primary or elementary substances, or of those at least which we regard as simple, is, indeed, greater in the mineral kingdom, than that of those which enter into the composition of animal or vegetable bodies; but they are for the most part found united in binary combinations, or are, at least, easily resolvable into a small number of such binary compounds. In the products of animal or vegetable systems, we find a less variety of ultimate principles; but this is more than compensated by the infinitely greater diversity of modes in which they are combined. The same elements, instead of forming with each other mere binary combinations, generally exist in more complicated states of union; there, four, five, or even a greater number of constituent substances, having their affinities nicely balanced, and harmonized into one individual combination.

(264.) From this diversity in the mode of union, there arise remarkable differences in the properties of different organized products, formed from the same ultimate principles: nor can we, as in bodies belonging to the mineral kingdom, with an exact knowledge of the nature and proportions of the component substances, proceed, by any artificial arrangement, to the actual formation of the compounds themselves. No approach has yet been made by human ingenuity, to the imitation of nature in these refined operations of vitality.

Balance of affinities.

(265.) Another consequence resulting from this difference in constitution between organized products and the inorganic bodies of the mineral kingdom, is that the affinities by which the elements of the former class of bodies are held in union, being nicely balanced, are more subject to change. The equipoise is easily disturbed and subverted. The principles have a constant tendency to react on each other, so as to give rise to a new order of combinations; which readily take place by slight alterations of circumstances. All organic products are susceptible of decomposition by heat alone; they are readily acted upon by various agents, as water or atmospheric air; and they are generally liable to spontaneous changes, to fermentation, and putrefaction.

(267.) Such, then, are the distinguishing features of the chemical properties belonging to the products of organization; simplicity as to the number of ultimate elements; complication in the mode and order of combination; unsteadiness in the balance of affinities retaining them in union, and consequent proneness to decomposition, and impracticability of their artificial formation by a reunion of their principles.

Tr com- pnt ele- ms.

(268.) Whilst the products of the animal kingdom participate with vegetable bodies in these common characters, which distinguish them from inorganic materials, they differ from the former in several subordinate circumstances of chemical relation. The constituent principles of animal substances are somewhat more numerous, and their affinities more nicely adjusted, and more easily disturbed. Their chemical constitution is the result of still more delicate processes, and of a more elaborate organization. The three great component elements of all vegetable bodies, are *oxygen, hydrogen*, and *carbon;* but animal substances generally contain, besides these, a considerable proportion of a fourth element, namely *nitrogen*, the presence of which has a considerable influence on the changes they undergo when subjected to the operation of foreign agents, or left to the spontaneous operation of internal causes of decomposition. *Phosphorus* and *sulphur* must also be enumerated among the component parts of the greater number of animal substances; and the affinities exerted by these elements also tend to modify the results produced by these various causes. The greater the number of elementary ingredients present in any assemblage, the greater will be the tendency to form binary or ternary combinations; and the more will the affinities be divided between different elements, and pass easily from one mode of arrangement into another. Hence the greater susceptibility to decomposition which characterises animal products, when compared with vegetable.

(269.) In addition to the substances already mentioned, we must also reckon among the constituents of animal substances, *lime, potash, soda*, and *iron;* but these exist only in small quantities.

(270.) Some of the most important qualities distinguishing animal substances are owing, in particular, to the predominance of nitrogen in their composition. This substance is disengaged from them in large quantities by the action of the nitric acid. This acid, indeed, itself contains nitrogen; but it has been ascertained, that in producing this effect, the acid does not undergo any decomposition; so that the nitrogen is furnished not by the acid, but entirely by the substance subjected to its action. *Ammonia* is evolved both during the putrefaction of animal substances, and also by the application of a heat sufficient for their decomposition; and this ammonia results from the combination of the nitrogen with hydrogen during these processes. *Cyanogen*, or *prussic acid*, is also a frequent product of these operations; and is known to consist chiefly of nitrogen. Under these circumstances, also, the phosphorus enters into new combinations, particularly with the hydrogen and azote, and forms compound gases, which are extricated both during the putrefaction and destructive distillation of animal substances. By becoming acidified by its union with oxygen, it enters into combination with earths, alkalies, and oxide of iron, and forms a variety of neutral salts. The same observations also apply to the sulphur which is found in certain quantities in several animal substances.

(271.) Another general difference in the chemical composition of animal and of vegetable substances, is that the former contain a smaller proportion of carbon, and a greater proportion of hydrogen than the latter. Carbon may be regarded as the base of vegetable matter, to which oxygen and hydrogen are attached; while hydrogen appears to be the principal component part of animal matter, and is there combined with nitrogen, oxygen, carbon, and phosphorus. Hence during the decomposition of animal substances by heat, the chief products are ammonia and empyreumatic oil, in both of which hydrogen is a principal constituent. In general animal matters contain less oxygen than vegetable, and hence afford less acid by their decomposition; and the coal which remains differs from vegetable charcoal in being much less combustible.

3. *Proximate Animal Principles.*

Proximate principles.

(272.) In the numerous and diversified products of the animal kingdom, we may trace different degrees of complication in the composition of their elements. Several substances present the appearance of greater simplicity, and appear to result from the more direct union of a few elements, and to preserve among various shades of modification the same general properties, and the same distinctive characters. The more compound products often admit of an intermediate analysis into these comparatively simpler constituents, which are distinguishable from each other by a certain uniformity of character, and which we may presume are obtained in the same state as that in which they existed in the compound subjected to the analysis. These form what are termed the *intermediate* or *proximate principles of animal bodies*, in contradistinction to the *elementary principles*, which are the result of the ultimate analysis of the substance. These proximate principles may be considered as forming by their mixture, or combination, all the varieties of animal matter; and they are therefore the more immediate object of attention to the chemist in his analysis of animal substances.

(273.) The only method resorted to by the earlier chemists, in the infancy of science, for ascertaining the composition of animal substances, was that of subjecting them to the process of distillation at a high temperature, by which their proximate principles were entirely destroyed, and either converted into new compounds, or resolved into their ultimate elements. Many of these being gaseous, were suffered to escape, and were totally disregarded. Scarcely any light could be thrown upon the composition of animal bodies by such an imperfect mode of examination. Successive improvements were afterwards introduced into this branch of chemical research, consisting chiefly in the application of various re-agents, from which instructive results were derived.

(274.) The modern art of animal analysis may be considered as comprising three different kinds of operations, which, however, admit of being variously combined. The first consists in observing the spontaneous changes resulting from various natural circumstances in which the substances may be placed; the second depends on the application of chemical agents, employed either as tests to indicate the existence of particular elements or proximate principles, or as menstrua, which, by their specific affinities, may separate the elements or primary compounds from each other; while the third set of operations, reverting to the original plan of destructive analysis, effects the complete decomposition of the substance, but carefully collects all the volatile and gaseous matter, and deduces an accurate estimate of the nature and proportions of the ultimate elements. We obtain, for example, a certain quantity of water, carbonic acid, and ammonia; and knowing the proportions of oxygen, hydrogen, and carbon, which they respectively contain, we are able to ascertain the precise amount and relative proportion of the elements which entered into the constitution of the substance analysed.

(275.) The general result of the investigations which have been conducted by the last of these methods is, that the simple bodies of which animal substances consist are comprised in the following list:

1. Oxygen
2. Nitrogen
3. Carbon
4. Hydrogen
5. Lime
6. Phosphorus
7. Sulphur
8. Soda
9. Potass
10. Chlorine
11. Magnesia
12. Iron
13. Silica
14. Manganese.

(276.) Of these, the first six may be considered as the principal elementary ingredients of animal substances. Magnesia and silica are found only in very minute quantities, and may therefore be in a great measure considered as foreign bodies. The soft parts of the body are composed almost entirely of oxygen, nitrogen, carbon, and hydrogen; while lime and phosphorus form the basis of the hard parts.

(277.) The proximate principles most generally met with in animal substances are,

1. Gelatin
2. Albumen
3. Fibrin
4. Mucus.

(278.) To these have been added some others, such as *urea, picromel, stearin, elain, osmazome*, and several *saccharine* and *acid principles*, which being more limited in their extent, will fall more properly under consideration in the review we shall give of the substances which chiefly contain them. We shall first then present an account of the properties of the four essential principles above enumerated.

4. *Gelatin.*

Gelatin.

(279.) Gelatin may be extracted by long continued boiling in water from almost all the hard and solid parts of the body, such as the skin, membranes, ligaments, cartilages, and even the bones themselves. By the slow evaporation of the water which thus holds it in solution, the gelatin may be obtained in a state of purity, when it appears as a hard, brittle, and semi-transparent substance, which breaks with a glassy fracture. It varies somewhat in its appearance, according to the source from which it has been obtained. Glue may be taken as an example of dried gelatin, in which, however, a few impurities are contained. Isinglass may be considered, on the whole, as the purest form under which gelatin is met with, and it exhibits most completely the characteristic properties of that proximate animal constituent.

(280.) One of the most striking characteristics of gelatin is the property it exclusively possesses, when united to a quantity of water, of dissolving slowly, but completely, forming a solution of an opaline colour, which is perfectly fluid when warm, but becomes concrete on cooling, assuming the tremulous appearance so well known as belonging to jelly. In this state it readily again becomes liquid, by the application of a gentle heat, and may, by the continuance of that heat, be brought back to the state of dryness. These alternate solutions and desiccations may be repeated for any number of times, without any change being produced in the chemical constitution of the gelatin. The proportion in which gelatin forms a solution capable of concreting by cooling, has been ascertained by Dr. Bostock in the following manner. One part of dry gelatin to 100 parts of water gave a solution which completely stiffened by cooling. But when the proportion of water was 150 parts to one of gelatin, a compound was produced, which though evidently gelatinous, did not assume the concrete form.

(281.) Solid gelatin undergoes no change if it be kept perfectly dry; but when united with water, either in the form of solution or of jelly, it very soon becomes putrid; an acid first makes its appearance, a fetid odour arises, and ammonia is afterwards formed.

(282.) The most ready and convenient test of the presence of gelatin in any fluid, is a solution of tannin; the addition of which immediately occasions, by the combination of these two principles, a copious precipitate, which assumes a solid form. This precipitate collects into an elastic adhesive mass, which soon dries in the open air, and forms a brittle resinous-like substance, very similar in appearance to over-tanned leather. It is perfectly insoluble in water, and is not susceptible of putrefaction. It is this combination of tannin with gelatin that constitutes the preservative part of tanned leather, and which enables it to resist the transmission of moisture. The solutions of tannin most conveniently applicable as tests of gelatin, may be prepared by an infusion of an ounce of gall-nuts in a pint of water; or, as Dr. Bostock has proposed, the extract of rhatania, digested in hot water, and filtered after it becomes cold. A considerable precipitate is produced by these infusions, when the proportion of gelatin to the water is so small as to compose only the five thousandth part of the solution. The precipitate afforded by tannin is not, however, to be considered as a decisive test of the presence of gelatin; for, as we shall presently find, it also occurs in consequence of the presence of albumen. In order to prevent any confusion from this cause, it will be necessary to have recourse also to another test, that of corrosive sublimate, which is found to precipitate albumen, but not gelatin. If, therefore, by adding corrosive sublimate, we obtain no precipitate, we may be certain of the presence of albumen.

(283.) Gelatin is insoluble in alcohol, but when already in solution in water, it is not precipitated by that fluid. Acids dissolve it with great facility, even when much diluted, especially when aided by heat. The nitric acid effects its decomposition, during which nitrogen, and then nitrous gas, are disengaged in considerable quantities; and oxalic and malic acids are evolved, and may be obtained from the residuum. Sulphuric acid, with the assistance of heat, partly converts it into a substance resembling sugar. Chlorine combines with gelatin, forming a white substance, which assumes the form of filaments.

The pure liquid alkalies dissolve gelatin very readily. The solution is a brown viscid substance, which possesses none of the properties of soap, and is not precipitated by acids. This property of remaining dissolved after acids are added to the alkaline solution, distinguishes gelatin from albumen, fibrin, and other animal products, and is therefore a valuable mode of discriminating its presence, and of separating it from them in analysis.

(284.) Gelatin is precipitated by several of the metallic salts and oxides, but not so unequivocally as to afford satisfactory tests of its presence. Like all the other constituents of animal bodies, gelatin, while it preserves its essential properties, is susceptible of many shades of variation, and appears therefore under a diversity of forms, such as glue, size, isinglass, &c; but although many valuable remarks on this subject are contained in Mr. Hatchett's *Observations on the Component Parts of Animal Membrane*, published in the Philosophical Transactions for 1800, we are still very much in the dark as to the circumstances which occasion the differences in the several kinds of animal gelatin.

5. *Albumen.*

Albume

(285.) The proximate principle which, from its composing the greater part of the white of the egg has been termed *albumen*, is most abundantly met with in almost all the parts of animals, whether solid or fluid. It is the chief basis of several of the more solid textures of the body, such as the membranous and fibrous structures, and the parenchymatous substance of the glands and viscera; and it also forms a large proportion of the blood and of the secreted fluids.

In the white of the egg, albumen exists in a state of solution in water, and combined with a small quantity of soda. By agitation with a still larger quantity of water, the two fluids unite, and form a viscid liquid, the component parts of which do not separate by standing.

(286.) The characteristic property of albumen is its capability of coagulating, or passing from a liquid to a solid form, by the action of heat, of acids, and of alcohol, and several metallic salts and oxides. This change takes place in undiluted albumen, at a temperature of about 160° of Fahrenheit. After it has been once coagulated, albumen is no longer soluble in water, unless by long boiling, aided by pressure. By a long continued gentle heat, coagulated albumen gradually has its moisture dissipated, and the solid matter, amounting to about one-fifth of the original weight, is left behind, in the form of a hard brittle transparent substance.

(287.) If the albumen be much diluted, it appears to be incapable of coagulation by the usual means; but still it was found by Dr. Bostock, that a solution containing only one thousandth of its weight of albumen, although not properly coagulated, was rendered perceptibly opaque by a boiling temperature; so that heat may be considered, for all practical purposes, as a sufficiently accurate test of its presence in any fluid. During coagulation there is no absorption of oxygen; nor is any gas extricated: and hence there appears to be no reaction of the principles of the albumen upon each other. The nature of the change which takes place during this transition from the fluid to the solid form, is by no means well ascertained. Dr. Thomson supposed the fluidity of albumen to depend on the presence of alkaline matter; and its coagulation to the removal or neutralization of this alkali; and some experiments which were devised by Mr. Brande tend strongly to support this theory. He found that a rapid and abundant coagulation took place in the white of an egg subjected to the action of a galvanic battery, around the negative pole, where the alkali must have been separated; while a thin film only collected round the positive pole. He discovered also, by these experiments, that galvanic electricity may be applied successively to the detection of very minute quantities of albumen, which would not be rendered sensible by any other test.

(288.) Another agent which immediately effects the coagulation of albumen, unless it be previously much diluted, is alcohol. Ether also produces the same effect.

(289.) Acids in general occasion the coagulation of albumen; but several of them afterwards redissolve the coagulum if assisted by heat. This is at least the case with the three mineral acids. The coagulum formed by acids always retains in combination a portion of the acid which has been employed. That produced by nitric acid is the least soluble; and hence nitric acid occasions a precipitate from solutions of albumen, which are so dilute as not to be affected by other acids. Thenard remarks that the coagulum produced by acids, is re-dissolved by pure alkalies, and even by ammonia, which does not dissolve albumen that has been coagulated by heat. Nitric acid, when concentrated, decomposes albumen, extricating from it azotic gas, and during its solution, nitrous gas. Oxalic and malic acids are formed, and a thick oily matter, soluble in alcohol, appears on the surface. On the other hand, when coagulated albumen is subjected to the action of dilute nitric acid, it is after some time converted into a substance having the properties of gelatin. For this highly curious fact we are indebted to Mr. Hatchett.[1] Alum, probably in consequence of its excess of acid, coagulates albumen, provided the solution be not very dilute. One part of albumen in five hundred of water is rendered slightly turbid by a solution of alum, but without any formation of a precipitate.

(290.) The triple prussiate or ferrocyanate of potass is, according to Dr. Henry, an extremely delicate test of the presence of albumen, and may be used to discover it in fluids to which other tests are inapplicable. To enable it, however, to produce a precipitate, a very slight excess of acetic acid should be previously added, either to the test, or to the liquid suspected to contain albumen.

(291.) Another delicate test of the presence of albumen is a solution of corrosive sublimate; and it is the more valuable, inasmuch as it has no effect on solutions either of gelatin or of mucus. Dr. Bostock found that a single drop of a solution of corrosive sublimate added to a liquor containing one thousandth of its weight of albumen, renders it visibly milky, and at the end of some hours a flocculent precipitate falls to the bottom of the vessel. The same re-agent produces a sensible effect on a liquid, containing only half that quantity, or one two-hundredth of albumen.

(292.) Many other metallic salts, throw down a precipitate from solutions of albumen, as the acetate of lead, the nitro-muriate of tin, the nitrate of silver, and the nitro-muriate of gold; but as they produce a similar effect on other species of animal matter, they are scarcely deserving of confidence as tests of any one in particular. A solution of tannin, which, when added to albumen, occasions, after some time, a precipitate, may sometimes afford useful indications in analytical inquiries, for it may be distinguished from that produced from gelatin by its want of density and cohesion.

(293.) Albumen is readily dissolved by the pure liquid alkalies, which disengage ammonia from it, and form with the residue a saponaceous compound. This soap, when dissolved in water, is precipitated by acetic or muriatic acids.

6. *Fibrin.*

Fibrin.

(294.) The proximate animal principle, known by the name of *fibrin*, or *animal gelatin*, exists in large quantity in the blood, and forms the basis of the muscular flesh of animals. When properly prepared, and freed from the admixture of extraneous matter, it presents a substance of a white colour, destitute of taste or smell, of a fibrous texture, and of a soft and elastic consistence. When dried it is brittle, and has a certain degree of transparency; it undergoes no change from the action of either air or water.

(295.) When exposed to heat, it contracts very considerably, and exhibits movements like horn, exhaling at the same time the smell of burned feathers. When subjected to great heat, it yields the usual animal products of water, oil, ammonia, carbonic acid, and carburetted hydrogen, with a large carbonaceous residuum. This charcoal is very difficult to incinerate, owing to the presence of phosphoric salts, which are fused by the heat employed for that purpose, and form a glassy coat on the surface. A considerable quantity of carbonate of lime is found in the residual ashes.

(296.) The acids exert a considerable action upon fibrin. Concentrated acetic acid renders it soft and transparent; and the whole mass is converted by heat into a tremulous jelly. By the addition of water, and the continued application of heat, a complete solution is effected, attended with the evolution of nitrogen. Fibrin combines with muriatic acid in two proportions; the one gives a neutral compound soluble in water; the other, containing an excess of acid, is insoluble, but becomes soluble by the action of pure water. Concentrated sulphuric acid decomposes and carbonizes fibrin. Diluted with six times its weight of water, this acid acquires a red colour by being digested with fibrin, but scarcely dissolves any sensible portion; but part of the acid is absorbed by the remaining mass, which becomes a compound of fibrin and an excess of sulphuric acid. Water deprives it of this excess, and a neutral combination is obtained, which is soluble in water, and has the same characters as neutral muriate of fibrin. The action of nitric acid upon fibrin is much diversified, according to its dilution or state of concentration. When the acid is diluted with a large quantity of water, a great abundance of nitrogen gas is disengaged. This gas is entirely derived from the fibrin, and not from the acid, which, as Berthollet ascertained, has suffered no decomposition during the process. The residuum, in this case, is principally oxalic acid, with a small quantity of malic and acetic acids, and a portion of fatty matter. When the nitric acid is undiluted, on the other hand, it undergoes decomposition, and nitrous gas, mixed with nitrogen gas, is disengaged. When fibrin is digested for twenty-four hours in nitric acid of the specific gravity 1.25, it is converted into a pulverulent mass, of a pale citron colour, which is deposited at the bottom of the liquid. By washing it in water, the excess of acid is carried off, and the colour gradually becomes of a deep orange. Fourcroy and Vauquelin considered this yellow matter to be a peculiar acid, which they distinguished by the name of the *yellow acid.* But Berzelius has shewn that it is merely fibrin combined with nitric and malic acids. When the action of nitric acid on fibrin is very slow, it is gradually converted into a state somewhat analogous to gelatin.

---

[1] See his paper already quoted from the *Philosophical Transactions* for 1800.

(297.) Fibrin, when subjected to the action of caustic alkali, increases in bulk, becomes transparent and gelatinous, and at length is entirely dissolved, forming a yellowish green solution. From this solution it is precipitated both by acids and alcohol, but seems to have undergone some change for it is not as before, soluble in acetic acid. Fourcroy had asserted, that the compound of fibrin and alkali resembles soap; but it does not, in fact, appear to have any analogy with saponaceous bodies.

(298.) Alcohol of the specific gravity of 0.81, converts fibrin into a kind of adipocirous matter, which is soluble in alcohol, and precipitated by the addition of water. It has a strong and unpleasant odour. The alcoholic solution leaves, on evaporation, a fatty residue, which did not pre-exist in the fibrin, but which, like the original substance, is soluble in acetic acid. By the action of ether, fibrin is converted into the same kind of adipocire, but which has a more offensive odour, and is in larger quantity.

Analogies between them.

(299.) After the account we have given of the three proximate principles which enter so largely into the composition of animal matter, namely, gelatin, albumen, and fibrin, it will be useful to take a comparative view of the analogies they present, and of the differences by which they are distinguished, both in their properties and composition. They are apparently composed of the same ultimate elements, combined in proportions which are not widely different. They admit accordingly of mutual conversion into one another, by processes which produce a slight alteration in the proportion of their constituents. By the action of the nitric acid fibrin is converted into a kind of gelatin, and a similar change has been effected on albumen by the same re-agent. All these substances are presented both in the liquid and solid forms, and pass readily from the former to the latter of these states, without any apparent change in their chemical constitution. They are all of them indestructible when perfectly dry, but readily undergo putrefaction when united with water. Yet the modes in which they are respectively acted upon by water are different, and affords an easy character of distinction between them. Gelatin is soluble in cold water; the solution when evaporated becomes gelatinous; and if this jelly be dried, it is still again soluble. Albumen is likewise soluble in water; but whenever the temperature is raised to 170°, it separates by coagulation, and this coagulum is not again soluble. Fibrin is clearly distinguished by its total insolubility in water at any temperature, at least under the common atmospheric pressure.

Comparative analysis.

(300.) Then these principles likewise differ in their composition; for though they seem to consist of some ultimate principles of nitrogen, hydrogen, oxygen, carbon, phosphorus, and sulphur, yet these differ somewhat in their proportions. The most accurate analysis of these substances into their ultimate elements are those of MM. Gay Lussac and Thenard, the results of which are exhibited in the following table:

	Gelatin.	Albumen.	Fibrin.
Carbon,......	47·881	52·883	53·360
Oxygen,......	27·207	23·872	19·685
Nitrogen, ...	16·988	15·705	19·934
Hydrogen,...	7·914	7·540	7·021
	100.	100.	100.

It appears from the above analysis, that the principal difference of composition occurs in the proportion of nitrogen. Gelatin contains the least of this element; albumen more; and fibrin a quantity considerably larger than either of the others. The latter substance appears therefore to be the most animalized product. It also contains the largest quantity of carbon, as appears indeed from the greater residuum of charcoal which it leaves after destructive distillation. Sulphur is perhaps peculiar to the composition of albumen. On the other hand, the proportion of oxygen is considerably greater in gelatin than in either of the other two substances. This predominance of oxygen, together with the less compactness of its mechanical composition, are probably the causes of the greater tendency which gelatin shows to pass into the acid fermentation. In this respect also, gelatin shows itself to be less completely animalized than the other proximate principles, and to partake more of the chemical character of vegetable substances, which are well known to evolve an acid in the progress of spontaneous decomposition. There are indeed some vegetables, as the tribe of fungi, that become alkaline by their putrescence; and these are found to contain nitrogen; so that gelatin on the one hand, and the fungi on the other, may be regarded as forming, on each side, the connecting links between these two great kingdoms of nature.

(301.) It is a curious subject of speculation to reduce the proportions resulting from the analysis of the French chemists, to those which are most reconcileable to the atomic theory. They will then stand as follows:

Number of atoms of	In Gelatin.	In Albumen.	In Fibrin.
Carbon,............	15	17	18
Oxygen,............	6	6	5
Nitrogen, ...	2	2	3
Hydrogen, ...	14	13	14

The weights, both absolute and relative, of the atomic elements, are shewn in the following table:

	Gelatin.		Albumen.		Fibrin.	
	Absolute.	Relative.	Absolute.	Relative.	Absolute.	Relative.
Carbon,....	90	50·00	102	53·40	108	52·94
Oxygen,...	48	26·67	48	25·13	40	19·61
Nitrogen,..	28	15·55	28	14·67	42	20·59
Hydrogen,	14	7·78	13	6·80	14	6·86
	180	100·	191	100·	204	100·

In the conversion of albumen into jelly, by the slowly continued action of nitric acid, we may conclude that the acid imparts a portion of its oxygen to the albumen, and perhaps adds also a small quantity of nitrogen; thus constituting the proportions assigned to gelatin by Gay-Lussac and Thenard.

7. *Mucus.*

M s.

(302.) The term *mucus* has been employed in very different senses by different writers. Some have applied it vaguely to almost every animal substance which was not referable to any other class. Fourcroy and Vauquelin, while they include under this term the viscid secretions which lubricate the alimentary and other passages that open at the surface of the body, they have admitted its claim to be considered as a peculiar proximate principle, but regard it as analogous to vegetable gum, from which they suppose it to differ only by containing a proportion of nitrogen. Their descriptive account of its properties, however, are deficient in the precision which the subject seems to require, and which have been aimed at by subsequent chemists. Berzelius, it is true, refuses to allow that there is any such common principle as mucus, and founds his opinion on the ground that the chemical characters of the fluids which bear that name, are very various in different parts of the body, and are modified in different situations, according to the particular purposes they are intended to fulfil. Mr. Hatchett, in his interesting paper on *the Component Parts of Animal Membrane*, has attempted to fix the meaning of the term more definitely. Viewing mucus as extremely analogous in its properties to gelatin, he considers these two substances as merely modifications of each other; the former characterized by its incapability of being gelatinized; the latter by possessing that property; while both are soluble in water.

Dr. Bostock, in his excellent papers on *the Analysis of Animal Fluids*, has endeavoured to establish definite characters as belonging to this fluid, when existing in a state of purity. He states that if the solid matter obtained from the evaporation of saliva to dryness, be re-dissolved in water, and filtered, the solution will consist of mucus alone, or with scarcely any extraneous substance. By a careful evaporation he found that the solution contained one two-hundredth part of its weight of mucus. He also obtained a similar principle by macerating an oyster in water, and evaporating the liquid. It thus appeared that the water had dissolved about one-fiftieth of its weight of animal matter. Mucus thus obtained resembles gum-arabic, excepting that it is somewhat more opaque. Like it, it has scarcely any taste, dissolves readily in water, and forms an adhesive solution. Alcohol added to this solution has no tendency to coagulate it. No appearance of coagulation is produced by exposing the fluid for some time to the heat of boiling water; nor is there any tendency to gelatinize, by evaporating and afterwards cooling the fluid. No distinct effect is produced on the solution of mucus, either by the nitro-muriate of tin, corrosive sublimate, or the infusion of galls. The subacetate of lead, or Goulard's extract, occasions an immediate opacity, and after some time, a flaky precipitate.

(303.) Dr. Bostock concludes that a decided and essential difference is thus established between mucus and jelly, by the different effects produced by tannin, and by subacetate of lead. Tannin is a most delicate test of jelly, but does not in any degree affect mucus. Goulard's extract, on the other hand, is a delicate test of mucus, but does not in any degree affect jelly. The bichloride of mercury, (corrosive sublimate), on the contrary, which is one of the most accurate tests of albumen, does not appear to affect either jelly or mucus.

Notwithstanding the attempts which Dr. Bostock made to devise a method of directly determining the proportion of mucus in a compound fluid, he was not able to succeed, in consequence of the facility with which Goulard's solution decomposes the different extraneous ingredients, both animal and saline, which are almost always present in substances that contain mucus, even in a state the nearest approaching to purity. The salts are particularly liable to act upon the metallic solutions employed as tests; so that it is impossible to say how much of the effect is owing to each of these separate causes. The precipitates thrown down from mucus by subacetate of lead, and nitrate of silver, were found by Mr. Brande to consist both of the muriates and phosphates of those metals. Mr. Brande also attempted to obtain mucus free from neutral salts, by subjecting it to the action of galvanic electricity. He thus detected a small quantity of albumen in saliva, which was not discoverable by the ordinary tests.

(304.) A great resemblance has frequently been noticed between the mechanical properties of animal mucus and vegetable gum; and Dr. Bostock found that they strongly resemble each other also in their chemical qualities. A solution of gum-arabic, containing one grain of gum to two hundred grains of water, was not affected either by the bichloride of mercury, nor by tannin. With the nitro-muriate of tin, and with the nitrate of silver, there was only a slight degree of opacity; but with the subacetate of lead there was a dense precipitate instantly formed.

(305.) On the whole, however, animal mucus in its chemical relations appears to be most nearly allied to albumen; and the constituent upon which its characteristic properties principally depend, would seem, as Dr. Bostock remarks, to be a mere modification of this substance.

Method of analysis.

(306.) We shall conclude our account of this substance by the following direction as to the order in which it will be most convenient to conduct our analytical inquiries of a fluid, which may be supposed to contain either albumen, jelly, or mucus. The first step is to observe the effect of the bichloride of mercury; if this produce no precipitate, we may be certain that the fluid in question contains no albumen. We should next employ the infusion of galls, and if this also occasion no precipitate, we may conclude that the animal matter held in solution consists of mucus alone. Such being the chemical properties of the chief proximate principles of animal organization, we have next to examine the mode in which these substances are produced in the economy.

Sect. II.—*Arrangement of the Functions of Assimilation.*

Reparatory or chemical functions.

(307.) The means provided by nature for meeting the various demands of the system, by converting materials derived from without into the proximate principles of animal organization, the properties of which we have now examined, constitute a separate class of functions distinct from all the others. They might not unaptly be termed the *reparatory functions;* but as the changes which are effected in the materials received into the body for its conversion into nutriment are wholly of a chemical nature, we thought they might, with still greater propriety, be termed the *chemical functions*, in contradistinction to those the objects of which are entirely of a mechanical nature, and which have already passed under our review.

(308.) The reparatory, or chemical functions, may be divided into two great orders; the first consisting of those which effect all the changes that the food undergoes during its conversion into blood; the second, of those which apply the blood, or nutriment thus properly prepared, to the various purposes for which it is wanted, and which effects in it those chemical changes that are required for those objects.

Series of reparatory processes.

(309.) The first order may again be subdivided into several subordinate processes, including, 1st, The preparation which the food undergoes in the mouth by *mastication*, or mechanical division. 2d, Its admixture with saliva and other secretions, which is generally termed *insalivation.* 3d, Its *deglutition*, or conveyance into the stomach. 4th, Its *digestion* in that cavity, and conversion into chyme, which may properly be termed *chymification.* 5th, The subsequent changes it undergoes in the intestines, by the influence of various agents, such as the bile, the pancreatic and intestinal secretions; and its ultimate conversion into chyle, and separation from the excrementitious portion, comprising the processes of *chylification*. 6th, Its *absorption* by the lacteals, its transmission to the heart, and its *sanguification*, or conversion into blood. To the above functions the title of *natural functions* was given by the older physiologists, and the name is retained in many modern works in medicine.

(310.) The second order comprehends, in like manner, a number of most important functions, which, from their immediate influence on the continuance of life, have been emphatically denominated the *vital functions*. They consist, 1st, of the *Circulation* of the blood, by means of the heart, arteries, veins, and capillary vessels. 2d, *Respiration*, by which every portion of the blood is subjected in its turn to the chemical action of the air respired; is freed from its excess of carbon, and becomes oxygenated, or arterialized, and fit to be applied to the purposes of the system. 3d, *Secretion*, a term which expresses a variety of changes effected in the blood, by passing through glands and other secreting organs, adapting it to different purposes in different cases. Closely allied in its object to secretion is the function of (4th) *Nutrition*, whereby the several parts of the body receive accessions to their growth, and are maintained in the condition requisite for the perfect performance of their requisite offices. 5th, *Absorption* by the lymphatics, for the removal of all superfluous or decayed particles in the body. 6th, The last function in this order, which completes the series of chemical changes going on in the living laboratory of the body, is *Excretion*, or the separation of useless or noxious materials from the blood, and their rejection from the system. We shall proceed to the consideration of these functions in the order in which they have been enumerated. But for the proper understanding of the subjects they involve, it will be necessary to premise an inquiry into the chemical nature of the substances which are received into the body as food.

Sect. III.—*Properties of Food.*

Properties of food.

(311.) The food of man is more various in its kind than that of any other animal; for it comprehends a great multitude of articles both of an animal and vegetable nature. Hence man has been regarded as entitled to the appellation of an omnivorous animal. His powers of digestion, however, though capable of being exercised upon a great variety of materials, are yet inadequate to the assimilation of many substances, which form the exclusive food of several of the larger quadrupeds whose structure and economy are not very remote from those of man. The human stomach and intestines are incapable of extracting nourishment from the fibrous or membranous parts of vegetables, like the ox, the sheep, and other herbivorous animals; nor have they the power of digesting hard and solid bones, like the hyæna, the dog, and other highly carnivorous quadrupeds. Neither the leaves of trees nor the grasses, have ever, in any age or country, been used as the food of man. Many savage races of the American continent, though possessing vast tracts of country abounding in trees and grass, have frequently been visited by the extremes of famine, by which whole districts have been depopulated. When Australia was first visited by Europeans, the native inhabitants were found only occupying the sea-coast, gathering up a scanty and precarious subsistence from the shell-fish casually thrown upon the shore; but the settlements which have since been made have occasioned their retirement into the interior, and their numbers have rapidly diminished. It is obvious that, had the leaves of the vegetables which grow wild in those regions been capable of affording the smallest sustenance, they would have necessarily been resorted to in these extremities of hunger. But no authenticated instance of the kind occurs in the history of the human race.

Food of man.

(312.) Man, however, seems to enjoy the exclusive privilege of having organs of digestion equally adapted to the assimilation of both animal and vegetable aliment of certain kinds; and the range which is allowed him in this respect is most extensive. Hence we find, that in most countries where there prevails a high degree of civilization, and where religious scruples do not interfere, both animal and vegetable food is indiscriminately employed by all who can procure them. In many parts of the globe, indeed, necessity compels a restriction to certain kinds of diet; and in some the same restriction is imposed as a religious duty. Thus the Gentoos live entirely on the vegetable produce of the earth, to which, however, they add the highly nutritious article of milk. The Birmans, who are a remarkably active and robust race, are said to live exclusively upon vegetable food. On the other hand, the inhabitants of the mouths of many of the African rivers, live wholly upon the produce of the ocean. The flesh of the rein-deer constitutes the principal food of the Laplander. In general it would appear that the inhabitants of cold climates consume a larger proportion of animal food than those of the torrid zone. Whence it has been, with much probability, inferred, that less combustible matter is required by the system in situations where the external temperature is habitually high; a remark which, if well founded, is conformable to the principle already laid down in our statement of the purposes to which a portion of the food is applied, namely, that of keeping up the animal temperature. In the ruder periods of society, when the arts of civilization had not yet diffused their beneficial influence over mankind, it is probable that men were more carnivorous than in the present state of the world. The introduction of the use of corn, and other grains of the same class, has effected in this respect an important change in the condition of the species; but it would appear that the introduction of this great benefit was very gradual, and must have required a long succession of ages before the cultivation of the gramina had attained any degree of perfection.

1. *Animal Food.*

Animal food.

(313.) The parts of animals which are chiefly consumed as food is the muscular flesh; but milk, and the different products obtained from milk, together with eggs, also compose articles of diet. The animals from which these aliments are derived, are principally the herbivorous mammalia, different tribes of birds and fish, a small number of the class of reptiles, and several species of mollusca and crustacea. The flesh of the mammalia and of birds consists principally of fibrin and gelatin, intermixed also with fat. Milk may be considered as an emulsion of albumen, oil, and sugar, suspended in a large quantity of water. The two former ingredients, when obtained separately, constitute respectively cheese and butter. The eggs of birds chiefly contain albumen, together with a small quantity of oil. Fish contains less fibrin, but a larger proportion of albumen and gelatin than the flesh of either quadrupeds or birds; and in some fish there is joined to these constituents a large quantity of oil. This also is the case with those crustacea and mollusca which are used as articles of diet. When we come, therefore, to analyze the proximate principles from which animal nutriment is derived, we find them reducible to the following: namely, fibrin, albumen, oil, gelatin, and sugar; together with a few others, such as ozmazome, which are of minor importance.

2. *Vegetable Food.*

Vegetable food.

(314.) The parts of vegetables most frequently consumed as food, are the seeds, seed-vessels, fruits, stalks, roots, and tubera, and more commonly the leaves. The most nutritious amongst the proximate principles resulting from the analysis of these vegetable materials, are gluten, farina, mucilage, oil, and sugar. The seeds of the cerealia or of rice constitute the chief bulk of the food in those countries where civilization has made any considerable progress. Of all these kinds of grain, wheat appears to contain, in proportion to its bulk, the greatest quantity of nutriment; and this arises from its abounding in gluten, which of all the vegetable principles appears to be best adapted to the human organs of digestion. In its properties it bears a strong resemblance to animal substances; and it appears, indeed, by chemical analysis, to contain a large proportion of nitrogen. Hence it may be considered as the most animalized of the vegetable products. Gluten is contained in most vegetables which afford farina, and is also found in the leaves of many esculent vegetables, such as the cabbage.

Farina.

(315.) *Farina* is found in great abundance in wheat and other grains, and also forms a large proportion of the nutritive portion of rice, and of certain tubers, among which the principal is the potatoe. The leaves, stalks, and seed-vessels of plants are rendered nutritious by the mucilage which they contain, which is generally united with a portion of sugar.

Sugar.

(316.) The saccharine principle contained in vegetables, and blended with their other elements, contributes greatly to render them nutritious; though in its pure state, as extracted from the sugar-cane, or the beet, it is rather used as a grateful addition to other articles of diet than as a separate source of nutriment. Sugar may be extracted from a great variety of plants besides those above mentioned. The maple, the birch, the parsnip, the cocao-nut, walnut, maize, and carrot, contain it in great abundance, as is the case, indeed, with every species of grain used as food. Almost all fruits are more or less saccharine. Figs, grapes, and dates, which contain it in large quantity, form a very considerable proportion of the food of the inhabitants of the south of Europe, and the African nations on the borders of the Mediterranean. All fruits contain a basis of mucilage, and in many this mucilage is combined with oil as well as with sugar.

Scale of nutriment.

(317.) Attempts have frequently been made to reduce all nutritious substances to a single principle common to all of them, and to establish accordingly a scale of nutriment, the place which any substance should occupy on that scale being regulated by the proportion in which this essential principle existed in it. Haller conceived that jelly might be considered as fulfilling this condition, and as being the essentially nutritive substance in nature.[1] Cullen thought that this property appertains to two substances, the nutritious matter being either of an oily or saccharine nature, or consisting of these two qualities combined.[2] Richerand considers alimentary matter as either gummy, mucilaginous, or saccharine.[3] Dr. Fordyce referred all nutriment to the presence of mucilage.[4] All these, and many other attempts at generalization, made by different physiologists at different times, are premature and unphilosophical, since they associate in the same class substances having properties totally dissimilar, although they concur only in that of affording materials for the support of the animal system. Perhaps the most exact classification of the kind is that of Magendie, who refers all alimentary substances, whether animal or vegetable, to the following heads, namely, farinaceous, mucilaginous, saccharine, acidulous, oily, caseous, gelatinous, albuminous, and fibrinous.

(318.) Prout, in a paper published in the *Philosophical Transactions*,[5] thinks that all the articles of food used by man may, according to their chemical relations, be arranged under three heads, namely, the saccharine, the albuminous, and the oily. Sugar, the basis of the first class of alimentary substances, he finds to consist of carbon in different proportions, from thirty to fifty per cent. chemically combined with water. The basis of albumen and oil are more compound, but are also united with water, the proportion of carbon existing in some of the oils being nearly eighteen per cent. He is of opinion that two at least of these elements must be blended together in our food in order to render it either nutritious or digestible. Milk, the food provided by nature for the young animal, exhibits the most perfect union of these three elements.

Oil.

(319.) It must be evident, however, upon a slight consideration, that notwithstanding all the attempts that have been made to establish an accurate scale of nutriment, more must depend upon the powers possessed by the digestive organs to convert the particular kind of food into nutritious matter, than upon its being able to supply the elements requisite for composing nutriment. Thus there are many substances, such as oil for example, which contain a very large proportion of the elements which compose the blood, but which are extremely difficult of digestion, and consequently cannot of themselves be considered as nutritious, although when blended with other substances which contain fewer of these elements, but which enable the stomach to exert a proper action upon the compound, they become highly nutritive. This remark applies also to sugar, which, although adding considerably to the nutritive qualities of those vegetable products which contain it, would not, if used alone, be capable of supporting life. Magendie found, that dogs fed upon sugar alone soon became unhealthy, and if that diet was persisted in, perished from inanition.[6] Dr. Stark made numerous experiments upon himself, to which, indeed, he ultimately fell a victim; from these it appears, that substances which afford most nutriment, if their use be persevered in for any length of time, to the exclusion of other diet, soon produce derangement of the stomach, and failure of its digestive power. Peculiarities are often met with in the stomachs of different individuals with respect to the power of digesting particular kinds of food. In this respect much depends upon previous habits; so that it is scarcely possible to establish any general rules with regard to the nutritious qualities of different species of aliment, that are not invalidated by innumerable exceptions. The quantity of liquid that is taken in along with the solid food is also exceedingly various in different individuals; that which is suited to the digestion of the one being found to disagree with another. If we except soups, which of course consist of the soluble parts of materials out of which they are prepared, and also milk, the liquids received into the stomach rarely contain any notable proportion of nutritious matter, but seem rather to aid the digestion of more solid food, either by supplying the place of a solvent, or by acting as a stimulus to the stomach. They are also in many cases necessary for supplying the loss occasioned by perspiration, which in hot climates, by regulating the temperature of the body, is essential to the preservation of health. These purposes are answered by many vegetable infusions, such as tea and coffee, and also by fermented liquors, although the latter contain to a certain extent many of the materials of nutrition, such as sugar and mucilage, besides the stimulant principle of alcohol.

3. *Condiments.*

Condiments.

(320.) With a view to the same stimulant effect, various substances are added in small quantities to our food, which act as condiments. Of these the principal is common salt, a taste for which seems to be natural to a great number of animals, and which, used in small quantity, has the effect of promoting digestion. Other condiments, such as pepper, mustard, garlic, and various other spices and aromatics, are employed chiefly from the agreeable impression they make upon the palate; but they in many cases check the tendency to fermentation which many kinds of food are liable to undergo in the stomach. As a general rule, to which, of course, there are many exceptions, whatever is agreeable to the palate is adapted also to the digestive powers of the stomach. A certain degree of variety in the articles of diet is more conducive to the nourishment of the body than confinement to any single article.

Sect. IV.—*Appetites.*

1. *Hunger.*

Hunger.

(321.) Hunger is a peculiar sensation excited in the stomach by the want of food, and by the presence of the gastric juice in that organ conjointly. It is evidently an affection of the nerves of the stomach, for it is a good deal dependent on the state of the nervous system. Its periodical recurrence at stated times shews that it is a good deal under the dominion of habit. Hunger often suddenly ceases upon the occurrence of sudden emotions of grief or anger, and is much influenced by other causes of mental excitation. Literary men deeply absorbed in meditation often forget that they have occasion for nutriment, and are unconscious of the calls of hunger. Hence such persons are often great sufferers from disordered digestion.

(322.) The presence of the gastric juice appears however to be a natural stimulus to appetite, its primary action being probably in the nerves of the stomach. A similar effect may be produced, when the stomach is full, by taking spirituous liquors, or high-seasoned dishes. Those physiologists who were inclined to refer the phenomena of the living body to mechanical causes, ascribed the sensation of hunger to the friction of the surfaces of the stomach against one another, which they supposed took place when it was empty; but the anatomy of that organ, which, from its rounded form, and from the softness of its texture, would seem totally incapable of producing friction by any of its movements, is totally at variance with this hypothesis. Others have conceived that the collapse of the stomach in its empty state, by deranging the position of the liver and spleen, drags down the diaphragm, and thus excites irritation in the nerves of those regions; and they endeavour to support this doctrine by the alleged fact, that hunger is prevented and appeased by wearing a tight girdle, which occasions pressure on the stomach and gives support to the neighbouring organs. But the instances already given of the dependence of hunger on the states of the nervous system, are sufficient to prove that it is not owing to any mechanical cause.

(323.) The chemical physiologists attempted to explain the phenomena solely by the action of the gastric juice on the coats of the stomach, which they imagined it tended to corrode, and hence gave rise to an uneasy sensation. It is much more probable, however, that the impression made by this secretion is exclusively on the nerves of the stomach; and there is no doubt but that this action is one of the principal causes of hunger; for it has been found, that, if after long fasting, when there is a considerable accumulation of gastric juice, and when the sensation of hunger is extremely intense, it at once ceases if the gastric juice be removed by an emetic; or even if it be much diluted by taking large quantities of hot water.

(324.) The effects of long abstinence from food are, great loss of strength, emaciation, discoloration of the blood and of the secretions, an increase of nervous susceptibility, fever, loss of sleep, painful sensations in the region of the stomach, followed by total loss of appetite, delirium, and death. It has been said, that the exterior of the bodies of those who die of famine has exhibited a shining appearance in the dark, as if they had been impregnated with uncombined phosphorus.

2. *Thirst.*

Thirst.

(325.) Thirst is a sensation somewhat analogous to hunger with respect to its cause and effect, and with respect of its depending on particular states of the nervous system. It is considerably more distressing and intolerable than hunger. The seat of the sensation appears to be in the mouth and fauces, although its origin is generally in the state of the stomach, or general condition of the system. In the healthy condition of the organs it is a natural impulse prompting us to supply the system with the fluids requisite for carrying on its functions. But in the case of fevers, and other morbid states, thirst is sometimes excessive, and, if indulged without restriction, would prove highly injurious. In cases where a preternatural opening has been made into the œsophagus through the neck, the sensation of thirst is found not to be in any degree assuaged by fluids applied to the mouth, or even swallowed, if they escape through the wound, and do not descend into the stomach; whereas, it is immediately relieved when the same fluids are introduced into the stomach.

Sect. V.—*Preparation of the Food for Digestion.*

Prepara tory pr cesses.

(326.) The preparatory processes to which the food is subjected previous to its introduction into the stomach, are partly of a mechanical and partly of a chemical nature. It is masticated by the teeth and jaws, and at the same time mixed with the saliva and mucous secretions of the membrane lining the mouth, fauces, and œsophagus. The effect produced by these operations is to reduce the food to a soft and uniform pulp, which is more easily acted upon by the solvent powers of the gastric juice than if it had been swallowed entire.

1. *Mastication.*

Mastic tion.

(327.) During mastication a great number of muscles are called into action. The principal of these are the powerful muscles that elevate the lower jaw, namely, the temporal, the masseter, and the pterygoid muscles, the latter of which are capable of giving at the same time some degree of lateral motion to the jaw, adapting it thereby to effect a grinding action by the medium of the teeth. The lower jaw forms a lever of the third kind with a double angle, the fulcrum being at the condyles, which are curiously articulated with the skull, by means of an interposed cartilage. Its motions are almost entirely confined to those of elevation and depression; but it has also a more limited extent of lateral motion.

Teeth

(328.) The teeth, which are the great agents in mastication, have already been described and their different classes enumerated, under the head of ANATOMY. The respective purposes served by each class are sufficiently evident from their shape and position in the jaw. The incisor, or front teeth, are employed for cutting or dividing the food like a pair of shears or scissors; the cuspidati, or eye-teeth, placed a little farther back in the jaw, are particularly adapted to lay hold of, and tear asunder, fibrous textures that afford considerable resistance; their action may be compared to that of pincers. Mr. Hunter, after reviewing their different forms in the different tribes of quadrupeds, is enabled to trace a similarity in shape, situation, and use of the cuspidati, from the most imperfect carnivorous animal, which he believes to be the human species, to the most perfect carnivorous animal, the lion. The bicuspidati and molares compose what are called the grinding teeth, and their chief office is the trituration of substances already torn off by the cuspidati, or cut by the meeting of the incisors. The molares especially, being placed nearer to the articulation of the jaw, or centre of motion, act with greater power in exerting pressure on whatever is between them. If we wish to break a very hard body, the shell of a nut for example, we instinctively place it between the backmost molares, where the resistance it opposes to fracture acts by the shortest lever.

The bony substance of the teeth is preserved from the injury to which it would be exposed by the friction of hard substances, and by the contact of corroding fluids, and the influence of the air, by being cased in enamel, which, as we have seen, is considerably harder than bone. In consequence of the peculiar mode of its formation, the enamel is incapable of being renewed by a fresh growth when it has been worn away by friction. When, however, the teeth are lost by age, accident, or disease, their alveoli close and are obliterated by absorption; the gums then acquire a degree of hardness, that renders them an imperfect substitute for the teeth in mastication.

ongue.

(329.) The chief agent in distributing the food so as to place it in proper situations between the teeth for the purpose of mastication, and for transferring it to the fauces, is the tongue. This organ consists almost entirely of muscular fibres, which are variously arranged, and interwoven together in a very intricate manner, so as to render it capable of motion in every possible direction. Its root is affixed to a bone which is peculiar to it, called the *os hyoides*, from its resemblance to the Greek letter υ, which furnishes a basis of attachment to the greater number of the muscles of the tongue, and the extremities of which being extended considerably backwards, serve to keep the palate expanded and always prepared to receive the food. But the tongue also contains a set of muscular fibres, which proceed longitudinally through the centre of that organ, unattached to any bone, and serving to contract its length. The tongue is thrust out of the mouth, not by any power of elongation in the muscles, as might at first sight appear to be the case, but by the contraction of that portion of the radiating fibres proceeding backwards from the inside of the jaw and the os hyoides, and drawing forwards the root of the tongue when they act alone. This complex structure is admirably adapted to the great variety of uses to which the tongue is applied, not only in mastication and deglutition, but also in speaking.

(330.) The muscular actions of the lips and cheeks are also intimately concerned in mastication; and ample provision is made for their varied movements by being furnished with so great a number of muscles as those which cover the face, and are attached more or less to the lips and corners of the mouth.

2. *Insalivation.*

(331.) While the food is under the action of the organs of mastication which effect its mechanical division, it is at the same time mixed up with the saliva. This fluid is found, when chemically examined, to consist principally of mucus and albuminous matter held in solution in water, together with a small proportion of saline ingredients.

iva.

(332.) Dr. Bostock considered that he had detected two kinds of animal matter in the saliva, one composing the soft masses, and giving it its consistence and physical characters, nearly similar to coagulated albumen, the other dissolved in the water of the fluid along with the salts, and resembling the serosity of the blood.[1] Berzelius regards the former of these substances as corresponding in its properties to mucus, and states the saline ingredients to be chiefly alkaline muriates, with a small quantity of lactate of soda and of pure soda.[2] Tiedemann and Gmelin state the solid contents of the saliva to vary from one to twenty-five per cent, and to consist of salts, mucus, and ozmazome, to which are added, in some cases, a little albumen and a little fatty matter, containing phosphorus. The soluble salts consist of alkaline carbonate, which gives an alkaline character to the fluid, acetate, phosphate, sulphate, muriate, and sulpho-cyanate. The alkali in man is almost solely potass; while, in the dog and sheep, it consists of soda, with very little potass. The presence of sulpho-cyanic acid, on the other hand, is almost peculiar to the human saliva, being scarcely perceptible in that of the dog. Some insoluble salts, namely, phosphate of lime, carbonate of lime, and carbonate of magnesia, are also detected in the saliva, but in very minute quantity.[3] Leurat and Lassaigne, whose investigations were nearly contemporaneous with those of Tiedemann and Gmelin, represent the chemical properties of the chyle as being essentially the same in all animals, and consider the animal matter it contains as a species of mucus.[4]

(333.) When viewed by a good microscope, the saliva is generally found to contain globules of very minute size.

(334.) The saliva is secreted by the parotid and other glands in the vicinity of the mouth, and is poured out in considerable quantities during mastication. It has been estimated that about six or eight ounces of saliva are at each principal daily meal mixed up and incorporated with the food. It flows much more abundantly during a meal, and particularly if the food that is eaten possesses stimulating qualities, and has a sapid flavour. The quantity is augmented by the appearance, or even the idea of food, when the appetite is keen. The influence of the nerves which supply the salivary glands is very marked in regulating their secretions, as we shall have occasion to observe more at length, when we come to consider the function of secretion. The pressure of the muscles of the cheek on the parotid gland assists no doubt in the quick discharge of the secretion of that gland by its excretory ducts; and the same remark applies also to the submaxillary and sublingual glands, which also prepare saliva, and whose ducts open into the mouth; for we find, that during mastication all the muscles about the mouth are in continual action. The tongue presses the food on all sides, and thrusts it between the grinding teeth, while the muscles of the cheek, but more particularly the buccinator, against which the food is pressed by the tongue, forces it back again under the teeth, until the whole has been sufficiently subjected to their action; and during the whole of this time it is gradually receiving additions of saliva, which thus become intimately and uniformly mixed up with every portion of the divided food. When completely chewed, it is collected together on the surface of the tongue, which sweeps round the different parts of the mouth for this purpose, and moulds it into the form of a bolus; and the point of the tongue being then raised, and its basis depressed, an inclined plane is formed, along which the bolus is propelled backwards, and delivered to the pharynx, which is expanded to receive it.

3. *Deglutition.*

(335.) The action of swallowing, simple as it may appear to be, is in reality extremely complex, consisting of a succession of muscular contractions, nicely adjusted and balanced, so as to co-operate harmoniously in the production of one general effect, the descent of the food along the œsophagus. The whole exhibits one of the most beautiful examples of mechanical contrivance that is to be met with in the body.

Deglutition.

(336.) The pharynx, as we have seen, is a large muscular bag, shaped like a funnel, capable of being contracted in diameter, and of compressing its soft contents by means of the muscles which are expanded round it, and are called the constrictors of the pharynx. Other muscles are provided for elevating it, that is, for bringing it nearer to the base of the tongue. While the food is passing downwards, the velum pendulum is expanded, thrown backwards, and raised by the muscles adapted to perform these motions, so that it closes the posterior nostrils, and acting as a valve, prevents any portion of what is swallowed from passing either into those cavities or into the eustachian tubes. The bolus is thus directed towards the œsophagus, being carried thither by the peristaltic motion of the pharynx, while the root of the tongue being at the same time depressed, the epiglottis is turned backwards, and being applied to the glottis, accurately closes its aperture, so that no part of the alimentary matter can pass into the larynx. The mass of food being now arrived at the upper part of the œsophagus, is propelled towards the stomach by the successive contractions of its circular fibres. The mucus, which is secreted in abundance by all the surfaces along which it passes, and continually lubricates them, very much facilitates its descent. The longitudinal fibres of the muscular coat of the œsophagus contribute their share in this action, by shortening and dilating those portions of the canal into which the food is about to enter. Dumas distinguishes four stages in this process; first, that by which the aliment is propelled towards the pharynx; the second, consisting in the dilatation of that cavity, by which it receives the bolus transmitted to it; the third, by which the pharynx closes upon its contents, and propels it downwards to the œsophagus; and the fourth, in which, by the action of the œsophagus, the food is propelled into the stomach.[1]

(337.) When any impediment exists to the due performance of these actions, fluids are swallowed with greater difficulty than solids, because the particles of the former having a continual tendency to spread themselves, it requires a closer and more exact application of the organs to prevent their escape, while they are compressed in giving to the fluid its proper direction. The action of suction performed by the tongue, with the assistance of the muscles of the cheeks and lips, which remove the pressure of the atmosphere from the surface of the fluid to which the mouth is applied, is also very complex. The tongue acts here as a piston; and sometimes the action is effected by the muscles of inspiration.

Sect. VI.—*Digestion or Chymification.*

Digestion. Office of the stomach.

(338.) The food has now passed from the œsophagus into the stomach, through its cardiac orifice, which has so been named from its supposed sympathy with the heart, near which it is situated. The office of the stomach is to convert the food which it receives into the soft pultaceous mass of a grey colour, which has been denominated *chyme*.[2] These secretions do not proceed from any glands that admit of being readily distinguished, their existence being rather inferred from the presence of the secretion. The membranes composing the coats of the stomach are capable of great distension, so as to contain a large quantity of food, while at other times that organ is contracted to a very small size, partly by the elasticity of its texture, but principally by the action of the circular and longitudinal fibres which encompass its cavity, and which constitute its muscular coat. These fibres are so disposed as to enable the different portions of the stomach to act separately and successively on its contents, producing what has been termed the *peristaltic*, or *vermicular motion*. Two purposes are answered by these actions; in the first place, the food contained in the stomach is agitated and thoroughly mixed together, while it is at the same time exposed to the chemical action of the gastric juice; and secondly, the ultimate effect of this motion is to carry the mass very gradually towards the pylorus, through which it is transmitted into the beginning of the intestinal canal.

(339.) While the food is thus rolled and agitated by the peristaltic action of the muscles, it is at the same time subjected to a degree of pressure, the purpose of which seems to be, to bring into closer approximation the solvent fluids with the materials on which they are to act, and thereby increase the chemical power of the former, and also to repress the evolution of gas, which has a tendency to be generated during the species of fermentation which the aliment undergoes in the process of digestion.

Gastric juice.

(340.) The principal agent in effecting those changes which constitute digestion, that is, which convert the aliment into chyme, is the gastric juice. The important office which this secretion performs has induced chemists to bestow great pains in obtaining its correct analysis, and in examining all its physical properties. When carefully collected, it appears to be a transparent and colourless fluid, having a saline and somewhat bitter taste, occasionally possessing acid properties, but probably in its natural and healthy condition being neither acid nor alkaline. It contains a small proportion of albumen, together with a matter which is either gelatin or mucus. But while it thus differs to all appearance in so trifling a degree from many of the other secretions, it yet possesses very extraordinary solvent powers over the substances usually employed as food. Even when made to act upon these substances in vessels out of the body, provided they are kept in a temperature equal to that of the human body, it will reduce them in a few hours to the state of a soft pulp, producing apparently the very same change which is induced upon the same species of aliment by the digestive process within the stomach. It is evident that the chemical analysis of the gastric juice affords as yet no clue to the explanation of this singular property. The power which the gastric juice possesses of coagulating milk, and other albuminous fluids, and of retarding the putrefaction of animal and vegetable substances subjected to its action, and even of counteracting this process when it has already commenced, are equally involved in mystery, and baffle all our endeavours to explain them on any of the hitherto known chemical principles.

(341.) There are three ways in which the gastric juice has been observed to act on alimentary matter; the first is that of coagulation, which is exerted on all the fluid forms of albumen, whether existing in the serum of the blood, or the white of the egg, or in different secretions, more especially milk. It is by means of this property, indeed, that cheese is obtained from the coagulation of its albuminous portion by the addition of rennet, which is an infusion of the digestive stomach of a calf. The object of this coagulation appears to be to detain the substance for a longer time in the stomach, and subject it more completely to the solvent power of the same fluid, by previously acquiring a solid form, which prevents its escape by the pylorus.

(342.) The second kind of action exerted on the food by the gastric juice is that of counteracting the tendency to putrefaction, and even to the ascescent fermentation. This effect takes place in a remarkable degree in many carnivorous animals, who frequently take their food in a half putrid state; and in whom the first operation of the gastric juice is to remove from it all putrescence; shewing that this secretion possesses the property not only of preventing putrefaction from taking place, but also of suspending its further progress when it has actually commenced.

(343.) The third species of chemical action exhibited by the gastric juice is that of solution. That this effect takes place independently of any concurrent mechanical operation of the muscular powers of the stomach has been very decisively proved by the experiments of Reaumur, of Stevens, and of Spallanzani. Those of Stevens in particular, are highly valuable, from being made on the human subject. He was fortunate enough to meet with a man who had been in the habit of swallowing stones, which he could afterwards, by a voluntary effort, reject by vomiting from his stomach. Taking advantage of this power, Stevens induced him to swallow hollow metallic spheres perforated with holes, and filled with different kinds of alimentary substances, which, after being allowed to remain a sufficient time in the stomach, were returned, and their contents examined. It was invariably found that the food under these circumstances of exposure to the gastric fluid alone, and protection from external pressure of a mechanical nature, was more or less completely dissolved, and reduced to the state of a pulp. He afterwards pursued a similar train of experiments on dogs, causing them to swallow the perforated spheres, and after a certain time destroying the animals, and examining the changes effected in their contents.

---

[1] *Physiologie*, tome i. p. 341.

[2] The older authors made no distinction between *chyme* and *chyle*, the latter substance being the product of the formation of the small intestines.

(344.) Spallanzani has also varied and multiplied experiments of this kind in a manner that leaves no room to doubt the truth of the conclusion deduced from them as to the solvent power of the gastric secretion. Dense membranes and even bones are reduced into a pulpy mass by this fluid in many animals, while at the same time many bodies of comparatively delicate textures, such as the skins of fruits, and the fibres of flax or cotton, are not in the slightest degree affected by it. This difference of action on different substances is analogous to the operation of chemical affinity, and corroborates the theory that digestion is effected principally by chemical agency. The results of these experiments have been fully confirmed by experiments made on the stomachs of persons, who, in consequence of a wound, had a permanent opening into that organ from the skin of the abdomen.

(345.) Portions of the stomach are sometimes found dissolved after death. This takes place more especially when death has occurred suddenly during the act of digestion. This effect can never take place during life, because the living structures resist the solvent power of the gastric juice, which affects only dead animal matter. Thus it happens that worms, and the larvæ of insects live for a considerable time in the stomach, without being acted upon by its secretions.

Evolution of gas.

(346.) Gas is frequently evolved in the stomach during the process of digestion; but this would appear to take place only in a disturbed or morbid condition of that process, and by no means to be a necessary attendant upon healthy digestion.

(347.) Acid is also frequently developed during imperfect digestion; but it appears from the experiments of Dr. Prout, which have been fully confirmed by other experimentalists, that this effect is also attendant upon healthy digestion, and that it is principally the muriatic acid which is thus disengaged from its combinations, and makes its appearance in a free state. The lactic acid, an acid which appears to be a modification of the acetic, also is present in considerable quantity.

Evolution of acid.

Professor Tiedemann and Gmelin, in an elaborate treatise on Digestion lately published, found the acetic acid always present in the gastric juice. They observe that water alone, at the temperature of the human body, is capable of dissolving many of the substances employed as food; and of these many that are not soluble in water are so in the diluted muriatic and acetic acids at a high temperature, and they are inclined to ascribe to a chemical solution of this kind the principal change effected by digestion.

(348.) Among the agents concerned in the digestion of the aliment, the high temperature at which the contents of the stomach and intestines is retained, must be considered as one of the most important. The heat of the body unquestionably tends to promote the chemical action of the secretions which effect these changes. While digestion is taking place, both orifices of the stomach are closed, and there often comes on a feeling of chilliness, especially in a weakly constitution, in consequence of the demand which the stomach makes upon it for an additional supply of heat to assist in the process that is going on. There is also disinclination to exertion, and frequently a tendency to sleep while digestion is performing. Yet the indulgence in this disposition, as well as violent exercise immediately after a meal, tend equally to retard the formation of chyme. The circumstances most favourable to perfect digestion, are gentle exercise, with cheerfulness, and moderate mental exertion.

(349.) It appears from Dr. W. Philip's experiments, which were conducted chiefly on rabbits, that food recently taken is always kept distinct and unmixed with that which has remained for some time in the stomach, the former being introduced into the centre of the mass previously present. The food is more digested the nearer it is to the surface of the stomach, and is least digested in the small curvature, more so at the larger end, and still more perfectly at the middle of the great curvature. The state of the food found in the cardiac portion is different from that found in the pyloric portion of the stomach; for in the latter it is more uniform in its consistence, more dry and compact, and apparently more thoroughly digested. Thus it would appear that it is at the large end of the stomach where the gastric juice is secreted in greatest abundance, that the first and principal operations of digestion take place, and that from this part the food is gradually propelled towards the small end, becoming more completely changed during its progress.

It appears from the experiments of De Beaumont on an individual who lived many years with a fistulous opening into the stomach, which allowed the contents of that organ to be at all times examined, that the different kinds of aliment all require to undergo the chemical action of the gastric juice in order to be reduced to the state of chyle; but that the rapidity of this process differs considerably, according to the delicacy of the natural texture of the food, and the extent of its previous mechanical division. Animal substances are found to be more rapidly converted into chyme than vegetable; and oily substances, although containing a large proportion of nutritious elements, are comparatively difficult of digestion. Some curious evidence was afforded by Dr. Roget and Dr. P. M. Latham, on the occasion of an epidemic scurvy which prevailed in the years 1823 and 1824, among the prisoners in the Milbank Penitentiary, that too liquid a diet, consisting of too large a proportion of soups, although abundantly supplied, did not furnish sufficient nourishment for the preservation of health; probably from their not being retained in contact with the coats of the stomach during the time requisite for their undergoing the process of digestion[1].

Theories of digestion

(350.) A great number of hypotheses were devised by the older physiologists in order to explain the process of digestion. These we shall only briefly enumerate, without engaging in any laboured refutation of what, in the present advanced state of science, does not require much examination to prove the fallacy. The ancients had generally adopted the opinion of Hippocrates, which was enforced by Galen, that the food was digested by what was called a process of *concoction*. This, however, seems to be only another term for digestion, instead of affording any explanation of its nature. Some physiologists considered digestion as resulting from a degree of putrefaction; a process which is in reality of a totally opposite nature, although agreeing in some minor points, such as the breaking down of the cohesion of the particles, and the occasional disengagement of gas. Others, reasoning from the analogy of the stomachs of granivorous birds, which are provided with a strong muscular apparatus for the purpose of grinding, conceived that a similar process took place in the human stomach, and that digestion was the effect of mechanical trituration. But the experiments of Stevens and Spallanzani, the results of which have been already stated, are alone sufficient to overturn this hypothesis.

---

[1] See *An Account of the disease lately prevalent in the General Penitentiary*. By P. M. Latham, M.D. London, 1825.

(351.) The earlier chemical physiologists ascribed digestion to a species of fermentation. This term, however, appears to have been misapplied, in as far as digestion is conceived to be identical with either the acetous or vinous fermentations; and if it were meant to convey the idea of a peculiar species of chemical change taking place in the stomach, and in no other situation, then nothing is gained by the substitution of the term employed for that of digestion, which must express precisely the same idea. More modern writers have imagined they were giving an explanation of the phenomena of digestion, by referring them simply to the action of the vital principle, or the vital powers, or the principle of life, or by whatever name they chose to designate an imaginary agent which gave rise to all those phenomena, not referable either to mechanical or chemical principles. But after the remarks we have elsewhere made on this radical error of substituting final for physical causes, and of prematurely generalizing the principles which actuate the living system, it is needless farther to insist upon the fallacy of this mode of reasoning.

(352.) A doctrine has lately been advanced, with greater semblance of truth, that digestion is essentially a nervous function; that is, one which is directly dependent on nervous power. A variety of facts unquestionably prove that the functions of the stomach are very much influenced by the states of the nervous system. The section of the par vagum, or eighth pair of nerves, in the neck of an animal, is followed by the almost total interruption of digestion; whence we may infer that the influence conveyed by these nerves is necessary both for the secretion of the gastric juice, and perhaps also for the muscular actions of the stomach. It is exceedingly remarkable, however, that where the galvanic influence is sent through the mutilated nerves, by means of a voltaic battery, digestion may be renewed, and goes on for a considerable time; whence it has been inferred by Dr. W. Philip, that the nervous power, or the agency which is conveyed through the nerves, and which influences secretion, is itself identical with the electric or galvanic fluid.

Function of the pylorus.

(353.) The pyloric orifice of the stomach is furnished with a circular band of fibres, covered by a fold of the nervous coat; and acting as a sphincter muscle, which closes the passage during the early stages of digestion, so as not to suffer the escape of the food until it has undergone the requisite changes which constitute its digestion. The aliment is conveyed to the pylorus in proportion as it has undergone these changes. There appears to exist in this part of the stomach a peculiar and extremely delicate sensibility, and a power of selecting those portions of the food that are properly digested, and of allowing them to pass, while those which are undigested are retained in the stomach.

It would appear, however, from some recent experiments, that a portion of aliment passes unchanged through the pylorus along with the chyme. We observe, for instance, that many hard substances, such as the stones of cherries and plums, find their way through the pylorus without much difficulty. The seeds of many plants are only softened by their detention in the stomach, and passing with no other change through the intestinal canal, are prepared for germination in the soil to which they may be transferred. Thus many species of plants and trees have been known to grow at places very remote from each other in consequence of their seeds having been conveyed by birds that had swallowed them.

CHAP. VII.—CHYLIFICATION.

(354.) The aliment, now converted by the process of digestion into chyme, after passing the pylorus, enters into the duodenum, which is the first of the small intestines. In the duodenum the chyme undergoes further changes, which are quite as great and as essential to its proper assimilation, as those which the food experienced in the stomach, and they are at the same time involved in equal obscurity. Almost all that is known respecting the nature of these changes, is, that soon after the chyme has been received into the intestines, it begins to separate into two parts; the one a white milky fluid, which is termed the *chyle;* and the other, residual matter, which afterwards becomes *fæces*, and is eventually ejected from the body.

(355.) Previously to our examining the processes by which this separation is effected, it will be proper to consider the chemical properties of the chyle.

1. *Properties of Chyle.*

Properties of chyle.

(356.) Chyle is the fluid which is prepared from the food taken into the stomach, and which, being the last process of digestion, is formed in the intestinal canal. It is only of late years that we have acquired any accurate knowledge of its chemical properties. It is evident that experiments on this fluid can only be instituted on quadrupeds, and that it is only by reasoning from analogy that we can extend the knowledge so obtained to the human economy. If chyle be taken from the thoracic duct of an animal a few hours after it has taken food, it has very much the appearance of cream, being a thick fluid of an opaque white colour, without smell, and having a slightly acid taste, accompanied by a perceptible sweetness. It restores the blue colour of litmus, previously reddened by acetic acid; and appears, therefore, to contain a predominance of alkali. When subjected to microscopic examination, chyle is found to contain a multitude of globules, of smaller diameter than those of the blood, and corresponding in size and appearance to those of milk. In about ten minutes after it is removed from the thoracic duct, it coagulates into a stiff jelly, which in the course of twenty-four hours separates into two parts, producing a firm and contracted coagulum, surrounded by a transparent colourless fluid.

(357.) The coagulated portion, according to Vauquelin, is a substance of a nature intermediate between albumen and perfect fibrin, marking the transition from the one to the other. It has perhaps, indeed, a closer resemblance to the caseous part of milk than to fibrin. It is rapidly dissolved both by pure and sub-carbonated alkalies, forming pale brown compounds. Its solution in ammonia has a reddish hue. The acids throw down a substance intermediate between fat and albumen, which an excess of nitric acid redissolves in the cold; and sulphuric, muriatic, oxalic and acetic acids, by boiling for a short time, also dissolve it. Diluted sulphuric acid also very readily effects its solution. Very dilute nitric acid gradually converts it into adipocire; when the acid is more concentrated, the coagulum assumes the appearance of gelatin; and when heat is applied, oxalic and carbonic acids are evolved. It is insoluble either in alcohol or ether.

(358.) That portion of chyle which retains the liquid form contains a portion of albumen, which may be coagulated by heat, alcohol, or acids. The clear liquid, reduced by evaporation to half its bulk, deposits crystals, which were found by Mr. Brande to bear a strong resemblance to those of sugar or milk.

(359.) A few saline bodies, similar to those existing in most animal fluids, were found by Dr. Marcet, to be present in chyle.

(360.) The principal ingredients in chyle are, therefore, according to Vauquelin, 1st, a large proportion of albumen; 2d, a smaller one of fibrin; 3d, a fatty substance which gives to the chyle the appearance of milk; 4th, several salts, such as carbonate of potass, muriate of potass, and prophosphate of iron.

(361.) Berzelius is strongly inclined to distrust the supposed analogy between chyle and milk, as having but little foundation in their real chemical nature.

(362.) It would be exceedingly interesting to ascertain the differences which exist in the properties of chyle taken from different orders of animals, that we might be able to trace the influence of different kinds of food upon this fluid. Dr. Marcet and Dr. Prout have made comparative experiments with this view upon the chyle taken from different dogs, some of which were fed exclusively on animal, and others on vegetable food. The chyle in the former case was found to be much whiter, contained more solid matter, and yielded more albumen than in the latter. The general results of these experiments are contained in the following table. Some faint traces of oily matter and of sugar of milk were obtained, but in quantities too minute to be estimated.

	Chyle from vegetable food.	Chyle from animal food.
Water	93·6	89·2
Fibrin	·6	·8
Incipient albumen	4·6	4·7
Saline matters	·8	·7

(363.) When both kinds of chyle were submitted to destructive distillation, the vegetable chyle produced three times as much carbon as the animal chyle; the latter, therefore, probably contained a greater proportion of hydrogen and nitrogen. The chyle of a horse, derived of course from vegetable food alone, was found by Vauquelin to be in a more animalized state than that which Dr. Marcet procured from dogs. Dr. Prout, also, comparing the chyle as prepared from vegetable and from animal food, found the former to contain more water and less albuminous matter, while the fibrin and the salts were nearly the same in both, and both exhibited traces of oily matter. On the whole, he states the difference between the two kinds of chyle as being less considerable than had been observed by Dr. Marcet. On tracing the successive changes which the chyle undergoes in its passage along the vessels, he found that its resemblance to blood increases in each of these successive stages of its progress.[1]

2. *Functions of Intestines.*

Chylification.

(364.) At the part of the duodenum where the separation of the chyme into chyle and residual matter takes place, the ducts from the pancreas and the liver terminate, so that the chyme is subjected to the action of the secretions from these two important glands, namely, the *pancreatic juice*, and the *bile*, which slowly distil into the duodenum. Sir Benjamin Brodie concluded, from experiments which he made upon living animals, that the formation of chyle is the immediate result of the admixture of bile with the chyme. In studying the changes which occur in this process, it will be necessary first to examine the chemical properties of these secretions.

Pancreatic juice.

(365.) The secretion from the pancreas, which flows into the intestine, and is mixed with the digested food almost immediately on its exit from the stomach, has, no doubt, some share in the process of chylification; but as it appears to be exceedingly analogous, both in its sensible properties and chemical composition, to the saliva, it is difficult to understand the mode of its operation, independently of mere dilution. As it is found, however, to contain a large quantity of albumen, a great portion of this substance may perhaps go to the formation of chyle.

3. *Properties of Bile.*

Bile.

(366.) The bile, a secretion prepared by the liver, is poured into the same part of the intestine as the pancreatic juice. Its great importance in the animal economy induced physiologists from the earliest times to pay much attention to its chemical properties. Its analysis has been attempted by Boyle, Boerhaave, and Baglivi, and more recently by Fourcroy, Cadet, Thenard, and Berzelius. But it unfortunately happens, that in several important particulars the accounts given by these different chemists do not accord with one another. These discrepancies, as Mr. Brande observes, seem partly to arise from the extreme facility with which chemical reagents react on this secretion, so that many of the supposed *educts*, or component parts which have been enumerated by different chemists, are probably *products* of the different operations to which it has been submitted, or, at all events, modifications of its true proximate elements.[2] The bile of the ox, from the facility of preserving it, has been that chiefly selected as the subject of experiment, and made the standard of comparison with that of man and other animals.

(367.) The substances to which this fluid owes its specific properties are, according to Thenard, first, a peculiar inflammable resin, soluble in alcohol; secondly, *picromel*, a substance insoluble in water and in alcohol, incapable of being crystallized, but forming, with resin and a small portion of soda, a triple compound which is soluble in water; and it is in this state that it exists in bile; and, thirdly, a yellow matter, distinct from either of the former. In addition to the soda, which is combined with the resin and picromel, bile contains a small quantity of phosphate, muriate and sulphate of soda, as also phosphate of lime, and a minute trace of iron.

(368.) Berzelius denies the correctness of the distinctions which Thenard has endeavoured to draw between the three animal ingredients of bile above mentioned. He gives to its characteristic principle, the name of *biliary matter;* and describes it as being of a resinous nature, and precipitable by acids; the precipitate, or *picromel*, or the *gallensteff* of Berzelius, being a compound of the acid employed and this biliary matter. According to Thenard, human bile differs from that of the ox chiefly in containing no picromel. M. Raspail considers bile to be essentially a saponaceous substance, with a trace of soda.

(369.) The peculiar matter of *bile* is found in the residual matter, and does not enter into the composition of chyle. The chief uses of the bile appear to be those of a chemical agent, promoting the decomposition of the chyme, and also stimulating the secretion of mucus, and the peristaltic motion of the intestines. Digestion may, however, go on to a certain degree, and imperfectly, although the flow of bile into the intestines be entirely prevented.

4. *Functions of the Small Intestines.*

(370.) Professors Tiedemann and Gmelin found, from their experiments, that the upper part of the small intestines contains a considerable quantity of uncombined acid, which is principally the acetic, mixed with a little butyric, and rarely with the muriatic On proceeding to the lower parts of the small intestines, they found the fluids had alkaline instead of acid properties. This gradual disappearance of acid is probably in part the effect of its neutralization by the free alkali contained in the bile. The following, according to these physiologists, are the changes which take place in the contents of the small intestines. The chyme, which is acid, mixes with the bile, the pancreatic juice, and the mucous secretion from the coats of the intestine. The muriatic acid combines with the soda of the bile, and at the same time disengages from it the acetic or carbonic acids with which it had been previously united. It also separates the mucus and cholesterine of the bile in the form of white flakes, which have often been mistaken for chyle. The pancreatic juice and the intestinal mucus contribute, in some unknown manner, to this effect. Their chemical changes are promoted, and the contents of the intestines successively propelled forwards along the whole tract of the canal, by the peristaltic actions of the muscular coat, the effects of which are analogous to those we have already described as taking place from a similar action in the stomach.

[2] *Cyclopædia of Anat. and Phys.* art. Bile.

5. *Function of the Spleen.*

Function of the spleen.

(371.) It is probable that the spleen is an organ subservient to some purpose connected with digestion; but what that precise purpose can be is a question involved in great obscurity. A vast number of hypotheses and conjectures have been hazarded on this subject; but they are, for the most part, devoid of even the slightest probability. Any theory that assigns a very important office to the spleen will be overturned by the fact, that in many animals the removal of this organ, far from being fatal, or interrupting in any sensible manner the continuance of the functions, seems to be borne with perfect impunity. Sir E. Home has of late years advanced an opinion, for which there appears to be some probability, namely, that the spleen serves as a receptacle for any superfluous quantity of fluid taken into the stomach, and which, if not removed, might interfere with the regular process of digestion. This excess he supposes is transmitted directly to the spleen by communicating vessels, and lodged there until it is gradually removed, partly by the veins, and partly by the absorbents.

(372.) It appears, indeed, from the observations of Bichat, Leuret, Lassaigne, and others, that during digestion, and even after copious draughts of liquids, the vessels of the spleen become exceedingly turgid with blood. Hence the opinion has arisen, that the chief use of the spleen is to relieve the stomach and intestines from that congestion which would otherwise take place in their blood-vessels during digestion. The very vascular, approaching to a cellular structure, of the spleen, which very readily admits of dilatation, would seem to countenance this hypothesis.

6. *Functions of the Large Intestines.*

Functions of the large intestines.

(373.) The functions of the large intestines are not confined to the mere conveyance and expulsion of feculent matter, although the exact nature of the changes which take place in their contents, and the subserviency of those changes to the object of nutrition, have never been clearly determined. It would appear that some important changes are effected in that enlarged portion of the canal which is termed the *cæcum*, and which has by some been regarded as a kind of supplementary stomach, in which fresh chyme is formed, and fresh nutriment extracted from the materials that have passed through the small intestines. This chymous product is supposed to be converted, as in the former case, into a species of chyle, which, from containing a greater proportion of oil, bears a resemblance to fat, and is in this state absorbed from the inner surface of the great intestines. The capability of the great intestines to extract nourishment from their contents is proved by the fact, that nutritious matter injected into them has been known to support life for a certain time, and also from their being able to effect the coagulation of milk.

(374.) A certain quantity of gas is almost constantly present in the intestinal canal, and often also in the stomach. Magendie and Chevreul, who have analysed these gases, found that what the stomach contained consisted of a mixture of oxygen and nitrogen; but that in the lower intestines the oxygen had wholly disappeared, as also a great part of the nitrogen, and that, instead of these, the component parts of the gas were carbonic acid, hydrogen, carburetted hydrogen, and a little sulphuretted hydrogen.

(375.) The time required for the completion of the processes we have described as taking place in the stomach, the small, and the large intestines, varies much, not only according to the nature of the food, but according to the conditions of the organs and of the general health, and to constitutional peculiarities. The digestion of food in the stomach is usually considered as requiring three or four hours. Animal food is longest retained, and undergoes the greatest alteration in the stomach. Vegetable food, on the other hand, passes more quickly and with less alteration, out of the stomach, and undergoes more change in the intestines than animal food.

SECT. VIII.—*Lacteal Absorption.*

Lacteal system.

(376.) The chyle, which has been prepared in the duodenum, and along the whole course of the small intestines, in the manner we have described, is received by absorption into the lacteals, and by them conveyed to the thoracic duct, which transmits it to the great veins in the vicinity of the heart. The lacteal vessels may be considered as forming part of the great system of absorbents which, as we shall afterwards find, are extensively distributed throughout the body. We shall therefore reserve their description until a general account is given of this system, in treating of the function of absorption generally.

(377.) The discovery of the lacteals was made in the year 1622 by Aselli, in the mesentery of a dog, which he had killed a few hours after the animal had made a plentiful meal. Their termination in the thoracic duct was discovered by Pecquet in 1651. They originate by open mouths from the villi of the inner coat of the small intestines, in the form of very minute tubes, which soon unite into one common vessel proceeding from each of the villi; and these vessels afterwards joining successively form larger and larger branches, which ascend along the mesentery, generally following the course of the veins, till they are collected at the root of the mesentery, and, after passing through numerous glands, terminate at the lower end of the thoracic duct, where there is an enlargement which has been called the *receptaculum chyli*.

(378.) Since uncertainty, however, still exists respecting the minute anatomy of the lacteals, at their origin from the intestine, many anatomists having in vain sought for the appearances above described. Their open orifices can only be seen when the lacteals are distended with chyle, and they are more readily detected in fishes where they have no valves, and where therefore the branches admit of being injected from their trunks. Their coats, although thin and perfectly transparent, yet possess considerable strength, so as to allow of being distended by injections without being ruptured; and even afford decisive indications of having the power of contracting and propelling forwards their contents. The utility of the numerous valves with which they are provided in every part of their course, in preventing any retrograde motion of the fluid they transmit, is sufficiently obvious.

(379.) The power by which the chyle is made to enter the open orifices of the lacteals, is by no means easily determined. It has been referred generally to capillary attraction. But the application of the laws which govern the ascent of fluids in rigid inorganic tubes, to the elastic vessels of the living system, is liable to much fallacy. The phenomena appear to indicate that the lacteals exercise, in the exclusive absorption of chyle, a power of selection somewhat analogous to that of chemical or electric attraction. It has been supposed, accordingly, that there is a specific attraction between chyle and the lacteal vessels, which causes that fluid to enter into them; while other fluids which are presented to the same vessels are rejected. This obscure subject has given rise to various speculations, which are more curious and ingenious than leading to any satisfactory conclusion. It is now generally agreed among physiologists, that the power which the lacteals possess of admitting the absorption of extraneous substances, if it exist at all, is exceedingly limited, and is exerted only on rare occasions.

Various experiments made on animals fully warrant the conclusion, that by far the greater portion of the nutritive matter imparted to the system is conveyed into the blood-vessels through the channels we have been describing, namely, the lacteals and the thoracic duct. On the other hand, there appears to be evidence that a large portion of the thinner fluids received into the stomach passes at once into the veins by the immediate absorption of these veins: for they always disappear rapidly from the stomach, in whatever quantity they are introduced. It is probable also, that some admixture of the contents of the lacteals with those of the blood-vessels takes place in the mesenteric glands, and that part of the chyle finds its way into the mesenteric veins by more direct channels than that of the general circulation.

(380.) An elaborate series of experiments was undertaken by Tiedemann and Gmelin, with a view to ascertain whether there exists any direct communication between the digestive cavities and the blood-vessels, exclusive of the known channel through the lacteals and thoracic duct. The experiments consisted in mixing with the food of certain animals various odorous, colouring, and saline materials, the presence of which might be easily detected by their appearance, odour, and other sensible or chemical properties; and in comparing, after a proper interval of time, the state of the chyle with that of the blood in the mesenteric veins. The odorous substances employed were camphor, musk, alcohol, oil of turpentine, and assafœtida. These were generally discovered to have found their way into the system, by their being detected in venous blood, in the urine, but not in the chyle. The colouring matters were sap-green, gamboge, madder, rhubarb, alkanet, and litmus; these appeared, for the most part, to be carried off without being absorbed; while the salts, namely potass, sulphuro-prussiate of potass, muriate of barytes, muriate and sulphate of soda, acetate of lead and of mercury, and prussiate of mercury, were less uniform in their course. A considerable portion of them seemed to be rejected, while many of them were found in the urine, several in the venous blood, and a very few only in the chyle. Hence the authors conclude, that the odorous and colouring substances never pass into the lacteals, and that saline bodies do so occasionally only, or perhaps incidentally; the whole of them are, however, found in the secretions, and they must, therefore, have entered into the circulation by some other channel than the lacteals.[1]

(381.) There appears not, as far as we know, to be any thing specific in the action of the thoracic duct, which, as it appears, transmits its contents into the subclavian vein, as it receives it from the absorbents.

SECT. IX.—*Sanguification.*

guifica-

(382.) The chyle consists, as we have seen, of alimentary matter, reduced to a certain state, which may be regarded as the first stage of animalization, having already made a near approach to the nature of that blood into which it is afterwards to be converted. This conversion of chyle into blood takes place after its introduction into the sanguiferous system of vessels, and while it passes round in the course of circulation. During this course, it necessarily traverses the minute vessels of the lungs, where it is subjected to the chemical action of atmospheric air, and its constituents gradually acquire the characteristic properties which they possess as the ingredients of the blood. The chief changes experienced are, first, that the fibrin of the chyle obtains a greater cohesive tendency, and a power of spontaneous coagulation; and, secondly, that the white globules of the chyle receive an addition of red colouring matter, and are invested with an external vesicle, by which their size is increased. But in order correctly to estimate their changes, it will be necessary to take a general review of the chemical and other physical properties of the blood.

Properties of blood.

(383.) The nature and properties of the blood have attracted a very large share of the attention of physiologists in all ages; and immense labour has been devoted to the investigation of its chemical constitution.

(384.) When examined immediately on its being drawn from the vessels, the blood appears as a smooth and homogeneous fluid, of an unctuous adhesive consistence, of a slightly saline taste, and of a specific gravity somewhat exceeding that of water. It exhales a vapour which has a peculiar smell; but which, when condensed and collected, affords a liquor not differing sensibly from water. Much importance was formerly ascribed to this vapour, which was dignified with the name of *Halitus*. As the blood does not preserve the same consistence at different times, its density is liable to variation. Haller states the specific gravity of human blood to be at a medium, 1.0527. Dr. Milne Edwards says that it varies from 1.052 to 1.057. Dr. Davy states that the specific gravity of arterial blood is 1.049, and of venous blood, 1.051. Although it appears homogeneous, it is found by microscopical examination to contain a large proportion of minute globular particles, diffused through a liquid.

Halitus.

Coagulation.

(385.) In a few minutes after its removal from the body, a thin film appears on the surface, and after a short time, which on an average is about seven minutes, the whole mass becomes cohesive, and what is termed its *coagulation* has taken place. After it has remained for some time in this gelatinous state, a separation of the mass into two distinct parts gradually takes place. A yellowish liquid oozes out from beneath the surface of the mass, and at length the whole is resolved into a clot, or solid portion of a dark red colour, which is called the *crassamentum*, or *cruor*, and consists chiefly of fibrin, and a yellowish liquid, called the *serum*. The proportion between these two parts has been variously estimated; and does not indeed admit of accurate determination, from its being variable in itself under different circumstances. On an average, however, it may be stated, that the crassamentum amounts to about one-third of the weight of the serum. Dr. Scudamore and Mr. Wood found, however, by taking the mean of twelve experiments, that the crassamentum amounted to 53.307 per cent. The period at which coagulation begins and is completed, varies not only with the condition of the blood itself, but also with the circumstances in which it is placed. It commences sooner as the vessel is more shallow; but on an average it may be said to begin in about three or four minutes, and to be completed in seven or eight. But the contraction of the coagulum continues for a long time after, and sometimes does not cease till the fourth day. It does not appear that the specific gravity of the blood is sensibly altered during its coagulation.

Crassamentum and serum

Rise of temperature.

(386.) Great difference of opinion has existed as to the occurrence of a change of temperature during this process of coagulation. The analogy of other instances in which the conversion of a fluid into a solid is accompanied with the evolution of heat, has induced many to think that a similar effect attends the coagulation of the blood. Fourcroy stated, that a rise of temperature actually takes place; but Hunter, on the contrary, adduced facts leading to an opposite conclusion. The result obtained by Fourcroy has, however, been confirmed by the experiments of Dr. Gordon, who found that the coagulating portion of a quantity of blood was warmer than the rest by about six degrees. On repeating the experiment on blood drawn from a patient labouring under inflammatory fever, the rise of the thermometer was no less than twelve degrees. Subsequent researches by Dr. John Davy, have, however, thrown considerable doubt upon the accuracy of the above conclusion, by pointing out some sources of fallacy in the investigation of Dr. Gordon. Dr. Scudamore, on the other hand, found that heat was produced during coagulation, but to a less degree. Vogel and Brande have ascertained that carbonic acid gas is disengaged; and this appeared to happen to an unusual extent in blood drawn soon after a meal.

---

[1] *Edin. Med. Journal*, xviii. p. 455, &c. The above analysis of these experiments is that given by Dr. Bostock in his work on Physiology, p. 617, note.

Conditions for coagulation.

(387.) The coagulation of the blood is a phenomenon not strictly analagous to any other with which we are acquainted, and has never been satisfactorily explained. The operation of external agents upon it is not so well marked as to enable us to refer it to any general operation of the physical properties of matter. Moderate differences of temperature produce scarcely any perceptible difference in the tendency which the blood has to coagulate. Within the range of from 67° to 105°, blood coagulates in the same time as at the usual temperature of 98°. Sir Humphry Davy found that no difference in this respect takes place when blood is exposed to nitrogen, nitrous, nitrous oxide, carbonic acid, carborated hydrogen gases, or atmospheric air, although the contrary had been asserted by Luzuriaga. Blood, indeed, coagulates more quickly when placed in a receiver from which the air is rapidly exhausted, when slowly drawn into a shallow vessel, or when exposed to atmospheric air, at a temperature of 120°. This process is retarded by a very low temperature. Mr. Hewson placed blood in oil at a temperature of 38°; at the expiration of six hours it continued fluid; but being then allowed to attain a warmer temperature, it became coagulated in twenty-five minutes. The same physiologist froze a portion of blood confined by ligatures in the jugular vein of a rabbit; when thawed, the blood became liquified, and coagulated. Admixture with certain neutral salts prevented altogether coagulation from taking place. This happened when half an ounce of sulphate of soda was mixed with six ounces of fresh blood; but on the addition of a double quantity of water coagulation took place. Dr. Turner states that the coagulation of the blood is prevented by the admixture of saturated solutions of chloride of sodium, hydrochlorate of ammonia, nitre, and potass; while, on the contrary, alum, and the sulphates of the oxides of zinc and copper, promote coagulation. Blood coagulates slowly when drawn quickly into a deep vessel, or when detained at rest in the vein of a living animal between two ligatures. In the latter case, Mr. Hewson found the blood two-thirds fluid after the lapse of three hours and a quarter. When the experiment was varied by blowing air into the vein, the blood was found to have coagulated in a quarter of an hour. Blood extravasated through the rupture of vessels, and retained in the cavities of the body, often preserves its fluidity for a very considerable time. If the causes which are capable of postponing coagulation have continued to operate beyond a certain period, the blood is prevented from coagulating; thus recent blood remains permanently fluid if it be constantly stirred for some minutes. It has been proved by the experiments of Hewson, Hunter, Deyeux, and Parmentier, that the coagulation of blood is not entirely prevented by diluting it with water; but Dr. Crawford[1] showed that this process is retarded for several hours by the admixture of blood with twelve times its bulk of water.

(388.) There are many conditions of the living system that have a prodigious influence on the tendency of the blood to coagulate, and that operate in a manner which it is impossible to explain. Many causes of sudden death, as a blow upon the stomach, or violent injury to the brain; lightning and electricity; several animal poisons, as that of venemous serpents; narcotic vegetable principles, as cyanogen; also excessive exercise, or even violent mental emotions, when they produce the sudden extinction of life, prevent the usual coagulation of the blood from taking place.

Vitality c blood.

(389.) The doctrine maintained by Hunter, that the blood possesses life, and that its coagulation is one of the acts of this living principle, is but little calculated to remove the difficulty; for the operation of this principle in producing coagulation would still be as much in need of explanation as the phenomenon itself, which it professes to account for. We must, in the present imperfect state of our knowledge, content ourselves with referring this phenomenon to an inherent disposition which the fibrin possesses to assume the solid form, when no counteracting cause is present. Dr. Bostock,[2] observes, that as it is gradually added to the blood particle by particle, while this fluid is in a state of agitation in the vessels, it has no opportunity of concreting; but when it is suffered to lie at rest, either within or without the vessels, it is then able to exercise its natural tendency.

(390.) We have already stated that the crassamentum consists chiefly of fibrin; but it owes its dark colour to the presence of what are called the red particles of the blood, and which are entangled in it during its coagulation. The serum, which is the part of the blood that remains fluid after the coagulation of the fibrin, is itself coagulated by heat, in consequence of the large proportion of albumen it contains; the remaining portion which still continues fluid, is termed the *serosity*. The following is therefore the arrangement of the principal proximate parts of the blood, in the order of analysis.

Analysis blood.

Coagulated blood consists of	Crassamentum	Fibrin
		Red particles.
	Serum	Albumen.
		Serosity.

Crassamentum.

(391.) The crassamentum is a mass of a soft consistence, which easily bears cutting with a knife. Its mean specific gravity is about 1·245. By long continued ablution in water, it may be freed from the red particles which it contains, and which are soluble in water. This may conveniently be effected by enclosing the crassamentum in a linen bag, immersing it repeatedly in water, and at the same time pressing it gently; or by allowing a stream of water to fall upon it, till the water runs off colourless. There remains a white, solid, fibrous, and elastic substance, which has all the properties of fibrin, and is almost exactly similar to the basis of muscular flesh obtained by long boiling. It may also be procured directly from recent blood, by stirring it, as it flows from the vessel, with a bunch of twigs; or receiving it into a bottle, and shaking it during its coagulation. When formed under these circumstances, it exhibits a fibrous appearance, and the whole is converted into an irregular net-work of dense fibres. Fibrin was formerly known under the name of *coagulable lymph*, or *gluten*.

Red globules.

(392.) The *red particles* or *globules*, contained in the blood, and enveloped in the fibrin during its coagulation, have long attracted the attention of physiologists, from the irregularity of their appearance, and the importance which was supposed to attach to them. The first notice which we find of them occurs in the writings of Malpighi, soon after the introduction of the use of the microscope. They were soon afterwards examined with great care and minuteness by the indefatigable Leeuwenhoek, whose name stands foremost among those who made observations with this instrument. They soon became the subject of much speculation, and laid the foundation of many fanciful hypotheses which were current at the time, but are now consigned to deserved neglect. Leeuwenhoek himself was led by his imagination to the belief that these red globules were each composed of a series of globular bodies of different orders descending in regular gradations. He supposed each to be made up of six particles of serum; each particle of serum of six particles of lymph, and so on in succession. This strange hypothesis, visionary as it now appears, was so accordant with the prevailing taste for mathematical disquisitions, that it was very generally adopted, and held a powerful sway over the opinions and reasonings of the physicians of that age. It forms a leading feature in the pathological speculations of Boerhaave; and although its futility was sufficiently exposed by Lancisi and Senac, it maintained its ground even to the time of Haller.

Their form. (393.) But a better spirit began at length to prevail; the illusive dreams of fancy were superseded by the sober and attentive observation of nature; and truth was sought by the judicious cultivation of experimental inquiry, the only legitimate path by which it can be approached. About the middle of the eighteenth century, the Abbe de la Torré, employing microscopes of considerable power, obtained the appearance of flattened annular bodies, with a perforation in the centre. Hewson, who observed them with still greater attention to accuracy, states them to be hollow vesicles of a flattened shape, and containing a smaller, solid, and spherical particle, which was freely moveable within them, or, as he compares it, "like a pea in a bladder." He asserted, that by adding water, these particles swell out into a globular shape, and afterwards burst and disappear, in consequence of their being dissolved in the water; but if moistened with an aqueous solution of any neutral salt, they preserve their natural flat shape. Cavallo describes them as much more irregular in their form than Hewson represented them; and he was led from his observations to the conclusion that the appearance either of a perforation, or of a central particle, is in reality an optical deception, arising from the refraction of the light by which the objects are viewed, as it passes through the convex surfaces of the globules. He also endeavours to explain the appearance which led Hewson to believe that the central nucleus is moveable within the external vesicle, by some apparent change in the position of the luminous image, in consequence of accidental variations in the direction in which the light is viewed. Very small artificial globules of solid glass which he constructed for the purpose, presented under the microscope very nearly the same appearances as the globules of the blood; and hence he concluded, that the latter, notwithstanding these appearances, were nearly globular and composed of a uniform material.

(394.) Notwithstanding the ingenuity displayed in this reasoning, the more profound examination which the subject has received from Dr. Young, induces us to revert, to a certain extent, to the opinion of Hewson. He observes that in such examinations it is only necessary to employ a full and unlimited light, in order to obtain a very distinct outline of what appears manifestly to be a very simple substance. But we should remember that where the substances to be examined are perfectly transparent, it is only in a confined and diversified light that we can gain a correct idea of their structure. The eye is best prepared for the investigation by beginning with the blood of a skate, of which the particles are, from their greater size, so conspicuous, and of so unequivocal a form, as at once to set aside the idea of a simple homogeneous substance. They are oval and depressed, like an almond, but less pointed, and a little flatter. Each of them contains a round nucleus which is wholly independent in its appearance of the figure of the whole disc, being sometimes a little irregular in its form, seldom deviating from its central situation, but often remaining distinctly visible, whilst the oval part is scarcely perceptible. This nucleus is about the size of a whole particle of human blood, the whole oval being about twice as wide, and not quite three times as long. The nucleus is very transparent, and forms a distinct image of any large object which intercepts a part of the light by which it is seen, but exhibits no inequalities of light and shade that could lead to any mistake respecting its form. But if we place some particles of human blood under similar circumstances, near the confines of light and shade, although they are little, if at all less transparent, we immediately see an annular shade on the disc, which is most marked on the side of the centre on which the marginal part appears the brightest, and consequently indicates a depression in the centre, which De la Torre mistook for a perforation. It is most observable when the drop is dying away, so that the particles rest on the glass; and when a smaller particle is viewed, it has merely a dark central spot, without any lighter central space. Dr. Monro had represented the globules of the blood as being of an exceedingly flattened shape, or, as he expresses it, "as flat as a guinea." But Dr. Young never saw them of this shape, although he states their axis as being sometimes not more than one-third, or one-fourth of their greatest diameter. He also states that they do not seem, as Hewson asserted, to have their dimensions much affected by the fluid in which they are suspended, since they may easily be spread thin on glass, and dried without much change in their magnitude, at least in the direction of the surface to which they adhere; and they remain distinct as long as the access of moist air is completely excluded. When they have been kept for some time in water, and a little solution of salt is added, their form and structure, as Hewson observed, are more easily examined, and appear to resemble those of a soft substance, with a denser nucleus; but the comparison which he makes of their being like a pea in a bladder, Dr. Young thinks is quite inapplicable.

(395.) It has commonly been asserted, and especially by Hewson, that these particles are readily soluble in water; but Dr. Young has shewn that this opinion is erroneous, and depends partly on their passing readily through the filtering paper, a circumstance observed by Berzelius, and partly on the extraction of a great part of their colouring matter, together with which they lose much of their specific gravity, so that instead of subsiding, they are generally suspended in the fluid. Their presence may still, however, be detected by a careful examination; and they seem in this state to have recovered in some measure their original form, which they had lost when first immersed in the water. A curious observation on the influence of circumstances on the form of the globules, has been made by Mr. Bauer. He remarks that in the skate they are oval during the life of the animal, but become flattened after its death. This circumstance may perhaps tend to reconcile some of the discordant statements which have been made on this subject.

Their size. (396.) The size of the red globules has also been very differently estimated by different observers. These discrepancies receive some explanation by the circumstance which Dr. Milne Edwards appears to have established, of the globules differing considerably in their size in the same individual.[1] The most accurate measurements appear to be those of Dr. Young, and of Captain Kater, who both agree that the particles of human blood are between the four-thousandth and the six-thousandth of an inch in their diameter; and they may therefore be taken at a medium at the five-thousandth of an inch. Mr. Bauer has stated them to be considerably larger, even as much as the one thousand-seven-hundredth of an inch in their entire state, and that the central part is the two-thousandth of an inch in diameter. But the observations of Dr. Young are more probably correct, from their coincidence with those of Captain Kater, which were conducted in a different manner.

Their colouring matter.

(397.) The difficulty of procuring the red particles in a separate state, unmixed with serum, is so great as to preclude us from obtaining any distinct knowledge of their chemical composition and properties. The colouring matter of the blood has been termed *hematine*, or *hematosine*. But according to M. Lecanu, the substance usually termed hematine is in reality a combination of albumen and the pure colouring matter of the blood, which he proposes to designate *globuline*. Although it appears from Dr. Young's observations, that the globules themselves do not dissolve in water, yet they impart to it the whole of their colouring matter. The watery solution turns syrup of violets green; and after some time deposits a flocculent precipitate, probably from the coagulation of albumen, the presence of which is indicated also by the effect of boiling the solution. Hence it has been concluded that the colouring matter consists of albumen, dissolved by an excess of pure soda. When evaporated and calcined in a crucible, a residuum is obtained, amounting to about one-thousandth of the weight of solid matter, and composed, according to Fourcroy and Vauquelin, chiefly of subphosphate of iron.

Presence of iron.

(398.) Berzelius,[1] who has made minute inquiry into this subject, informs us that the colouring matter of the blood, separated from the other part, leaves one-eightieth of an incombustible residuum, of which rather more than one-half is an oxide of iron. The existence of iron in the blood was first discovered by Menghini; but its amount was much over-rated both by himself and many of the earlier chemists who succeeded him. It is difficult to determine in what state this iron exists in the blood. It would appear not to be in the state of any of the known salts of this metal; because before the blood has been calcined, the iron escapes detection by any of the tests which usually indicate its presence in solutions; and yet the solubility of the colouring matter in the serum would, on the other hand, appear to support the opinion of its possessing saline properties. Berzelius has been able to deduce from his numerous experiments on this point, merely the negative conclusion, that no salt of iron which he tried was capable of being combined with the serum, so as to produce a compound similar to the colouring matter of the blood; thus refuting the alleged synthetic proof adduced by Fourcroy, who had stated that subphosphate of iron dissolves in albumen, and imparts to it a bright red colour, resembling that of blood.[2]

(399.) It has long been the prevailing opinion that the blood derives its red colour from the iron it contains; but the truth of this opinion has been called in question by many writers of high authority, and in particular by Dr. Wells[3] and by Mr. Brande.[4] The experiments of Dr. Wells, however, as is remarked by Dr. Bostock, seem only to prove that the colour of the blood is not occasioned by any salt of iron, or by iron in such a state as to be affected by the ordinary tests. Mr. Brande procured the colouring matter from venous blood in a detached state, by removing the fibrin from it by agitation while it was coagulating, and suffering the red globules to subside in the serum, from which they could be obtained in a concentrated form. Examining this portion by means of different reagents, he arrived at the conclusion, that the colouring principle of the blood is an animal substance of a peculiar nature, susceptible, like the colouring matter from vegetables, of uniting with bases, or mordants, and therefore admitting of being applied in the art of dyeing. The most effectual mordants for the colouring matter of the blood are the salts of mercury, especially the nitrate and bichloride, or corrosive sublimate. On examining the colouring matter distinct from the crassamentum, Mr. Brande did not discover a greater proportion of iron than exists in the other principles of blood. These results, in as far as they relate to the quantity of iron, are at variance with the later and apparently more elaborate experiments of Berzelius, who still maintains that the colouring matter of the blood contains iron, not indeed discoverable by reagents, but decisively proved to exist in its ashes. In every respect, except in containing that metal, the colouring matter agrees with fibrin and albumen; and he seems disposed to believe that its colour, though not depending on the presence merely of an oxide of iron, may be produced by a compound of which the oxide is an essential part.

Vauquelin's experiments[5] may in some respects be deemed to corroborate those of Brande, inasmuch as they show that iron cannot be detected by liquid tests in solutions of the colouring matter; but they at the same time show that this metal is readily detected by these tests in the fluid from which the colouring matter has subsided.

(400.) The changes in the colour of the blood produced by its exposure to different gases, are probably owing to their action on the red globules. Arterial blood is blackened, and venous blood rendered darker, by nitrogen, or carbonic acid gases; but its bright florid hue is restored by exposure to oxygen gas. We shall have occasion to revert to this subject in treating of respiration.

Lymph globules.

(401.) Besides the ordinary red globules, others of a much smaller size have been detected by Mr. Bauer floating in the serum, and even apparently generated while the fluid is under examination. To these Sir Everard Home gave the name of *lymph globules*.[6]

Serum.

(402.) The serum of the blood, or the fluid part which is left after the separation of the crassamentum, is a transparent and apparently homogeneous liquid, of a yellowish and sometimes greenish colour, of a saline taste, and adhesive consistence. Its specific gravity is variable, but may be taken, on an average, at about 1·025. When exposed to a temperature of 160°, the whole is converted into a firm white mass, perfectly analogous to the white of an egg which has been hardened by boiling. It may, in fact, be regarded as identical with coagulated albumen, the chemical properties of which we have already described.

Serosity.

(403.) Although the whole of the mass of serum appears to be rendered solid by the process of coagulation, yet if this coagulum be cut into slices, and subjected to gentle pressure, or if it be placed on the mouth of a funnel, a small quantity of a slightly opaque liquor drains from it, which is called the *serosity*. It has a saline taste, and a peculiar odour, and consists of several ingredients. Its existence as a substance distinct from the albumen was first pointed out by Dr. Butt in 1760, and its properties were farther examined by Dr. Cullen, who speaks of it as a solution of fibrin in water. Hewson believed it to be of a mucous nature. Parmentier and Deyeux published, in 1790, an elaborate set of experiments which they made upon it, from which they drew the conclusion, that the animal substance contained in the serosity was gelatin. This statement seemed so satisfactory, from the apparent accuracy of the investigation, that it was generally acquiesced in. Not only was jelly considered as one of the constituents of the blood, but means were pointed out for ascertaining its proportion; and its supposed agency in the economy was made the foundation of many physiological speculations. But Dr. Bostock has since proved that this opinion is not founded in fact. He was unable to detect the smallest quantity of jelly either in the serosity of the blood, or in any other of the albuminous fluids. In this conclusion he is fully supported by the testimonies of Berzelius, Marcet, and Brande.

[5] *Annales de Chimie et de Physique*, i. 9.

[6] *Ibid* for 1819, p. 2.

(404.) It may be inferred from the experiments of Mr. Brande, that serosity consists of a small quantity of albumen, still retained in solution by a large proportion of alkali. According to Berzelius, the serosity contains no sulphuric acid, and only a vestige of the phosphoric, and consists chiefly of water, with some pure soda holding albumen in solution, of muriates of soda and of potass, of lactate of soda, and a peculiar animal matter which always accompanies the lactate. Dr. Bostock found the amount of solid contents to vary from the forty-sixth to the seventieth part of its weight, or, on an average, about the fiftieth. It has been a matter of dispute which of the mineral alkalies exists in serum in an uncombined form. Dr. Pearson maintained that it was potass; but Drs. Bostock, Marcet, and Berzelius, with much greater appearance of correctness, allege that it is soda.

(405.) The component parts of human serum, according to the analysis of Dr. Marcet, are—

Water,....................................	900·
Albumen,..................................	86·8
Muriates of potass and soda,...........	6·6
Muco-extractive matter,................	4·
Subcarbonate of soda,....................	1·65
Sulphate of potass,......................	·35
Earthy phosphates,......................	·6
	1000·

(406.) This analysis coincides very nearly with that of Berzelius, who considers the substance termed by Dr. Marcet *muco-extractive matter* to be impure lactate of soda. But Dr. Bostock is led by his experiments to the conclusion, that a peculiar animal substance exists in the serosity, not coagulable by heat, or by any other means; not affected by corrosive sublimate, or by tannin, which are the appropriate tests of albumen and of jelly respectively, but copiously precipitated by muriate of tin, and still more readily by the acetate of lead; and he thinks this substance is quite independent of the lactate of soda, which may exist at the same time in the blood.

zome

(407.) Wienholt discovered that the serosity contained a small quantity of the peculiar substance which exists in greatest abundance in the flesh of animals, and was first noticed as a distinct proximate principle by Rouelle. It was subsequently termed *ozmazome* by Thenard, who examined its properties more minutely. This substance is of a yellowish brown colour; it is soluble both in water and in alcohol, and is precipitated by infusion of nutgalls, nitrate of mercury, and by the acetate and nitrate of lead. It is still a matter of uncertainty what connexion exists between this substance and the muco-extractive matter above mentioned. There is also another proximate principle, namely, *urea*, of which we shall afterwards have occasion to speak, which is found in small quantity in the blood, when that fluid is in its natural state, but which is abundantly found in the blood of animals from which the kidneys have been removed. Besides these, Dr. B. Babington discovered the presence in the blood of an oily substance, separable from the other parts by means of ether. Lecanu, in addition to this oily matter, found a crystallizable fatty matter in the blood; and similar observations have been made by Chevreul. Manganese is said to have been detected in the blood by Wurzer. M. Boudet has also lately discovered a new substance in the serum, which he has termed *uroline*. This is a white, slightly opalescent substance, fusible at 94° Fahrenheit, not forming an emulsion with water, soluble in alcohol, not saponifiable, and apparently containing nitrogen.

CHAP. VII. CIRCULATION.

Sect. I.—*Apparatus for Circulation.*

Purposes answered by the circulation.

(408.) The object of the function of circulation is twofold. The first is to distribute to all the organs that due share of nutritive fluid which they require for the performance of their respective offices, for the maintenance of their temperature, and for nutrition, and to keep up a constant supply of this fluid. The second, and no less important object, is to expose every portion in succession of this fluid, which is the blood, to the influence of atmospheric air in an organ appropriated to this particular purpose; the continual renewal of the action of the oxygen contained in the air upon the blood, being necessary for the maintenance of its salutary qualities, and indispensable to the preservation of life. The organs in which this process is carried on are the *lungs;* and the function by which it is accomplished is *respiration.* The great agent for the distribution of the blood both generally to the organs of the body, and specially to the lungs, is the *heart;* the pipes through which it is conveyed to those parts are the *arteries;* those through which it is brought back to the heart, the *veins.* A set of finer vessels interposed between the minute extremities of the arteries, and the minute beginnings of the veins, are called the *capillaries.* The structure and distribution of all these parts, have already been described in the treatise on ANATOMY, to which we of course refer for the descriptive details. The following brief recapitulation, however, of the structure of the heart will assist us in understanding the physiology of its action.

1. *Cardiac Apparatus.*

Heart.

(409.) The heart is a hollow muscle, of a conical shape, occupying the central and inferior part of the cavity of the thorax, having its *basis* turned towards the right side, and its point or *apex* towards the left, nearly opposite to the space between the sixth and seventh ribs. Its lower surface is somewhat flattened, where it lies upon the diaphragm. Its basis, with which the great vessels are connected, is covered with fat. The whole heart, and the roots of the large blood-vessels at its basis, are protected by a general investment of membrane, which is a reflected production of an extended serous membrane, forming a cavity for its reception, and for allowing it considerable freedom of motion. This membrane, which is remarkable for its strength, is called the *pericardium,* and is situated between the laminæ of the mediastinum, which are separated in order to contain it.

Its cavities.

(410.) The heart is principally made up of muscular fibres, the course of which is extremely complex; some extending longitudinally from the basis to the apex, others taking an oblique or spiral course; and a third running in a more transverse direction. There are two considerable cavities, called *ventricles,* distinguished, according to their situation, into the right and left ventricle. The former has also been called, in reference to its functions, the *pulmonic,* and the latter the *systemic* ventricle. They are separated by a strong and thick partition, called the *septum ventriculorum,* which is composed of fleshy and tendinous fibres. Attached to these, at the basis of the heart, are two hollow and fleshy projecting appendages, called the *auricles,* the cavities of which are also separated from each other by a partition, distinguished by the name of *septum auriculorum,* and they open into those of the ventricles. The right auricle, which, together with the right ventricle, is placed

Its valves.

more in front, receives the blood from the venæ cavæ, and transmits it to the right ventricle, by which it is propelled into the trunk of the pulmonary artery. The left auricle, in like manner, collects the blood from the four trunks of the pulmonary veins, and transfers it into the left ventricle, by which it is forcibly driven into the aorta, or main trunk of the arterial system of the body at large. The membrane which lines the cavities of the heart, and the great vessels just mentioned, is produced so as to form valves at the two orifices of both the ventricles; that is, where the auricles open into them, and also at the origin of the arterial trunks which arise from the ventricles. The valves placed between the right auricle and ventricle, are usually three in number, and are called *valvulæ tricuspides;* but in the left ventricle there are only two, and these are named the *valvulæ mitrales.* The membranes which form these valves are attached so as to project somewhat forward in each of these cavities, and are connected with tendinous strings, called *chordæ tendineæ*, which arise from detached and projecting portions of the muscular substance of the heart, named from their cylindrical form, *carneæ columnæ.*

(411.) The valves at the origin both of the pulmonary artery and of the aorta, are three in number, and are called the *valvulæ semilunares*, from their semicircular figure; their convexities are turned towards the ventricle; they are concave next to the cavity of the artery; and in the middle of their loose edge is found a small hard triangular substance called *corpus aurantianum*, and sometimes *corpusculum Morgagni*, or *sesamoideum.* When these valves are made to approach each other, by the pressure of the blood in the artery in the direction of the ventricle, they unite so as completely to close the passage, and prevent any of the blood from returning. Opposite to the semilunar valves, the artery bulges out and forms three projections, which have corresponding pits or depressions within, and are called, from their discoverer, *sinus Valsalvæ.*

(412.) Where the two venæ cavæ meet, there is a small angular projection, which has been called the *tuberculum Loweri.* The term *auricula* more properly applies to the jagged portions which project from the sides of the base of the heart, like the ears of a dog from its head; whilst the expanded cavity where the venous tubes enter is called the *sinus venosus.* On the side next to the auricula, there is a remarkable semilunar fold, projecting within the cavity, between the vein and auricle, so as to be convex next to the vein, and concave next to the auricle. This doubling has been called the *Eustachian valve.* Between the concave part of this fold, and the opening into the ventricle, is the orifice of the coronary vein, which returns the blood that has circulated through the substance of the heart itself, and which is provided, at this point, with its proper valves. In the septum auriculorum is seen a depression, the *fossa ovalis*, which is the remains of a passage of communication between the right and left auricles that had existed in the fœtal state. The sides of the fossa ovalis are strong and thick, and have received the name of *isthmus Vicussenii*, or *columnæ*, or *annulus fossæ ovalis.*

2. *Sanguiferous System in general.*

Sanguiferous system. Double circulation.

(413.) The blood-vessels, consisting of arteries. veins, and capillaries, compose by their assemblage what is termed the *sanguiferous system;* and the channels which they form for the transmission of the blood constitute a double circuit. The principal circuit consists of that through which the blood is distributed to all parts of the body indiscriminately, and which includes therefore the whole system. But there is also another circuit of lesser extent, which is performed by the blood, by its being sent from the heart to the lungs, and again returned to the heart, after circulating through those organs. This is termed *the lesser circulation,* by way of contrast with the circulation through all the rest of the body, which constitutes *the greater circulation.* For effecting this lesser circulation, a distinct set of blood-vessels, namely, the *pulmonary vessels*, is provided.

(414.) Thus, there are two separate systems of blood-vessels, which have no communication with each other, except through the medium of the heart, which is the common origin and termination of both. The *aortic system*, or, as some modern anatomists have chosen to designate it, the *systemic system*, is that which, taking its rise from the left ventricle of the heart, begins with the *aorta*, or main trunk of the arteries which transmit the blood to the body at large, and is completed by the veins which are collected into two trunks, called *venæ cavæ;* which trunks, again, terminate in the right auricle of the heart. The *pulmonary system*, on the other hand, comprises the pulmonary arteries, which arise by a single trunk from the right ventricle of the heart, and after circulating the blood through the lungs, are continued into the pulmonary veins, and terminate by four large trunks in the left auricle of the heart.

Coats o the vesse

(415.) All these vessels, whether arteries or veins, may be comprehended under the following general description. They are flexible and elastic tubes, for the most part of a cylindrical shape, and composed principally of a membranous or fibrous structure formed into distinct layers, and composing what are called the *coats* of these vessels. The number of these coats has been differently estimated by different anatomists; but it is now generally agreed that those proper to the vessels themselves are principally three: the *external*, the *internal*, and the *middle*, or what has been called the *muscular* coat. Besides these tunics, each vessel is surrounded by a loose and flocculent cellular substance, which connects it with the parts through which it passes, and accompanies it in its whole course; but this substance, being merely a continuation of the cellular substance which fills up all the vacuities of the body, is common to the vessel and to other parts, ought not properly to be considered as belonging to the former, but as adventitious; although some anatomists have dignified it with the title of the *cellular coat.*

(416.) The first proper coat of the vessel is the external coat, which is thicker than the rest, and formed of a membranous structure, in which are intermixed a few filaments of fibro-cellular substance, disposed obliquely with respect to the course of the vessel, and interwoven with the membranous fibres. The innermost membrane is thinner than the former, of a whiter colour, more or less pellucid, and presenting a more uniform homogeneous structure. Its inner surface is perfectly smooth, and much resembles in appearance the serous membranes. Between these membranous coats, there exists a layer of fibres, which have been generally supposed to be muscular, constituting what has been accordingly called the *muscular coat.* Compared with the diameters of the vessels, these coats are proportionably thicker in the smaller than in the larger vessels.

(417.) After giving this general description of the structure of the blood-vessels, we proceed to notice some of the peculiarities which distinguish each class of blood-vessels.

3. *Arterial System.*

Structur of arteri

(418.) Each of the great arterial trunks, belonging respectively to the aortic, and to the pulmonic systems, are furnished, at their origin from the ventricles of the heart, with valves of a semilunar shape, adhering by one of their sides to the margin of the aperture of the ventricle, or mouth of the artery, and having their loose edges turned towards the axis of the artery. These valves are formed by a duplicature of the internal coat, which contains between their folds a thin layer of ligamentous fibres, giving them considerable strength. No valves are found in any other part of the arterial system.

(419.) The external coat of an artery is formed by a dense tissue of fibres, which are interwoven together in different directions, generally very obliquely with regard to the length of the vessel. This texture becomes more compact as we trace it towards the interior, so that the individual fibres can with difficulty be distinguished, unless by a forcible tearing asunder of the substance they compose. Hence the older anatomists have distinguished this inner layer of the external coat, as forming a separate tunic, to which they have given the name of the *nervous coat*, implying thereby a participation in the structure of tendons which were not at that time distinguished from nerves. The division of the external coat into these two layers, is well marked in the larger arteries; but in proportion as we examine the smaller branches, we find a more uniform appearance, the whole assuming the firm and compact texture of fibrous membranes. This portion of the arterial structure is exceedingly strong and elastic, both with respect to a force stretching it in the direction of its length, and also transversely, or in that of its diameter. Its toughness is such that it is not easily cut asunder by a thread employed as a ligature upon the vessel.

(420.) The intermediate, or muscular membrane, is of considerable thickness, has a yellow colour, and is composed of fibres, all of which are arranged circularly; that is, in the circumference of the cylinder. In the large arterial trunks, these fibres form a distinct layer or tunic; but the membrane acquires a still greater proportional thickness in the smaller branches, and then admits of subdivision, by dissection, into several layers. The exterior layers are less dense than the interior; and those which are innermost are the densest of all. The elasticity and firmness of this coat is chiefly in the direction of the circular fibres of which it consists; so that it opposes considerable resistance to any force which tends to dilate the vessel, but yields readily to any power applied for its elongation. It may be considered as partaking of the properties of muscular and ligamentous structures.

(421.) The internal membrane of arteries, which has also been called the *nervous*, *arachnoid*, or *common coat*, is the thinnest of the three; although still, in the larger arteries, it admits of division into two or more layers. The innermost of these is extremely thin and transparent, and its surface is smooth and highly polished, in order that no resistance may be opposed to the motion of the blood. The outer portions are white and opaque, and pass gradually into the substance of the muscular tunic with which it is connected. Its elasticity is very small, and its power of resistance is limited, so that a ligature applied on the vessel generally produces a laceration of the internal coat.

ribu-
of the
ries.

(422.) The general form of the arterial system, if it were isolated from all other parts, would resemble two trees, the trunks of which would be constituted by the aorta, and by the pulmonary artery, and which divides and subdivides successively into smaller and smaller branches, till they arrive at an extreme degree of tenuity. Each portion which intervenes between these divisions preserves the same uniform diameter, and is therefore exactly cylindrical. Each branch is of course smaller than the trunk from which it arises; but the sum of the areas of all the branches into which an artery divides itself, is in general greater than the area of that artery; and consequently the total capacity of the arterial system is progressively increasing in proportion to the number of subdivisions which take place. Hence the whole system may in reality be considered as composing a conical cavity, of which the aorta is the apex, and the ultimate subdivisions the base. The number of subdivisions in the whole course of an artery scarcely ever exceeds twenty, according to the estimate of Haller, who took pains to ascertain this point. The most usual mode of ramification is that of bifurcation, or division of a trunk into two branches, which generally form between them an acute angle. In some instances, especially among the larger arteries, we meet with a branch sent off at right angles from the main trunk, or still more rarely at an obtuse angle.

Anastomoses.

(423.) Arteries have numerous communications among their different branches. These communications, or *anastomoses*, as they are called, are effected sometimes by the reunion of two arteries of nearly equal size, which happen to be proceeding in similar directions, so as to compose one common trunk, which proceeds in an intermediate direction, sometimes by collateral branches proceeding obliquely from the one to the other; while on other occasions, arteries unite from greater distances, so as to form a wide arch, in which each appears to be continuous one with the other; and from the convex side of which, branches are again sent off, which are distributed in minuter ramifications. In some parts the anastomoses are so frequent and numerous, as to resemble a net-work, or plexus of vessels.

(424.) The principal arteries of the limbs are generally found running in situations where they are best protected from injury, and where they are most secure from pressure during the actions of the muscles. Hence they are chiefly met with in the hollow spaces formed on the inner side of the flexures of the joints.

4. *Venous System.*

Veins.

(425.) The chief peculiarities in the structure of the veins, as distinguished from that of the arteries, consist in the greater thinness, and diminished density of their coats, the tenuity or absence of the muscular tunic, and the numerous valves which occur in different parts of their course. The outer coat resembles that of the arteries, but does not present so dense or so fine a texture of fibres; and it possesses less absolute strength. The middle coat is formed of fibres which are more extensile and flexible than those of arteries; and their direction, instead of being transverse, is principally longitudinal. These fibres are not constantly met with in all the parts of the venous system, but vary much in their proportion to the rest of the structure in different veins, as well as in their directions and thickness. It is only in the large veins, near the heart, that this coat presents any appearance of muscular fibres. The inner coat is thin and transparent, like that of the arteries; but differs from the latter in being more extensible, less easily torn, and in its containing a certain proportion of ligamentous fibres in its composition. Some of the veins, such as those within the cranium, which are called *sinuses*, as well as the veins which traverse the bones, being protected by the surrounding parts, appear to consist altogether of this inner coat, and are unprovided with either the muscular or the cellular coats.

(426.) The large veins follow in general the course of the arteries, but are usually twice as numerous; so that where we meet with an artery, we generally find it accompanied by two veins. Their general disposition is arborescent, like the arterial system; but with reference to the function they perform, they may be more aptly compared to the roots than to the branches of a tree; for in following the course of the blood in its circulation, they may be said to take their rise from the minutest vessels, and successively uniting into larger and larger tubes, to terminate by one or two main trunks in the heart. The total capacity of the venous system is at least twice as great as that of the arterial system. The distribution and general mode of ramification of the veins, correspond very exactly to that of the arteries, presenting the same ramified appearance, and the same frequent anastomoses. These collateral communications are exceedingly numerous in the superficial veins, and wherever they are liable to partial obstruction from external pressure. It is in these situations also, that we meet with a great number of valves in the course of the veins. The veins of the deep-seated organs are generally unprovided with valves in any part of their course. The arteries, as we have already seen, have no valves except at their commencement.

Portal system.

(427.) Besides the two venous systems appropriated to the greater and lesser circulations, the former uniting in the venæ cavæ, and the latter in the pulmonary veins, and therefore corresponding to the two arterial systems, there is also another, and more partial system of veins, peculiar to the circulation in the liver, and other viscera of the abdomen. This particular system, which is that of the *vena portæ*, as it is called, is complete within itself; that is, it constitutes a tree, having a common stem, with its proper roots and branches, the whole of which is placed as an intermediate system between the ultimate branches of the gastric, intestinal, and splenic arteries, of which the roots of the vena portæ may be considered as the continuations, and first radicles of the proper hepatic veins, which are the continuations of the ultimate ramifications of the vena portæ. By this arrangement, the blood which has circulated through the stomach, the intestines, and the spleen, is distributed by a new set of veins, throughout the substance of the liver, and is returned to the general mass of blood in the venæ cavæ, after circulating through that organ.

To this peculiar venous system there is no corresponding arterial system.

5. *Capillary System.*

Capillaries.

(428.) The ultimate ramifications of the arteries, as well as the beginnings of the veins, are, in almost every part of the body, vessels of such extreme tenuity, as to be imperceptible without the assistance of the microscope; and they cannot even then be discerned, unless the part be artificially prepared by the injection of some coloured substance into the vessels, or unless they have been accidentally enlarged by disease, so as to have received the colouring matter of the blood. Hence the ancients, who were ignorant both of the art of injecting, and of the power of the microscope, were precluded from a knowledge of the existence of these minute vessels. They believed that a substance, which they termed *parenchyma*, and which they conceived to be of a spongy texture, was interposed between the terminal branches of the arteries, and the beginning of the veins; and this opinion was adopted almost universally by anatomists before the epoch of the discovery of the circulation, and was entertained even after this period, by a great number of eminent anatomists, down to the present day. But the injections of Ent, and the microscopical observations of Malpighi and of Leewenhoek, have sufficiently demonstrated the continuity of the canals by which the blood is made to pass from the arteries into the veins. The researches of modern anatomists, indeed, by shewing the amazing extent to which the minute division of the vascular system is carried, and in which they pervade every part of the frame, have finally exploded the hypothesis of the existence of interposed parenchyma, and have given rise to another hypothesis of an opposite kind, namely, of all the textures of the body being ultimately resolvable into vessels.

(429.) The name of *capillary vessels* is given to those minute branches of either arteries or veins, whose diameter is finer than a hair, and which can therefore scarcely be distinguished by the unassisted eye. Authors have endeavoured to establish three gradations of size in this class of vessels; the largest being those which can be but just perceived by the eye without a magnifying glass; the next, those which require the aid of the microscope for their detection; and the third, those which are capable of admitting only a single red globule of blood, and of which the calibre must consequently be only a very little larger than these globules.

(430.) The larger capillaries undergo several subdivisions in their course, before they arrive at this extreme degree of tenuity; and indeed, their lateral branches of communication are so multiplied as they proceed, that the whole forms a general and extensive net-work of vessels. The total capacity of the capillary system far surpasses that of the arteries and veins; and they contain therefore by much the greatest portion of the blood in the natural and healthy state of the circulation.

(431.) The vascular branches which form the channels of communication between the arteries and the veins, are, with but very few exceptions, referable to the class of capillary vessels. In this continuous course it is scarcely possible to mark with precision, at what point the arterial portion may be said to terminate, and the venous portion to commence. Neither the limit of size, nor the change of direction, is sufficient to lay the foundations of such a distinction; for the alteration of diameter is gradual, and the inflexions are various, and frequently tortuous, so that no determinate criterion can be assumed as characteristic of either artery or vein. Hence arises the propriety of constituting a distinct class of capillary vessels.

(432.) The texture of the capillaries, from the minuteness of their size, scarcely admits of accurate observation. Their coats are thin, soft, pellucid, and therefore invisible to the naked eye, and hardly discernible with the microscope. It is most probable that they are formed, in every instance, by a prolongation of the internal coats of the larger arteries and veins with which they are continuous.

Serous capillari

(433.) As the capability of admitting coloured substances is apparently an indispensable condition for their being visible, the existence of vessels of still smaller diameter, containing only colourless fluids, must more or less be matter of conjecture. A very great number of anatomists and physiologists, however, among whom may be enumerated Boerhaave, Vieussens, Farricnus, Haller, Soemmerring, Bichat, Bleuland, Chaussier, have admitted the existence of another order of capillaries, or *serous vessels*, as they have termed them, of which the diameter is too small to admit even a single red globule, and which therefore circulate only the serous part of the blood. On the other hand, the reality of these pretended vessels is contested by Prochaska, Mascagni, Richerand, and others. Béclard, in his *Anatomie Générale*, has given a review of the arguments employed on both sides in this controversy, which is by no means as yet set at rest, and which will probably have to be decided, more by considerations of a physiological than of an anatomical nature.

Erectile tissues.

(434.) In speaking of the communications between the arteries and the veins, it remains only to be noticed, that in many parts of the body there appears to be interposed between the extreme branches of each, a spongy or cellular structure, into which the arteries occasionally pour out blood, so as to distend these cells, and from which the veins arise by open orifices, and absorb the blood, in order to unload the cells, and remove the accumulation which has taken place. Such a structure has been denominated the *erectile tissue*. It is exemplified on a large scale, in the spleen, and in some of the sexual organs. We shall notice this structure afterwards.

Vascula of differ parts.

(435.) The different parts and textures of the body are supplied with vessels in very different proportions. The organ which ranks first in respect to its vascularity, is the lungs; after which come the integuments, the pia mater, and choroid coat of the eye; next the glands, the glandular follicles, the lymphatic glands, the cortical substance of the brain, the nervous ganglions. To these will succeed in the order of vascularity, the muscles, the periosteum, the adipose tissue, the medullary nervous substance, the bones, and the serous membranes. The tendons and ligaments are amongst the least vascular parts. Still less so are the cartilages, and the arachnoid membrane of the brain; and lastly, the epidermis, and its appendages, as the nails and hair, together with the enamel of the teeth, may be considered as parts entirely devoid of vessels.

uantity f blood.

(436.) The actual mass of blood which the organs of the circulation have to move through the channels we have just pointed out has been variously estimated by different physiologists. The lowest computation is that of Müller and Abeildgaard, who made it out to be only eight pounds. Borelli estimated it at twenty pounds; Planche at twenty-eight; Haller at thirty; Dr. Young at forty; Hamberger at eighty; and Keill at one hundred. Blumenbach states the proportion in an adult healthy man to be one-fifth of the entire weight of the body; but Dr. Good, who has collected these authorities, is disposed to place but little reliance on the latter mode of estimation, on account of the great diversity in point of weight and bulk of adults, whose aggregate quantity of blood would appear to be nearly the same. He thinks the mean of the above numbers, which is between thirty and forty pounds, may safely be taken as nearest to the truth. The proportion of the whole mass of blood which is contained in different parts of the vascular system, varies according to age. In early life, there is nearly an equal quantity contained in the arteries as in the veins. In the adult, one-fourth only is contained in the arterial, and three-fourths in the venous system; and the disproportion is greater as age advances.

Sect. II.—*Phenomena of the Circulation.*

1. *Course of the Blood in its Circulation.*

ourse of e blood.

(437.) Having premised this general outline of the course which the blood takes during its circulation, we shall now follow the several steps more in detail, examining, as we proceed, the evidence afforded us that such is its real course; and we shall lastly inquire into the several powers concerned in its propulsion.

ffice of e heart.

(438.) We shall, for this purpose, begin at that part of its circuit at which the blood is brought back from the lungs, after receiving the vivifying influence of the air, and being thereby *arterialized*, as it has been called. The pulmonary veins, which convey it in this state to the heart, are collected into four great trunks, which open into the left auricle of the heart. As soon as the auricle is distended beyond a certain degree by this flow of blood into it, it contracts and pours the whole of its contents at once into the left ventricle. The constant stream of blood which is flowing towards the auricle from the lungs, prevents any portion of the blood of the auricle from flowing back into them when the auricle contracts. No sooner has the ventricle received this blood, which has passed into it by a sudden influx, than it is stimulated to a vigorous contraction of its muscular fibres, which, surrounding the cavity in a spiral direction, contract its cavity, and, exerting a powerful pressure on the contained fluid, propels it with prodigious force into the aorta. The contraction of the ventricle is attended with the raising of the mitral valve, interposed between it and the auricle, and the sides of that valve being closely applied to the aperture by which the blood had entered the ventricle, all return of the blood into the auricle is thereby prevented. The whole of it rushes, therefore, as an impetuous torrent into the aorta, or main trunk of the arterial system. The blood which has entered the artery is again prevented from flowing back into the ventricle, by a valvular apparatus of the same kind as that which occurs between the auricle and the ventricle. These valves, placed at the entrance of the aorta, are called the *sigmoid*, or *semilunar valves.* They are three in number, each being attached by its convex edge to the coats of the artery, to which it is closely applied when the stream of blood is flowing in a direction from the heart, but which is immediately raised, and the three loose edges joining together, form a complete barrier to the passage of the blood when moving in the contrary direction.

stemic ulation

(439.) The blood, having passed into the aorta, is conveyed through its branches and ramifications to all the parts where these ramifications extend, till it reaches the capillaries, where it moves more slowly, yet still proceeds on its course, supplying every part with the materials necessary for the maintenance of their nutrition and vital powers. From the capillaries the blood is brought back by the minuter branches of the veins, which, uniting successively to form larger and larger trunks, are at length collected into the two venæ cavæ, the one descending from the head and superior parts of the body, and the other ascending from the inferior parts, and both joining at the right auricle of the heart. The same process now takes place in the right cavities of the heart, which was described as occurring in the left. The right auricle is filled with blood from the venæ cavæ; it contracts and pours its contents into the cavity of the right ventricle, which, being in its turn stimulated to contract, propels the blood it had received from the auricle into the trunk of the pulmonary artery; which artery likewise distributes it, by a similar system of ramifications, to the membrane lining the air vesicles of the lungs. All retrograde motion of the blood is prevented as effectually in this case as in the former, by the interposition of the tricuspid valves between the auricle and ventricle, and by the semilunar valves placed at the entrance of the pulmonary artery.

Pulmonary circulation.

(440.) From the ultimate ramifications of the pulmonary artery the blood is conducted into the capillary vessels, which are spread over the membrane of the air-cells of the lungs, where it undergoes the change of quality from venous to arterial, consequent upon its exposure to the chemical action of the oxygen which is contained in the atmospheric air admitted into those cells. From these capillaries it is collected by the pulmonary veins, and returned, as before stated, to the heart, to be again distributed to every part of the body.

Systole and diastole.

(441.) While one portion of the blood is circulating in the system, another portion is circulating in the lungs. Both auricles are filled at the same moment, and contract together; each sending its blood into the corresponding ventricle. In like manner, the two ventricles contract simultaneously, and propel their contents into their respective arterial trunks. The contraction of the heart is called *the systole;* its relaxation *the diastole.*

2. *Proofs of the Circulation.*

Discovery of the circulation.

(442.) The discovery of the course which the blood takes in its circulation, a discovery of such vast magnitude, that almost the whole of the present doctrines of physiology and pathology are either directly founded on it, or are more or less immediately related to it, was made in the beginning of the seventeenth century. It was one of the earliest fruits of that active spirit of inquiry, and rational process of investigation, which, since the era of Bacon, was beginning to diffuse itself in Europe. It was an honour reserved for our illustrious countryman Harvey, whose fame must live as long as science is cherished among men. While it is the fate of other discoveries, that their authors are either soon forgotten, or only known to a small class of those who devote their attention peculiarly to the subject to which they relate, the name of Harvey is become familiar to all who have any acquaintance with general literature, or pretensions to a liberal education. However firmly the truth of his great discovery be established in the present time, it was, in its first promulgation, keenly contested by many contemporary physiologists. To us who have no such prejudices to warp our judgment, and who are furnished with so large a body of evidence on the subject, the controversy appears exceedingly frivolous and absurd. Yet we must recollect that in every subject of human opinion, it requires a considerable time to wean mankind from errors which have been long and deeply rooted in their minds, however palpable such errors may appear to the eyes of those who have not been so blinded. As it may still, however, be satisfactory to know the grounds upon which the doctrine is founded, we shall briefly enumerate the leading facts and arguments that establish it.

Proofs of the circulation. 1. Ligatures.

(443.) The most striking proofs that the course of the blood along the arteries is from the heart towards the extremities of those vessels, and along the veins in the contrary direction, are obtained from ligatures on those vessels. If any of the larger arterial branches be tied, that portion of the vessel which is situated between the ligature and the heart, immediately swells, becomes distended with blood, and exhibits strong pulsations; and if while in this state it be punctured, the blood rushes out with violence, and in successive jets, corresponding to the pulsations of the heart. The part beyond the ligature, on the other hand, or that farthest from the heart, is flaccid and empty, and affords no blood when divided; it is also void of pulsation. Phenomena precisely the reverse of these are exhibited when similar experiments are made on the veins; in them, the part most distant from the heart becomes turgid, while the nearer part is empty. This last experiment is one that is made every time a person undergoes the operation of blood-letting. A ligature is applied round the arm, from the pressure of which on the subcutaneous veins, they are made to swell every where below the ligature, that is, farther from the heart; while all the veins above the ligature are empty, the blood having been propelled onwards in its course towards the heart. Those parts which are swelled pour out their blood profusely on being punctured; and when the bandage is removed, the flow is stopped, in consequence of the blood finding a ready passage to the heart.

2. Valves.

(444.) In the veins, we have additional evidence, from the structure of the valves, that the blood can move only in one direction, namely, towards the heart. The valves at the entrance of the ventricles and arterial trunks, which allow of motion only in a particular course, lead to a similar conclusion with respect to the direction of the current in its passage through the heart. It is impossible by artificial means to force fluid injections through the heart, in a course contrary to that in which the blood moves; and the same insuperable resistance is experienced in the attempt to pass injections in other parts of the circulating system, when in opposition to the natural course taken by the blood, while the same fluids readily find their way from the arteries into the veins, when thrown in that direction.

3. Microscopic observation.

(445.) Ocular demonstration of the course of the blood while circulating in the smaller arterial and venous branches, and also in the capillaries, is afforded by the microscope, when a very thin and transparent membrane in which such vessels are distributed is placed in the field of a good microscope. The web between the toes of a frog, the surface of its vesicular lungs, the mesentery, the membrane in the tail of small fishes, are all of them capable of exhibiting these phenomena, and present, indeed, a spectacle of the highest interest.

4. View of the heart.

(446.) The successive action of the cavities of the heart, in the order above enumerated, may also be seen when the hearts of living creatures are exposed to view; and this spectacle may be afforded without pain to the animal, if, after its head has been completely separated from the body, respiration be kept up by artificial means.

5. Transfusion of blood.

(447.) The transfusion of the blood of one animal into the vessels of another is a curious illustration of the doctrine of the circulation. In this operation, the artery of one animal is connected by a tube with the vein of another animal; the consequence of which is that the first is gradually emptied of its blood, while the vessels of the other are in a state of repletion. If an opening be made at the same time in the veins of this second animal, the blood originally belonging to it will escape, and thus the whole mass of its circulating fluid will be changed. Experiments of this kind were at one time very common, but they have long ceased to excite curiosity, and are now rarely practised.

6. Wounds of vessels.

That the blood moves with great rapidity and force through the larger vessels, is proved by the immense quantity that is quickly lost if any great artery or vein be wounded.

Sect. III.—*Powers concerned in the Circulation.*

(448.) We have next to enquire into the nature and magnitude of the forces by which the blood is impelled in its course, the resistance opposed to its progress, and the general laws by which its movements are regulated.

(449.) The subject will naturally divide itself into four parts; namely, as relating to the powers of the heart, of the arteries, of the capillaries, and of the veins.

1. *Action of the Heart.*

Action of the heart.

(450.) The intention and purpose of the auricles, which are placed as ante-chambers to the ventricles, is to receive the blood in a constant stream from the veins, which fill it gradually and equably, so that when the distension has reached a certain degree, the auricle may contract and discharge the whole of its contents, with a sudden impetus, into the ventricle. The thickness and muscular force of the auricles are very inferior to those of the ventricles, which being destined to propel the blood with considerable momentum into the arterial system, are exceedingly powerful, but seem to require the stimulus of a sudden and forcible distension, in order to excite them to a sufficiently energetic action. It appears, indeed, that this mechanical distension and separation of their sides from the influx of fluid, is the natural stimulus that excites them to contraction; for they are not affected by any of the causes which produce contractions in the voluntary muscles, such as irritation of the nerves which supply the heart. On the other hand, the mere introduction of warm water into these cavities, when previously emptied of blood, is sufficient to renew the action of the heart.

Absolute force of the heart.

(451.) It is exceedingly difficult to form any probable estimate of the absolute force exerted by the heart, and more particularly by the left ventricle, in propelling its contents. No inquiry in physiology was pursued with more ardour, has been the subject of more various controversy, or has given rise to so many voluminous and elaborate calculations.

(452.) It will be quite evident that a very considerable power is required, in order to enable the heart to propel the blood through the arteries, when we consider the enormous resistances opposed to its progress, and when we also take into account the great velocity given to it in its motion. The column of blood already contained in the arterial system, must have its velocity accelerated, in order to admit of the passage of fresh blood into the aorta. The arteries require also to be distended for the admission of this additional quantity of blood, every time that the ventricle contracts. The angles and flexures which the blood is obliged to follow in its course through the vessels, must be causes of retardation, and must be productive of a loss of force, which the muscular power of the heart is ultimately called upon to supply. The operation of all these retarding causes is so complicated, that we need not be surprised at the problem of the force exerted by the heart, having baffled the skill of the best mathematicians, and their calculations being so widely different from one another. Thus, while Keil estimated the power of the left ventricle at only five ounces, Borelli calculated that its force could not be less than one hundred and eighty thousand pounds. Dr. Hales computes it to be exactly fifty-one pounds and a half; while Tabor concludes its amount to be one hundred and fifty pounds. Such irreconcilable results sufficiently show the futility of most of the reasonings on which they are founded, and the impossibility of making any satisfactory approach towards the solution of the problem. We should, on the whole, be more disposed to place confidence in the estimate of Hales, who moreover states, that the velocity with which the blood passes into the aorta, is about one hundred and fifty feet per minute, or two feet and a half per second; and that the quantity of blood passing through the heart during each hour, is about twenty times the whole mass of blood contained in the body; or, in other words, that the whole mass completes twenty entire circulations in an hour. The great velocity of the blood in the vessels is exemplified by the fact, that a fluid introduced into one of the jugular veins of a horse, has been detected in the opposite vein, and even in the vena saphena of the leg, in the course of half a minute.

(453.) It has been keenly disputed whether the heart is able completely to empty its cavities at each contraction; and the question, which is not one of any real importance, is hardly yet decided.

(454.) Another subject of controversy which was much agitated among the French physiologists in the middle of the last century, is, whether the heart is shortened or elongated during its systole; that is, whether the apex approaches the base during the contraction of the ventricle, or recedes from it. From the numerous observations of Spallanzani, as well as of other experimentalists, there seems to be no doubt that during the systole all the parts are brought nearer to the tendinous ring surrounding the auriculo-ventricular orifices, which may be regarded as the fixed pivot of its movements, and consequently the length, as well as the other diameters of the heart, is shortened. During this action, however, the curvature being suddenly straightened, the apex is projected forwards, and produces that striking against the ribs which is felt by the hand applied externally to the chest.

apacities the ntricles

(455.) The right ventricle having only to perform the lighter task of circulating the blood through the lungs, is much inferior in thickness and strength to the left ventricle, which has to propel the blood through the whole aortic system, forming a course of much greater magnitude than that of the pulmonary vessels. But, on the other hand, the capacities of the two ventricles are nearly equal, as might be expected, when it is considered that the same quantity of blood which is forced out from the one, must, in the course of circulation, pass through the other; and that both the ventricles contract the same number of times in a given interval. The quantity of blood expelled by the heart at each contraction, is estimated by Blumenbach at two ounces. So that, reckoning the whole mass of blood at thirty-five pounds, or four hundred and twenty ounces, and the contractions to be repeated seventy-five times in a minute, the whole of the blood will have passed through the heart in about three minutes; thus agreeing very nearly with the estimate of Hales already stated, (§ 452.)

ritability the art.

(456.) It has been supposed that the heart exerts some force in the diastole as well as systole; and that the recoil of the muscles when they spring back, after they have performed their contraction, creates a force of suction, which promotes the flow of blood in the great veins towards the heart. But the truth of this proposition is exceedingly dubious.

(457.) The movements of the heart are completely involuntary; that is, are entirely beyond the control of the will. Nor are its natural actions accompanied by any sensations. They are, generally speaking, totally independent of the nervous system; for they may be maintained after the destruction of the brain and spinal cord, and even after all the nerves which supply the heart have been divided. Yet these movements are capable of being influenced, often very suddenly, by an impression made upon any considerable portion of the nervous system. The regular contractions of the heart appear to be excited simply by the stimulus of distension from the periodical influx of blood into its cavities. This organ is evidently endowed with a very high degree, and a very peculiar kind of irritability, not subject, like that of the voluntary muscles, to exhaustion, by the most powerful exertions, reiterated for an indefinite time.

2. *Actions of the Arteries.*

Action of the arteries.

(458.) Whatever be the velocity with which the blood is projected from the heart into the aorta, that velocity is soon retarded, in the course of its progress from the larger to the smaller branches of that arterial trunk. This is amply illustrated by the observation of the effects which follow the division or wounds of arteries in different parts of their course. A wound of the carotid artery is almost instantly fatal, from the deluge of blood which rushes out from the opening. The division of the other large arterial trunks is no less certainly fatal, if means be not at hand to stop the torrent that gushes out with resistless impetuosity. In the smaller arteries, such as those in which the motion of the blood can be viewed with the microscope, the current is very languid and feeble. It is, in reality, however, much slower than it appears to be; for it should be recollected, that in viewing the magnified image of an object, its motion is magnified in the same proportion as its dimensions.

Retarding forces.

(459.) The cause of this continual retardation of the blood is to be traced in the structure of the arterial system itself. The velocity of a fluid passing through a tube of unequal diameter in different parts, must be inversely as the area of the tube at each respective point of its length; that is, inversely as the square of the diameter. Accordingly, if we suppose two cylinders of different diameters joined together, and that a fluid is passing from one end to the other, it must evidently move with less velocity in the wider than in the narrower part; for if it did not, it would leave behind it a vacant space. But a vacuum of this kind can never take place in the living body, in which, with whatever other properties they may be endowed, the fluids are still obedient to the laws of hydraulics. The arterial system consists of an assemblage of tubes, which, though they continually diminish in their diameter as they divide into branches, yet as the united area of the branches is always greater than that of the trunk out of which they arose, they constitute, when taken as a whole, a system of channels of continually increasing capacity, as we follow them from the heart to the extremities. The whole cavity through which the blood moves, may therefore be represented by a cone, having its apex at the heart, and its base at the termination of the minutest arterial ramifications. The beginning of the aorta is, in reality, the narrowest part of the whole channel, considered with reference to the united areas of the successive order of branches as they divide. The sum of all the areas of the minutest ramifications of the arteries existing in the body, comprising myriads of myriads of vessels, if they could be collected together, would form an area of immense extent. No wonder, therefore, that the motion of the blood, when it arrives at this part of the circulation, should be so prodigiously retarded as actual observation shews us that it is.

(460.) Notwithstanding this great difference in the velocity of the blood in different parts of its arterial circulation, it would appear from the experiments of Poiseuille, that the pressure exerted by the blood, as measured by the column of mercury it will support at different distances from the heart, is not very different.

Elastic power of arteries.

(461.) The arteries being always full of blood, and their coats distended by its presence, the elasticity of these coats is always exerted, and produces a constant pressure on the blood, independently of any force that may urge it forwards. The entry of a fresh quantity of blood forced into them by the action of the heart, produces a slight additional distention of their coats, and a consequent reaction of their elasticity. This reaction of the arteries in each interval of the heart's pulsation, tends much to equalize the motion of the blood; and has the effect also of propagating the impulse originally given to it by the heart very quickly to the remoter parts of the arterial system. The velocity with which this impulse is transmitted, is much greater than the actual motion of the blood, and partakes of the nature of a wave, which, as is well known, advances with incomparably greater rapidity than the progressive motion of the fluid itself. It is the impulse given to the sides of the artery by this wave, as it may be called, which constitutes the *pulse*, and which is more particulary rendered sensible on compressing the artery with the finger.

Their muscular action.

(462.) It has been a much disputed question, both here and on the continent, whether the arteries assist the circulation by exerting any contractile power of their own. The evidence in favour of their exerting such an action is very strong, and apparently irresistible. The power of the heart, however enormous we may suppose it to be, would appear to be quite inadequate to drive the whole mass of the blood through the infinite number of narrow and contorted channels through which it actually moves, were it not assisted by some additional force, derived from the contractions of the arteries themselves. Many facts prove that variations in the impetus of the blood, and in the quantity which circulates in particular parts, occur at different times, quite independently of any general alteration of the circulation, or of any corresponding change in the action of the heart. The only assignable cause for such differences is a variation in the extent of action of the arteries. Numerous experiments show that stimuli applied to the smaller arteries occasion in them a temporary constriction at the points where irritation has been excited; which, after a certain time, goes off spontaneously. Various other facts also prove that the arteries have a power of spontaneous contraction; this power is exhibited in the most unequivocal manner when an artery has been cut across; the consequent hæmorrhage being, after some time, stopped by this action of the coats of the artery. This contractile force of arteries is probably derived from muscularity, although the muscular structure is not distinctly perceptible. It is considerably greater in the smaller than in the larger arteries; and it is probably greatest of all in the capillaries.

(463.) Notwithstanding the facts above stated, the muscularity of the arteries is denied by some of the most eminent of the continental physiologists; and among others, Magendie, Broussais, Adelon, Alard, Rolando, and Müller.[1]

3. *Action of the Capillaries.*

Action of the capillaries.

(464.) The particular agents by which the circulation is carried on in the capillary vessels cannot be very precisely determined; and the subject has given rise to much controversy among physiologists. The action of these vessels is evidently of the greatest importance in relation to every other function, and more especially to the production of every permanent change which may take place in the form or composition of the organs. The variable state of the circulation in different organs at different times, must be occasioned principally by diversities in the actions of the capillaries. It appears from the experiments of Hunter, that while the larger arteries possess a greater proportion of elastic power, the smaller arteries have a comparatively greater muscular contractility; and this reasoning may, with great appearance of probability, be extended to the capillaries. It would appear, indeed, from various observations on the inferior animals, and in particular from those made by Dr. W. Philip, that the circulation in the capillaries may be kept up for some time after the pulsation of the heart has entirely ceased, and even when that organ has been altogether removed from the body. In many cases, indeed, the capillaries, when viewed with the microscope, have been seen to contract on the application to them of stimuli, which, in other cases, excite contractions in the muscular fibre. The pulsatory motion of the blood given to it in the arteries by the periodical contractions of the heart, is scarcely sensible in the smaller arteries, and is totally lost in the capillaries, where we find the blood moving in a uniform stream. This is a necessary consequence of the tortuous course of the channels through which it passes, and of the numerous communications among these vessels, which equalize the effects of the original impulse, and extend them over the whole period of time that intervenes between one pulsation and the next.

4. *Action of the Veins.*

Action o the veins Vis à ter

(465.) The blood which is returned from every part of the system by the veins, is gradually accelerated in its progress towards the heart, for a similar reason that it was retarded in its transmission through the arteries, namely, that the capacity of the channel through which this fluid is passing is continually diminishing; for the united area of the beginnings of the veins is incomparably smaller than the conjoined area of the two venæ cavæ. The office of the veins generally appears, on the whole, to partake more of a mechanical action than that of the arteries, though it is probable that the smaller veins may derive from their structure powers analogous to those of the capillaries. The power which impels the blood forwards in the veins is chiefly the impulse it has already received, and the pressure exerted on it from behind, or what has been technically termed the *vis à tergo*. This force is assisted also in many situations by the pressure made on the veins by the action of the neighbouring muscles, which, in consequence of the valves placed in the course of the veins, preventing all retrograde motion in the blood, must contribute to force it onwards towards the heart. It is probable, however, that the veins are not altogether destitute of a power of contraction, though less considerable than that possessed by the arteries; and that the exertion of this power has some share in accelerating the motion of the blood in the venous system. Whatever power may arise from the force of dilatation exerted by the auricles of the heart during their diastole, which, however, we have reason to believe is very trifling, must be added to the account of the forces that tend to promote the motion of the blood towards those cavities. Some have supposed that a similar power is derived from the expansion of the chest in the act of inspiration; but this, if it exist at all, is of very inconsiderable amount. The venæ cavæ near their termination in the auricles, are furnished with a distinct layer of muscular fibres, apparently for the purpose of enabling them to resist the retrograde impulse communicated to the blood by the contraction of the auricles.

5. *Pulmonary Circulation.*

Pulmona circulatio

(466.) There is nothing very different in the circulation through the pulmonary arteries, capillaries, and veins, from what takes place in the corresponding vessels of the systemic circulation, excepting that junctions are occasionally formed between the smaller branches of the branchial arteries which have their origin from the aorta, and the branches of the pulmonary artery. The phenomena which occur in asphyxia, or death from suffocation, prove that the pulmonary capillaries have a distinct action of their own in carrying on the circulation. The beautiful net-work formed by the inosculating branches of the pulmonary capillaries was first observed by Malpighi, and has received the name of *Rete mirabile Malpighi.* The pulmonary veins are wholly destitute of valves, not being exposed to variations of pressure from the actions of the surrounding muscles. They are furnished, like the venæ cavæ, with a reinforcement of muscular fibres, in the neighbourhood of the left auricle in which they terminate.

---

[1] See Milligan's *Translation of Magendie*, and Bostock's *Physiology*, p. 244.

(467.) In one respect, the vessels of the pulmonary circulation differ from those of the systemic, namely, that the arteries are carrying dark-coloured blood, and the veins florid blood; the former being termed *venous*, from having the qualities of that which is returned by the veins of the system; the latter being termed *arterial*, because it has the qualities of that which circulates in the systemic arteries.

CHAP. VIII.—RESPIRATION.

bjects of spiration.

(468.) The object of the function of respiration is the conversion of venous into arterial blood, by its exposure to the chemical influence of atmospheric air received into the lungs. This arterialization of the blood is a process more essential to the continuance of life than even the assimilation of aliment. The necessity for air is more imperious than the demand for food; and the interruption to its supply cannot be continued for a few minutes without being fatal to life. In comparing the extent to which this function is carried on in the different classes of animals, we shall find that in general the intensity of all the vital actions is nearly in proportion to the perfection in which the objects of this function are accomplished.

(469.) The consideration of the function of respiration, then, comprises an inquiry into the three following objects; first, the mechanical means by which the air is alternately admitted and discharged from the lungs; secondly, the provision made for bringing the blood to the lungs, and exposing it to the action of the air; and, lastly, the chemical changes which are produced on the blood by the action of the air in that organ. The means of fulfilling the second of these objects has already been sufficiently explained in the account we have just given of the circulation. It remains, therefore, that we consider the first and third branches of the inquiry.

Sect. I.—*Mechanism of Respiration.*

chanism espira-

(470.) The anatomical structure of the organs of respiration, namely, the lungs with its air passages, including the trachea. bronchiæ, and air cells, together with the general conical cavity of the thorax, bounded by the sternum in front, the spine behind, and the ribs on every other side, while its lower side, or basis of the cone, is closed by the diaphragm, have already been fully detailed in the treatise on Anatomy, to which it is only necessary here to refer.

(471.) The mechanical act of respiration is divisible into two periods, that of *inspiration*, during which air is drawn into the lungs, so as to distend their vesicles, and *expiration*, during which the air which had been so received is expelled.

piration.

(472.) Inspiration is accomplished by enlarging the capacity of the thorax in all its dimensions. This is effected by the action of different sets of muscles. The principal muscle of inspiration is the diaphragm, which has an arched form, the convexity being towards the chest. Its attachments by radiating fibres arising from a central tendinous portion, and inserted into the ribs which form the lower margin of the chest, are such, that when they contract they draw down the middle tendon, and render the diaphragm more flat than it was before. Hence the space above is enlarged. The flattening of the diaphragm takes place chiefly in the fleshy lateral portions, but the middle tendon is also slightly depressed.

(473.) The second set of muscles employed in inspiration are those which elevate the ribs; and the principal of these are the two layers of intercostal muscles. Each rib is capable of a small degree of motion on the extremity by which it is articulated with the vertebræ. This motion is chiefly an upward and a downward motion. But since the ribs, as they advance from the spine towards the sternum, bend downwards in their course, the effect of the vertical motion just described will be that of raising the sternum, and increasing its distance from the spine; enlarging, consequently, the capacity of the chest. The intercostal muscles are disposed in two layers, each passing obliquely, but with opposite inclinations, from one rib to the adjacent rib. Hence they act with the advantage of oblique muscles on the principles formerly explained.

(474.) Thus there are two ways in which the chest may be dilated; first, by the diaphragm, and, secondly, by the muscles which elevate the ribs. In general, when the respiration is natural and unconstrained, we chiefly breathe by means of the diaphragm; but we also employ the intercostal muscles when the respiration is quickened or impeded by any cause. If respiration should be rendered difficult several other muscles are called into play in aid of the intercostals; namely, the great muscles situated in the back and sides, which connect the ribs to the spine and to the scapula; and several of the muscles of the neck are also thrown into action as auxiliaries on these occasions, when the respiration becomes laborious.

(475.) The glottis is kept open, during inspiration, by the muscles of the larynx which perform that office; and when a forcible inspiration is made, the nostrils are expanded, the lower jaw depressed, and every action which can in the remotest degree concur in the effect of removing all obstruction to the passage of the air into the trachea, is exerted.

(476.) Having thus shown how the cavity of the thorax is dilated, let us next trace the effect of this expansion upon the lungs. It is obvious, that if when, by the descent of the diaphragm and elevation of the ribs, the cavity of the chest is enlarged, the lungs were to remain in their original situation, an empty space would be left between them and the sides of the chest. But no vacuum can ever take place in the living body; the air already present in the air-cells of the lungs must, by its elasticity, expand these organs; and the external air, having access to them by means of the trachea, will rush in through that tube in order to restore the equilibrium. This, then, is *inspiration.*

Expiration.

(477.) The expulsion of the air from the lungs constitutes *expiration.* This takes place as soon as the air which had been inspired has lost a certain portion of its oxygen, and received in return a certain quantity of carbonic acid gas and of watery vapour, by having had communication with the blood in the pulmonary capillaries. When thus contaminated it excites an uneasy sensation in the chest, and the intercostal muscles relaxing, the ribs fall into their original situation, and the relaxed diaphragm is pushed upwards by the action of the abdominal muscles. The lungs, being compressed, expel the air they had received, and this air escapes through the trachea. The movements of inspiration are in like manner prompted by an uneasy sensation consequent upon the presence of venous blood in the pulmonary system.

(478.) Thus the lungs are merely passive agents in the mechanism of respiration; for it does not appear that they have, as was at one time supposed, any inherent power of extension or contraction, if we except only that arising from the elasticity which they possess in common with all membranous textures. Hence, if an opening be made in the sides of the chest, the lung on that side immediately collapses, in consequence of the internal pressure of the air against its air-cells, which kept the lung expanded, being balanced by the external pressure of the atmosphere which has been admitted on the outer surface of the lung.

(479.) The alternations of inspiration and expiration, which together constitute one act of breathing, take place, in ordinary health, about once for every four pulsations of the heart; and as both are generally accelerated in the same proportion, the same rule usually holds good in states of disease.

Quantity of air respired.

(480.) The quantity of air taken into the lungs at each inspiration has been very variously estimated by different experimentalists. It differs, indeed, considerably in different persons, and in different states of the system; but from the concurrent testimony of the most accurate experimentalists, the average quantity appears to be about forty cubic inches. By a forcible expiration there may be expelled, in addition to this quantity, about a hundred and seventy inches more. But even after this effort has been made, there still remain about a hundred and twenty cubic inches in the lungs; so that, adding all these quantities together, it will appear that the lungs are capable of containing, while in their most expanded state, after ordinary inspiration, about three hundred and thirty cubic inches of air. One eighth of the whole contents of the lungs, therefore, is changed at each respiration. If we suppose that we respire twenty times each minute, the quantity of air respired during twenty-four hours will amount to six hundred and sixty-six cubic feet.[1]

Sect. II.—*Chemical Effects of Respiration.*

Chemial effects. 1. On the air respired.

(481.) Before we inquire into the changes produced on the blood by its exposure to the air in the lungs, it will be proper to notice the changes which the air undergoes by this process. The air of the atmosphere is found by chemical analysis to consist of seventy-nine per cent of nitrogen, twenty of oxygen, and one of carbonic acid.[2] When expired, the principal change which has taken place in it is the substitution of a certain quantity, which, on an average, is about seven and a half per cent, of carbonic acid gas for a nearly equal quantity of oxygen gas, and the addition of a quantity of aqueous vapour. Air which has passed through the lungs only once is incapable of supporting the combustion of a taper, which is accordingly extinguished the moment it is immersed in the air. The weight of the oxygen consumed in the air respired in the course of a day, will be found to amount to about two pounds and a quarter avoirdupois, or nearly 15,500 grains, occupying in its gaseous state a volume of 45,000 cubic inches, or a little more than 26 cubic feet. The quantity of carbonic acid expelled from the lungs is somewhat less than this; its total bulk in the twenty-four hours amounting on an average only to 40,000 cubic inches, or 23·2 cubic feet. Its total weight is 18,600 grains, or 2·86 pounds avoirdupois. The weight of the quantity of carbon contained in this amount of carbonic acid is 5,208 grains, or very nearly three quarters of a pound; and that of the quantity of oxygen is 13,392 grains. Hence the quantity of oxygen which disappears from the air respired, over and above that which enters into the composition of the carbonic acid gas, is 2,108 grains, and had occupied, while in a gaseous state, 5000 cubic inches. The only way in which we account for the disappearance of this oxygen is, by supposing it to have been absorbed by the blood.

(482.) The numbers given above are, of course, to be taken as imperfect approximations to the truth, being deduced as the mean of the best authenticated observations, in which, however, there exist such great discrepancies as to render any accurate appreciations nearly hopeless. An excellent summary of the results which have been arrived at by different experimentalists, with critical remarks on their respective values, will be found in *Dr. Bostock's Elementary System of Physiology.*[3]

(483.) Much difference of opinion has prevailed with respect to the absorption or evolution of nitrogen during respiration. From the accurate experiments on this subject made by Dr. Edwards, it appears that on some occasions there is a small increase, and in others a diminution of the nitrogen of the air respired. But the limits within which we must confine ourselves in this treatise, forbid our entering into the experimental details from which this conclusion is deduced.

(484.) The quantity of water exhaled from the lungs in the course of a day, has been estimated by Dr. Thomson at nineteen ounces, and by Dr. Dalton at twenty-four.

(485.) It should be observed, however, that the quantity of carbonic acid thrown off from the lungs, is liable to great variation from several causes; it has been found by Dr. Prout to be greatest at noon, and least at midnight. It has also been ascertained that it is less in youth than in middle age; and that it is diminished by causes which induce fatigue or lessen the vital energies.

2. On blood.

(486.) We have next to inquire what changes have, in the meanwhile, been effected in the blood by the action of the air to which it has been subjected in the lungs. A visible alteration in the first place, is produced in its colour, which, from being of a dark purple, nearly approaching to black, when it arrives at the air cells by the pulmonary arteries, has acquired the bright intensely scarlet hue of arterial blood when brought back to the heart by the pulmonary veins. In other respects, however, its sensible qualities do not appear to have undergone any material change. Judging from the changes produced on the air which has been in contact with it, we are warranted in the inference that it has parted with a certain quantity of carbonic acid and of water, and that it has in return acquired a certain proportion of oxygen. Since it has been found that the quantity of oxygen absorbed, is greater than that which enters into the composition of the carbonic acid evolved, it is obvious that at least the excess of oxygen is directly absorbed by the blood; and this absorption, constitutes, no doubt, an essential part of its arterialization.

(487.) It has been much disputed whether the combination which seems to be effected between the oxygen of the air and the carbon furnished by the blood, occurs during the act of respiration, and takes place in the air cells of the lungs, or whether it takes place in the course of circulation. On the first hypothesis, the chemical process would be very analogous to the simple combustion of charcoal, which may be conceived to be contained in the venous blood in a free state, exceedingly divided and ready to combine with the oxygen of the air; and imparting to that venous blood its characteristic dark colour; while arterial blood, from which the carbon had been eliminated, would exhibit the red colour natural to blood. On the second hypothesis, we must suppose that the whole of the oxygen which disappears from the air respired, is absorbed by the blood in the pulmonary capillaries, and passes on with it into the systemic circulation. The blood becoming venous in the course of the circulation, by the different processes to which it is subjected for supplying the organs with the materials required in the exercise of their respective functions, the proportion of carbon which it contains is increased, both by the abstraction of the other elements, and by the addition of nutritive materials prepared by the organs of digestion. The oxygen which had been absorbed by the blood in the lungs, now combines with the redundant carbon, and forms with it either oxide of carbon, or carbonic acid, which is exhaled during a subsequent exposure to the air in the lungs. Many facts tend strongly to confirm our belief in the latter of these hypotheses.

---

[1] See Bostock on *Respiration*, and also his *Physiology*, 3d edition, pages 321 and 361.

[2] The recent experiments of De Saussure tend to show that the proportional quantity of carbonic acid gas in atmospheric air is even less than this. He estimates it at only four parts by volume in a million volumes of air.

[3] We refer particularly to the 3d section of chap. vii. p. 336—362.

(488.) It appears from a multitude of experiments, as well as from observations of the phenomena which take place in asphyxia, (that is, in the suspension of the vital actions from an interruption to respiration, as in hanging or drowning, or immersion in any gas not fitted for respiration,) that if the blood be not arterialized, and if, retaining its venous character, it be circulated in that state through the arteries of the system, it will act as a poison to the organs to which it is sent, destroying both the nervous and sensorial powers, and impairing the irritability of the muscles; and that this is the cause of the rapidity with which death ensues under these circumstances. It thus appears that respiration requires to be constantly kept up in order to free the blood from the continual additions of carbon which are made to it by the various processes of assimilation and absorption. It is also a principal agent in perfecting the animalization of the chyle, which is added to the blood, and in converting it into fibrin.

SECT. III.—*Animal Temperature.*

volution heat.

(489.) Since we find that the human body, as well as those of all warm-blooded animals, is constantly maintained during life at a temperature higher than that of the surrounding medium, at least in temperate climates, it becomes interesting to inquire into the sources whence this heat is evolved. The union of carbon and oxygen which takes place in consequence of respiration, is the most obvious of these sources; and suggests that the evolution of animal heat takes place in a manner somewhat analogous to the ordinary combustion of carbonaceous fuel. The circumstance of the equable heat of every part of the body, excepting the immediate surface where it is cooled by the contact of the air, and by cutaneous perspiration, would be in perfect accordance with the theory of Dr. Crawford already explained; for if the combination of oxygen with carbon take place gradually in the course of the circulation, it will follow that the evolution of heat will also take place at the same time, and in the vessels employed in the circulation. Or even if the combination took place in the lungs, if it could be shewn, as Dr. Crawford endeavoured to prove, that arterial blood has a greater capacity for caloric than venous blood, all the heat that would have been evolved in the pulmonary vessels would be absorbed by the arterial blood, and given out in the course of its circulation, during its gradual conversion into venous blood, which has a less capacity for caloric.

(490.) It would appear, however, from some recent experiments of Dulong and Despretz,[1] that only three-fourths of the whole quantity of caloric produced by the living system can be explained by the combination of oxygen with carbon in respiration. Probably, therefore, several of the other chemical changes induced on the blood by the processes of secretion and nutrition, contribute to the further evolution of caloric, and to the maintenance of the animal temperature. This evolution appears, although primarily dependent on respiration, to be in a great measure controlled by the action of the nervous powers; and to be regulated by a variety of circumstances in the condition of the other functions, especially that of the circulation, which are very imperfectly known; and the inquiry into which would lead us into a field of discussion far too extensive for the limits within which we must confine ourselves in the present treatise. We must content ourselves, therefore, with again referring to the work of Dr. Bostock for more ample information on these subjects.

CHAP. IX.—SECRETION.

Object of secretion.

(491.) Secretion is that function by which various substances are either separated from the blood or formed from it, in order to be applied to some useful purpose in the economy. We have noticed, in the course of the preceding inquiries, several instances of fluids prepared from the blood, and rendered subservient to different uses in the economy. The saliva, the gastric and pancreatic juices, the bile, and the mucus lubricating the surface of the alimentary canal, are all examples of secretions subservient to digestion and assimilation.

(492.) Such being the general purpose answered by this function, we have first to examine the apparatus provided for its performance; secondly, the nature of the effects obtained; and, thirdly, the peculiar powers which are concerned in their production.

SECT. I.—*Apparatus for Secretion.*

Organs of secretion.

(493.) The apparatus employed by nature for the performance of secretion varies considerably in its structure, in different instances, according to the nature of the product which is to result from the operation; and according as that product is merely separated from the blood, in which it may already have existed, or is formed by the combination of certain elements and proximate principles furnished by that fluid. In the simplest cases, where that product is principally aqueous, and apparently consists of nothing more than the serous portion of the blood separated from it by mere transudation, we find no other organs requisite than those smooth membranous surfaces which we have already described under the name of the *serous membranes*. The mucous secretions proceed, in like manner, from the modified, yet still simple action of a membranous surface, of a rather more refined structure, namely, the *mucous membranes.* The more elaborate products of secretion, on the other hand, which are apparently formed by combinations of pre-existing elements, are obtained by the agency of organs of a more complicated structure, which are denominated *glands.*

SECT. II.—*Glandular Apparatus.*

Glands.

(494.) The essential part of the structure of a gland consists in a collection of tubes, more or less convoluted, united by cellular substance into masses of a rounded form, constituting a *lobule.* Each lobule has a separate investment of membrane; and the whole aggregate of lobules is furnished with a general membranous envelope, or capsule. In every gland we meet with a complex arrangement of numerous arteries, veins, nerves, and lymphatics, provided with ramified excretory ducts, which conduct away the secreted matter that has been prepared in the substance of the gland.

Conglobate glands.

(495.) The above description of a gland does not include those organs, which, although resembling the proper glands in their general appearance, perform no distinct office of secretion, and are therefore unprovided with any excretory duct. This is the case with those bodies belonging to the absorbent system, which bear improperly the title of *lymphatic* or *conglobate glands.* The spleen, the renal capsules, the pineal gland, the thyroid gland, and the thymus, are, in like manner, improperly included in the class of glands; for we have no evidence of their secreting any fluid, and indeed know nothing of their real functions.

Glandular system.

(496.) The catalogue of glands, strictly answering to the definition, will comprise the following organs, namely, the liver, pancreas, and kidneys; the salivary, lacrymal, and meibomian glands; the tonsils, the ceruminous glands of the ear, and the sebaceous glands of the face; the mammæ, the prostate, the testicle, Cowper's glands, the glandulæ odoriferæ, and the extensive system of mucous glands about the head and trunk. These parts, although differing widely from each other in many respects, agree in a sufficient number of particulars to allow of being classed together in one organic system, which Bichat has termed the *glandular system.*

---

[1] See *Muller's Physiology*, by Baly, p. 83.

(497.) Most of the glands are arranged in pairs, as the kidneys, testicles, salivary and lacrymal glands, while others are single, as the liver and the pancreas.

Texture of glands.

(498.) The organization of the glandular system is exceedingly complex, and cannot be unravelled without great difficulty. The tissue of which they are composed presents us with no regular arrangement of fibres, such as we see in the muscles, ligaments, nerves, or bones; but the whole structure is made up of a congeries of vessels and cells, having no very firm cohesion amongst themselves, and hence admitting very readily of being separated by slight mechanical causes. While organs which have a more extensive fibrous organization possess considerable powers of resistance, a very moderate degree of violence is sufficient to tear asunder the texture of a gland. The resistance in the latter case is owing solely to the cohesion of the cellular tissue which connects their parts, and which differs in its density and strength in different glands.

Conglomerate glands.

(499.) There are three different ways in which the glandular tissue, or *parenchyma* of glands, as it has been generally termed, is disposed. In those glands which have been called *conglomerate,* a term which, as we have seen, has been used in contradistinction to the *conglobate,* or lymphatic glands, the organ is made up of distinct portions, connected together by a large quantity of loose cellular tissue, in the intervals of which the vessels and nerves are situated. These larger lobes are again made up of smaller lobes united in the same way. By successive divisions we obtain smaller and smaller component portions, till we arrive at last at very small bodies still visible to the naked eye, and which are called by anatomists *glandular acini.* These successive lobules are firmer in proportion as they are smaller, being surrounded and connected with the adjoining portions by shorter and denser cellular substance. The second, third, and even the fourth subdivisions of these lobes may easily be followed with the scalpel. The acini themselves are of a roundish figure and pale colour, and readily distinguishable from other parts by the absence of fibres. The microscope shows them, however, to be still farther divisible into smaller portions, between which are seen plates of cellular substance, and if we attempt to pursue these subdivisions with successively greater magnifying powers, we do not find that we can reach their limit. The above description is particularly applicable to the salivary, lacrymal and pancreatic glands.

Acini.

(500.) The second modification of glandular structure occurs in the liver and the kidneys, in which it is impossible to trace these successive divisions into lobules, after we have distinguished the primary lobes which they present. Their structure exhibits an uniform and even tissue, made up of glandular acini, closely united together into one substance. The connecting cellular substance, if any such exist, is very short and small in quantity; and hence these organs may be torn asunder with great ease, and their ruptured surfaces present the appearance of granulations.

(501.) The third description of glands applies to the prostate, to the tonsils, and in general to all the mucous glands.

Structure of glands.

(502.) On examining the course of the blood-vessels, the small arteries which enter into a gland are found to ramify in various ways through a mass of cellular texture. But it is a matter of great uncertainty what specific structure intervenes between the secreting arteries and the commencement of the excretory ducts. Two opinions have long divided anatomists on this subject. Malpighi, who was one of the first who investigated the minute anatomy of glands, asserted that the acini invariably contain a central cavity, or *follicle,* as it was termed, on the inner surface of which the arteries are distributed, while the secreted fluid is collected in the follicle, and conveyed away by the branch of the excretory duct which arises from the follicle. He considered the mucous glands of the alimentary canal, which undoubtedly present a structure of this kind, as the most simple forms of glandular structure; the larger glands being only aggregations of these simpler structures.

(503.) The theory of Ruysch, who also bestowed extraordinary care in the examination of glandular structures, is founded on the supposed continuity of the extremities of the arteries with the commencements of the excretory duct. This theory is so far opposed to that of Malpighi, that it pre-supposes all the glands to consist merely of an assemblage of vessels and of cellular substance, without any membranous cavities interposed between the arteries and excretory ducts. The opportunities of dissection which Ruysch enjoyed, and his unrivalled skill in the arts of injecting the vessels, and tracing their modes of distribution, gave great weight to his opinions, which seemed to be immediate deductions from what he saw, and had established as matters of fact. Fluids could be made by injection to pass very readily from the blood-vessels into the excretory ducts, both in the kidneys and liver. After these organs have been accurately injected, they may be resolved, by subsequent maceration, into small clusters of blood-vessels; what Malpighi had represented as hollow acini, seemed to be in reality composed of a congeries of these minute vessels. This appeal to the evidence of the senses, and the admirable preparations which supported it, brought over almost all the anatomists of that time to the opinion of Ruysch; and Boerhaave himself, who had been a zealous defender of the doctrine of Malpighi, and written in support of it, was at length induced to adopt the views of Ruysch.

(504.) This controversy was sustained for a great many years in the schools of medicine; and the opinions of anatomists continue even at the present time to be divided upon this subject. Probably both these opinions may in part be correct, as applied to different glands, though not universally true; and secretion may perhaps be in some cases performed by continuous vessels, and in others by an interposed parenchyma, of a cellular or more intricate organic apparatus.

(505.) As the structure of the secreting organs admits of great variety, it may be useful to advert to some of the terms by which these minute parts have been designated. The terms *acini, cotulæ, cryptæ, folliculi, glandulæ, lacunæ, loculi, utriculi,* have been almost promiscuously used; being, as Bell humorously observes, "so many names for bundles, bags, bottles, holes, and partitions." The term *acinus* has been already explained, (§ 499). *Cotulæ* are merely superficial hollows, from the surface of which the secretion is poured forth. A *crypta* is a soft body, consisting of vessels not completely surrounded with a membrane, but resolvable by boiling or maceration. *Follicles* are little bags appended to the extremity of the ducts, into which the secretion is made, and from which it is carried off by the ducts. *Lacunæ* are little sacs, opening largely into certain passages, and into which generally mucus is secreted.

Excretory ducts.

(506.) The *excretory ducts,* whatever may be their exact origin, consist at first of an infinite number of capillary tubes, which, like the veins, soon unite together into more considerable tubes. These generally pursue a straight course through the glandular tissue, unite with one another, and form at last one or more large tubes. The only exception to this general proposition occurs in the excretory ducts of the testicle, which pursue a singularly tortuous course before they unite into the vas deferens on each side.

(507.) There are three varieties in the mode of termination, with regard to the excretory ducts of glands. In the first case, the ducts unite into several distinct tubes, which open separately, and without any previous communication. Sometimes these separate apertures are met with in a more or less distinct prominence, as in the breasts, the prostate, and the sublingual glands. At other times, the orifices are found in a depression, or kind of cul-de-sac, as in the tonsils, and in the foramen cœcum of the tongue. In the second case, which includes the greater number of glands, their fluids are poured out by a single tube, having a simple orifice. In the third case, some glands deposit the produce of their secretion in a reservoir, where it is retained, in order to be expelled at particular times: as is exemplified in the kidneys, liver, and testicles. In this case there must be two excretory tubes; one to convey the secretion from the gland to the reservoir, and the other to transmit it to its final destination. The size of the excretory ducts will, of course, be regulated very much by their number: when several are produced from one gland, they are very small, and sometimes scarcely perceptible. Those which are single are longer with reference to the size of the gland, and generally pass for some distance, after quitting the gland. In the pancreas, however, this is not the case, the common duct being concealed in the substance of the gland.

(508.) Whatever the arrangement of the excretory ducts may be, they all pour their fluids, either on the surface of the body, or on the surface of some of the mucous membranes. In no instance do they terminate on serous or synovial surfaces, or in the common cellular membrane. All the excretory ducts are themselves, indeed, provided with an internal mucous membrane, which is a continuation of the cutaneous, or mucous surface on which they terminate. In addition to this they are furnished with an exterior coat, formed of a dense and compact membranous and fibrous substance. Every excretory duct may therefore be considered as made up of these two coats, namely the external one, which is membranous, and the internal one, which is mucous.

Th y of Mü r.

(509.) Among the latest theories relating to the structure of the organs of secretion, is that adopted by Müller,[1] who conceives that the glandular organization consists essentially of a modification of the excretory duct, the remote extremity of which, or that most distant from the discharging orifice, is closed; and the particles of which exhibit a fine net-work, or plexus of minute blood-vessels, whence the secretion is in the first place derived, and afterwards conveyed away by the duct, into the cavity of which it is poured. The duct itself may be variously divided and subdivided; and its trunk and ramifications may be variously contorted and convoluted in different cases, without, however, constituting any material difference in its essential structure.

SECT. III.—*Arrangement and Properties of the Secretions.*

Arr e- men f the secre ns.

(510.) The classification of the various secretions which are met with in the system has been attempted by different physiologists, but great difficulty has presented itself in fixing on a principle susceptible of being practically applied to substances of such different chemical and mechanical properties, as are those which are to be the subjects of this arrangement. Haller,[2] adopting for his basis their chemical qualities, distributed them under the four classes of aqueous, mucous, gelatinous, and oily. Fourcroy arranged them under eight heads; namely, the hydrogenated, the oxygenated, the carbonated, the azotated, the acid, the saline, the phosphated, and the mixed.[3] Richerand adopts the six classes of lacteous, aqueous, salivary, mucous, adipose and serous;[4] and Dr. Young those of aqueous, urinary, milky, albuminous, mucous, unctuous, and sebaceous.[5]

(511.) Dr. Bostock[6] distributes the secretions under the eight heads of the aqueous, the albuminous, the mucous, the gelatinous, the fibrinous, the oleaginous, the resinous, and the saline; an arrangement which, in a chemical point of view, is the clearest and most natural that has yet been devised. We shall briefly notice these several classes in the order above stated.

1. *The Aqueous Secretions.*

Aqueous secretions.

(512.) The aqueous secretions are those which consist almost entirely of water, and of which the properties depend principally on its watery part; any other ingredient it may contain being in too small a quantity to give it any specific characters. The two secretions which are referable to this class are the cutaneous perspiration, and the exhalation from the lungs.

(513.) With regard to the fluid of perspiration, it seems doubtful whether it contains any ingredients that are constantly present in it, or that are essential to its nature. It appears to differ, indeed, considerably in different individuals; and varies even in the same individual, according to the state of the system. Its analysis was attempted by Berthollet, and afterwards by Fourcroy; but the most complete examination into its properties is that of Thenard, who considers it to be essentially acid, and that acid to be the acetic. He found in it, also, an appreciable quantity of the muriates of soda and of potass, with traces of the earthy phosphates and of oxide of iron, together with a very minute quantity of animal matter. Berzelius, on the other hand, who has examined this fluid still more recently, finds the free acid to be the lactic, accompanied with the lactate of soda. An elaborate analysis of the fluid of perspiration in a person labouring under disease, has also been made by Dr. Bostock.[7] The aqueous exhalations from the lungs appears to be so perfectly similar to that from the skin, as not to require further notice.

2. *The Albuminous Secretions.*

Albuminous secretions.

(514.) The albuminous class of secretions are numerous, and comprehend both solid and fluid substances. We have already seen that all membranous and fibrous textures, but especially the latter, are composed principally of a material corresponding in its chemical properties to coagulated albumen, (See § 165). But there are many fluid secretions which contain large proportions of this ingredient in an uncoagulated, or liquid state; such as the secretion which exudes from serous membranes, and also occupies the interstices of the cellular texture, and which has been termed the *liquid of surfaces*, (See § 135). This fluid also contains, besides coagulable albumen, an animal matter similar to that which is found in the serosity of the blood, and a small quantity of the usual saline matters which enter into the composition of almost all animal products.

3. *Mucous Secretions.*

Mucous secretions.

(515.) The mucous secretions are characterised by the presence of a substance which does not pre-exist in the blood, but which is prepared by a proper secretory or glandular action. The properties of this substance, or *mucus*, have been already noticed, (§ 301). To the head of the mucous secretions, Dr. Bostock is inclined to refer also the saliva, the gastric and pancreatic juices, the tears, and the semen.

[7] *Medico Chirurgical Transactions*, xiv. 424.

4. *The Gelatinous Secretions.*

Gelatinous secretions.

(516.) The gelatinous secretions derive their essential character from the predominance of gelatin in their composition. This substance is found in great abundance in most of the solids, and particularly in the membranous structures. It is strictly a product of secretion; for it is not met with in the blood, and must therefore be formed by some chemical change in the elements of the blood, from which the materials for its preparation are derived. There is reason to believe, from the discovery of Mr. Hatchett of the possibility of converting albumen into gelatin by digestion in diluted nitric acid, during which the albumen combines with an additional quantity of oxygen, that some change analogous to this is effected in the living body during the process of its secretion. The characteristic properties of gelatin have already been noticed, (§ 279.)

5. *The Fibrinous Secretions.*

Fibrinous secretions.

(517.) The fibrinous secretions compose the fifth class, and are so named from their correspondence in chemical properties to the fibrin of the blood, which fibrin is probably the source from whence these secretions derive this ingredient. They constitute the organic products most completely animalized in their chemical constitution; and they at the same time retain, in their physical properties, the peculiar cohesive tendency and fibrous character of the substance from which they are produced. The muscular fibre is the principal, if not the only substance which comes under this head.

6. *The Oleaginous Secretions.*

Oleaginous secretions.

(518.) The oleaginous secretions derive their essential character from the presence of an oily ingredient. They compose a numerous and varied class, comprehending those in which the oil forms the greatest part of the substance, and those in which it is more or less mixed with a large proportion of other animal principles. The fat is the principal secretion included in the first division; a substance which, from its being extensively deposited in various parts of the body, must evidently be formed by some peculiar action of the capillary system of vessels. As it consists almost wholly of hydrogen and carbon, we must conclude that its formation is effected by the exclusion of nitrogen and oxygen from the proximate elements of the blood, and the consequent intimate combinations of their carbon and hydrogen. It is well known that the formation of fat, by whatever chemical operation it may be effected, often proceeds with great rapidity, whenever circumstances favour its production. The marrow, as was formerly observed, belongs also to this class of secretions. Dr. Bostock is disposed to refer to the same head the substance termed *cholesterine*, which forms the basis of biliary calculi.

Milk.

(519.) Milk is a secretion owing its principal characters to the oil which it contains, and which is combined with albumen, so as to form a kind of natural emulsion. When collected in a separate mass, it forms the well-known substance termed *butter*. The oily particles are, however, in the original state of milk, merely diffused by mechanical mixture throughout the watery fluid, as is evident from the appearance of milk under the microscope, when it exhibits a multitude of extremely minute globules, swimming in a transparent liquor. The size of these globules has been variously estimated by different observers, and indeed appears to be by no means uniform, varying in different instances from the 10,000th to the 5000th of an inch in diameter. These oily globules have a tendency to adhere together when the milk is allowed to rest, and in the course of a few hours collect at the surface in the form of cream, and by further coalescence they compose *butter*. The albumen may be obtained from the remaining fluid by the ordinary means of coagulation, and constitutes curd, which, as is well known, is the basis of *cheese*. The clarified liquor which remains, yields, by evaporation, a saccharine substance capable of being crystallized, and which is known under the name of *sugar of milk*. It differs from common sugar by being less soluble in water, and by its total insolubility in alcohol. Milk contains, besides these ingredients, several saline substances, as the muriate and sulphate of potass, the phosphates of lime and of iron, and also a peculiar animal matter, which yields a precipitate with infusion of galls. Milk is found to differ from the blood, and from most of the animal fluids, by the base of its salts being potass instead of soda. A peculiar acid, called the *lactic*, is formed by the fermentation of milk, and even alcohol may be obtained during this process. By the action of nitric acid on the lactic acid, a new acid is produced, termed the *saccholactic* or *mucic acid*, which unites readily with alkaline or earthy bases, and forms a peculiar class of salts.

Cerebra substance

(520.) The substance of the brain bears a considerable analogy to the oleaginous secretions, more especially to that of milk; for it consists of albumen intimately combined with a peculiar oily ingredient. Rather more than one-fourth of its solid substance consists, according to Vauquelin,[1] of a fatty substance, and nearly one-third of albumen; the remainder being composed of osmazome, phosphorus, acids, salts, and sulphur.

7. *The Resinous Secretions.*

Resinou secretio

(521.) The resinous secretions, which compose the seventh class, derive their specific characters from an ingredient which is soluble in alcohol, and is analogous to resin. Of these the most remarkable is the substance which constitutes the basis, or specific ingredient, of bile. (See § 366.)

Circulat in the liv

(522.) In connexion with the process of secretion which takes place in the liver, we have here to notice the remarkable peculiarity which occurs in the mode in which the blood is circulated through that organ. The liver is supplied, like the other organs, with arterial blood, by the hepatic arteries, which are branches from the aorta. But it likewise receives a still larger quantity of venous blood, which is distributed through its substance by a separate set of vessels derived from the venous system. The veins which collect the blood that has circulated in the usual manner through the abdominal viscera unite together into a large trunk, termed the *vena portæ*; and this vein, on entering the liver, ramifies like an artery, and ultimately terminates in the branches of the hepatic veins, which transmit the blood in the ordinary course of circulation to the venæ cavæ.

(523.) This complex arrangement of the vessels which compose the hepatic system has lately been unravelled with singular felicity by Mr. Kiernan, who in a paper contained in the *Philosophical Transactions*, gives an account of his valuable discoveries, of which we shall present the following abstract. The hepatic veins, together with the lobules which surround them, resemble in their arrangement the branches and leaves of a tree, the substance of the lobules being disposed around the minute branches of the veins like the parenchyma of a leaf around its fibres. The hepatic veins may be divided into two classes, namely, those contained in the lobules, and those contained in canals formed by the lobules. The first class is composed of interlobular branches, one of which occupies the centre of each lobule, and receives the blood from a plexus formed in the lobule by the portal vein; and the second class of hepatic veins is composed of all those vessels contained in canals formed by the lobules, and including numerous small branches, as well as the large trunks terminating in the inferior cava. The external surface of every lobule is covered by an expansion of Glisson's capsule, by which it is connected to, as well as separated from, the contiguous lobules, and in which branches of the hepatic duct, portal veins, and hepatic artery, ramify. The ultimate branches of the hepatic artery terminate in the branches of the portal vein, where the blood they respectively contain is mixed together, and from which mixed blood the bile is secreted by the lobules, and conveyed away by the hepatic ducts which accompany the portal veins in their principal ramifications. The remaining blood is returned to the heart by the hepatic veins, the beginnings of which occupy the centre of each lobule, and when collected into trunks, pour their contents into the inferior cava. Hence the blood which has circulated through the liver, and has thereby lost its arterial character, is, in common with that which is returning from the other abdominal viscera, poured into the vena portæ, and contributes its share in furnishing materials for the biliary secretion.

---

[1] *Annales de Chimie*, lxxxi. p. 37.

(524.) The general conclusion which Mr. Kiernan draws from his anatomical researches is, that the hepatic artery is destined solely for the nutrition of the liver, and has no direct connexions, except with the branches of the vena portæ, after its own blood has become venalized.

rea.

(525.) Urea is another substance of a resinous nature, which may be ranked among the secretions, and which constitutes the peculiar or specific ingredient in urine. It is remarkable for containing a very large proportion of nitrogen, which is by this channel discharged from the system. This substance has been found in the blood of animals from whom the kidneys had been removed.

smazome.
erumen.

(526.) The peculiar proximate animal principle, termed by Thenard *osmazome*, is referred by Dr. Bostock to the class of resinous secretions. It was procured originally from the muscular fibre, of which it forms one of the component parts; and it appears to be the ingredient in which the peculiar flavour and odour of the flesh of animals principally depends. It is found, however, in most of the component parts of the body, as well solids as fluids. The *cerumen*, or ear-wax, appears also from the analysis of Vauquelin, to have a relation to the resinous secretions.

8. *The Saline Secretions.*

ine se-
tions.

(527.) This class comprehends all those fluids in which saline ingredients predominate; they are very numerous, are dispersed over every part of the system, and are more or less mixed with its constituents. They consist of acids, alkalies, and neutral and earthy salts. The following are the acids entering into the composition of animal substances, and which are, for the most part, united with alkaline or earthy bases; namely, the phosphoric, muriatic, sulphuric, fluoric, lithic, lactic, benzoic, carbonic, and oxalic acids; and perhaps also the rosacic and the amniotic. Soda, potass, and ammonia, are found in almost all animal fluids; but only the first of these is met with in an uncombined state. Of the earths, lime is by far the most abundant; magnesia is found in small quantity, and also silex.

(428.) With reference to their saline qualities, Dr. Bostock proposes a division of the secretions into four classes. 1. Those which are nearly without any admixture of salts. 2. Those which possess a definite quantity of salts, and these salts different from those which exist in the blood. 3. Those containing salts similar both in their nature and quantity to those of the blood. And, 4. Such as contain salts different from those in the blood, and which are also variable in quantity. The fat, the saliva, the liquor of surfaces, and the urine, may be given as examples of each of these divisions.

SECT. IV.—*Theory of Secretion.*

eory of
etion.

(529.) The nature of the powers and processes by which the products of secretion are prepared, is a subject involved in the greatest obscurity. There is scarcely any question in physiology, indeed, the investigation of which presents greater difficulties. At the very outset of the inquiry we are embarrassed by the very imperfect state in which the science of organized chemistry still remains; and it follows as a necessary consequence, that the precise nature of the chemical changes effected during secretion cannot be properly understood. That the operations themselves are of a chemical nature, must be inferred from their results, consisting of substances which differ in most instances very considerably from the constituents of the blood, whence their elements are obtained. The blood is evidently the great reservoir of nutriment, and the fountain whence all the materials of the secretions are derived. In a few instances, as we have seen, the process of secretion appears to consist simply of the separation of some of the proximate principles of the blood. The operation is, in that case, more of a mechanical than of a chemical nature, and is analogous to mere transudation or filtration, subject, however, to a certain power of selection exercised by the secreting organ. In the greater number of instances, however, the product of secretion appears to be a new formation, differing entirely from any of the proximate principles contained in the blood, and resulting therefore from a new combination of its elements.

(530.) Scarcely any light has been thrown on this mysterious subject by the anatomical investigation of the organs of secretion. Their intimate structure is generally so minute and complicated, as to elude the severest scrutiny of the anatomist, even when assisted by the best optical instruments. What increases the difficulty of finding any clue to the labyrinth, is, that we often see parts having apparently very different structures giving rise to secretions which are nearly identical in their qualities; and conversely, we see substances having very different properties produced by organs very closely resembling each other in their structure.

(531.) Sometimes we find no distinct secretory apparatus, the whole process appearing to be conducted in the capillary vessels, out of the sides of which the product seems to transude. In other instances, the secreted fluid exudes from the smooth surface of a membrane, as is the case with the serous secretions in all the closed cavities of the body, such as those of the peritoneum, pleura, pericardium, and pia mater. The matter of perspiration finds its way through the skin and cuticle without any visible ducts or even pores, appearing simply to transude through the bibulous substance of the latter.

(532.) In other cases we find the secreting membrane furnished with minute processes, or *villi*, from the extended surface of which the secretion is produced. At other times, there are *follicles*, or *crypts*, as they are called, into which the secreted fluid is poured, and where it is collected previously to its discharge by its appropriate channels. These minute cavities are occasionally grouped together, and covered with a denser investing membrane common to the whole assemblage, constituting the masses which are called *glands*. But no practical advantage has arisen from the technical or anatomical classification of glands, neither has any information of value been gathered from the examination of the mode in which the blood-vessels are distributed in those organs; although this mode of distribution is apparently very different in different cases, each seeming to be intended for the application of some definite but unknown principle of action. Being wholly in the dark with regard to the specific objects intended to be answered, we can form no rational conjecture as to the designs of nature in the contrivances she has adopted. We see, in some instances, the smaller arteries divide suddenly, as soon as they have reached the gland, into very numerous minuter branches, like the fibres of a hair pencil. This has been called the *pencillated structure*. The arrangement in other cases is somewhat different, though similar in its principle; the minuter branches spreading out from their origin, like rays from a centre, and forming a *stellated structure*. Sometimes we observe the arteries of the secreting organ much twisted and contracted in their course, and collected into spiral coils, before they terminate. All the varieties of secreting organs, as Mr. Mayo observes, appear to be only contrivances for conveniently packing a large extent of vascular surface into a small compass. So intricate, indeed, are those complex arrangements, that it is impossible to attempt to unravel them with any prospect of success. In a word, nothing hitherto known relative to the structure of glands has explained the mode in which they act, or has thrown any light upon the nature of the substances they produce.

Hypothesis of fermentation. Of organic filtration.

(533.) In this, as in other subjects, where facts are wanting for its elucidation, we find numberless hypotheses proposed in their stead. Secretion was formerly pronounced to be a species of fermentation, by those who could attach no definite idea to the term they employed. Others sought to explain secretion by various mechanical hypotheses, supposing it to be the result of a mere organic filtration of particles already existing in the blood; they racked their imaginations for the invention of forms of apertures and channels capable of admitting particles having corresponding figures, and of refusing a passage to the rest. Leibnitz compared the glands to filters, of which the pores were originally impregnated with a particular fluid, which fluid would therefore be allowed to pass, to the exclusion of all other fluids, in the same manner as a paper impregnated with oil prevents the passage of water, but allows oil to be transmitted. This unchemical theory proceeded on the hypothesis that all the secreted matters pre-exist ready formed in the blood, and require only to be separated by the glands; a supposition of which the later improvements in animal chemistry have sufficiently exposed the falsehood.

(534.) But even admitting the operation of the secretory organs to be wholly of a chemical nature, we are still completely in the dark as to the means which nature employs in the hidden laboratories of organization; nor do they appear in any way reconcileable to the ordinary laws of chemical affinities to which inorganic substances are obedient. The means employed are superior to mere chemical agency, in the same degree as the operations of chemical affinities transcend those of mechanism. All that we can conceive to be the office of the different series of vessels, which, by ramifying into smaller and smaller tubes, have the effect of subdividing the blood, as by a strainer, to certain degrees of tenuity, is that merely of preparing it for the changes it is to undergo in that stage of the process in which the essential conversion consists. Farther than this we cannot venture to speculate, knowing, as we do, so imperfectly either the changes produced, or the means by which these changes can be effected; unless, indeed, we endeavour to call to our assistance the power of galvanism, which has been, in modern times, proved to be so important and powerful an agent in effecting changes of chemical composition. But the analogy is yet too vague to serve as the basis of any solid theory.

Influence of the nerves.

(535.) There is no doubt that in many cases the process of secretion is considerably influenced by the condition of the nervous powers. Thus the section of the par vagum is invariably followed by the diminution or total suppression of the gastric juice, and by the increase of the secretion of bronchial mucus. Under these circumstances, the secretions of the stomach are restored by directing a stream of galvanic electricity through the nerves that have been divided; a fact which is explicable only in one of two ways, namely, either by supposing that the galvanic influence is the same as the influence derived from the nerves, or that galvanism excites a fresh exertion of the nervous influence, in the portion of the nerve on which its action is directed.

Organic affinities.

(536.) On the whole, as it appears impossible to refer the phenomena of secretion to any of the other known laws of matter, whether chemical or mechanical, it becomes us to acknowledge our ignorance of the real causes that produce them, and to ascribe them to the agency of those powers to which we have given the name of the *organic affinities;* by which term, however, we are far from wishing to imply that these affinities essentially differ in their kind from the ordinary chemical affinities which regulate the combinations of the same elements in unorganized bodies; but only that their operation is modified by the peculiarity of the circumstances in which they are placed. One of the principal causes of this peculiarity appears to be the influence of the *nervous power;* a power carefully to be distinguished from the sensorial powers, hereafter to be considered, and wholly of a physical character, exercised by the nervous system, and controlling the actions of the blood-vessels, and more especially of the capillaries, and also those chemical changes which produce the evolution of animal heat, regulating in a particular manner the processes of secretion, and in some instances producing the contractions of the muscles in a way directed to some beneficial purpose, and in cases where the interference of the mind does not take place. But of this latter exercise of the nervous power we shall have to speak more at large when we come to treat of the involuntary motions.

Nervous power.

CHAP. X.—ABSORPTION.

Objects absorption.

(537.) The objects of the function of absorption are, first, the removal of those materials which have become unserviceable and noxious from the situations where their presence is injurious; and, secondly, their transmission into the general mass of circulating fluids. The lymphatic vessels are appropriated to this office, and form, with the lacteals, which perform a similar service with respect to the chyle, one extensive system of vessels denominated the *absorbents*.

SECT. I.—*Structure of the Absorbent System.*

Lacteals and lymphatics.

(538.) The absorbent system, then, is understood to comprehend two sets of vessels, distinguished only by a certain difference in the office which they perform, but agreeing in their structure and general functions. The first are the *lacteals*, which, as we have seen, are appropriated to the conveyance of the chyle, or nutritious fluid prepared in the intestines, into the general reservoir of nutriment, the sanguiferous system. The second are the *lymphatics*, which perform a similar office with regard to the materials of the body itself, that have become either useless or noxious, or with respect to foreign substances applied to the external surface, or introduced into any part of the body. The same general description, as to structure, will apply to both these systems of vessels.

Distribution of th lymphati

(539.) Absorbent vessels are met with in almost every part of the body. They may be regarded as analogous, or even supplementary in their office, to the veins; and accordingly, their structure and mode of distribution are very similar to that portion of the sanguiferous system. The absorbents arise from the various surfaces of the body, external as well as internal, by very minute branches; but whether these branches commence by open orifices, or imbibe the fluids they receive through the medium of their coats, we have hitherto no certain knowledge. The lesser branches of the lymphatics, like those of the veins, join together to form larger branches; while these again successively unite into larger and larger trunks, till they conduct their contents into the veins, into which they open. They communicate with one another freely in their course; and these connexions are frequently so numerous and intricate, as to form an extensive net-work, or plexus of lymphatic vessels. They are furnished with numerous valves, which, like those of the veins, are of a semilunar or parabolic form, disposed in pairs, and placed so as to prevent any retrograde motion of the contents of the vessels.

eir ts.

(540.) Like the veins, the absorbents have thin and transparent coats, which are possessed of considerable strength, so as to admit of being distended much beyond their natural size without being ruptured, by injected fluids urged into them with considerable force. When they are thus enlarged by injection, they resemble a string of beads; an appearance arising from the numerous valves they contain, and which occur at short, but generally unequal intervals.

(541.) The absorbent vessels are formed of two coats, which in the principal trunks are very distinct from each other. The external coat is the one which constitutes the chief bulk of the vessel, and gives it its general form. It is of a membranous structure, and is connected with the surrounding parts by a loose tissue of cellular substance. It exhibits, where it joins the inner coat, more or less of a fibrous structure; and some anatomists have pretended even to have perceived traces of muscular fibres at this part. The interior membrane which lines the former, is more thin and delicate; and it is by duplicatures of this membrane that the valves are formed. These valves are remarkable for their strength, not being ruptured without the greatest difficulty.

mphatic nds.

(542.) The continuity of the course of the absorbents is interrupted in a variety of places, by small rounded bodies, which have been called *lymphatic* or *conglobate* glands, and which are situated on the track both of the lacteals and lymphatics. They seem to have a similar relation to the absorbents which the ganglia have to the nerves; and they have, on that account, been sometimes called the *lymphatic ganlia.* They are of various sizes; the smaller being placed near the origin, and the larger on the more considcrable trunks of these vessels. Those of greatest magnitude are situated at the root of the mesentery, in the course of the lacteals, and are denominated the *mesenteric glands.* These glands are sometimes detached, and sometimes in groups or clusters, and generally of an oblong rounded shape, and somewhat flattened, bearing some general resemblance to an almond. Their colour is a whitish red, of more or less intensity, according as they are situated more externally. Those of the mesentery are nearly white; those of the spleen brown; and those belonging to the lungs are of a very dark, or almost black hue. Each gland is enveloped in a thin, fibrous, and very vascular membrane, surrounded with dense cellular tissue, which sends down processes into the substance of the gland, dividing it into numerous compartments.

a rentia.

(543.) It would appear from the extensive researches of Mascagni, that every absorbent vessel, during its course, passes through one or more of these glands. Previous to their penetrating into the gland, each absorbent trunk branches out suddenly into numerous subdivisions, distinguished by the name of *vasa inferentia.* These vessels are distributed on the surface of the gland in a radiating form, so as to surround it with a kind of net-work. After they have entered the gland, their course becomes extremely difficult to unravel, from their numerous and minute ramifications, their tortuous course, and their frequent communications. It would appear, however, that while some acquire and retain an extreme degree of tenuity, others become dilated, and form cells, somewhat resembling the erectile tissue formerly described. That portion of the vessels which is destined again to collect the fluid, and conduct it forwards on its course, appears to have a similar structure, presenting a congeries of minute ramifications, and of dilatations or cells.

a entia.

(544.) By the successive reunion of these branches, they are all collected into a certain number of trunks which emerge from the gland, under the name of the *vasa efferentia.* The total capacity of the vasa efferentia is, in general, less than that of the vasa inferentia. Large clusters of lymphatic glands exist in the neck, the groin, the axilla, as well as in the course of the greater trunks, not far from their termination in the thoracic duct.

Thoracic duct.

(545.) The great trunks of the lymphatics occupy two principal situations; the one near the surface, and the other more deeply seated; and for the most part they follow the course of the veins. The main branches are finally reduced to three or four great trunks, which terminate for the most part in the thoracic duct. This is a vessel of considerable size, passing upwards close to the spine, in a somewhat tortuous course, to about half an inch above the trunk of the left subclavian vein. It then bends downwards, and opens into that vein, nearly at its junction with the jugular vein. Another similar, but shorter trunk, is found on the opposite side, which pours its contents into the right subclavian vein.

Lymph.

(546.) The nature of the lymph, or fluid contained in the lymphatic vessels, is but imperfectly known, in consequence of the difficulty of collecting it in sufficient quantity for examination. When viewed under the microscope it is seen to contain a number of colourless globules, much smaller and less numerous than the red particles of the blood.[1] Mr. Brande separated a small quantity of albumen from it by the application of voltaic electricity: he found that it also contained some muriate of soda. Berzelius states that the lactates are likewise present in it, derived, as he supposes, from the decomposed substance of different parts of the body, which is taken up by the absorbents. Reuss, Emmert, and Lassaigne obtained fibrin from the lymph of the horse, and Nasse and Müller[2] obtained some also from human lymph. When removed from the body, this fluid fibrin coagulates in less than ten minutes. Besides the above ingredients, Tiedemann and Gmelin state that the lymph contains salivary matter, osmazome, carbonates, sulphates, muriates, and acetates of soda and potass, with phosphate of potass.

SECT. II.—*Function of the Absorbents.*

Office of the lymphatics.

(547.) While the office of the lacteals is confined to the absorption of a particular kind of fluid, namely, the chyle, the power of the lymphatics extends to the removal of every species of matter which enters into the composition of the body, as occasion may require, as also various extraneous substances that may happen to be placed in contact with their mouths. Whether the lymphatics have the power of taking up solid materials of the body without their being previously liquified, is a point which is yet far from being determined. We are certain that the hardest and densest structures, such as the bones, are liable to absorption, in various instances, not only during the natural processes of their formation and growth, but also on occasions when they are subjected to extraneous pressure. We find that the bones are modelled by the pressure even of soft living parts, during their natural growth, or morbid enlargement. The rapid disappearance of the red tinge which the use of madder in the food had communicated to the bones, when that food is discontinued, has been supposed to warrant the conclusion that the particles of bones are at all times undergoing a quick periodical renovation. But it appears from more recent inquiries, that this inference has been too hastily drawn: the change of colour being the result of the disappearance of the colouring particles of the madder only, without its being at all necessary to suppose that the earthy particles of the bone are themselves changed, or successively absorbed and deposited along with the madder.[3]

Powers of absorption.

(548.) The nature of the process by which the particles to be absorbed are prepared for being taken up by the lymphatics;—the mode in which they are conveyed to the orifices of these vessels, if indeed they take their rise like the lacteals, by open orifices;—and the power by which they find their way into these vessels, and are conveyed onwards to their termination in the thoracic duct, are all subjects involved in the greatest obscurity. Capillary attraction is the only power to which the rise of the lymph in the lymphatic vessels appears to bear any near resemblance; but the analogy is far too vague and remote to be of much assistance to us in the solution of the difficulty. How far the powers recently discovered, and which have been termed *endosmose* and *exosmose*, whereby membranous substances allow the transmission in a certain direction, of particular fluids only, to the exclusion of others, are concerned in the phenomena, remains a subject for future investigation. It seems likely, however, to throw some light on the processes both of secretion and absorption; and perhaps may furnish an explanation of the selection evinced by the lymphatics in absorbing certain materials in preference to others. Absorption takes place with great facility from the mucous surfaces, and also from those formed by ulceration. It also takes place from the surface of serous membranes, though with less activity. From the external surface of the skin, absorption takes place with great difficulty, and only under particular circumstances, as when substances are forcibly pressed through the cuticle. Considerable absorption often occurs from the interior of the pulmonary air-cells. Absorption from the surface of the body is diminished, or even suspended, by greatly diminishing the pressure of the atmosphere on the part, as by the application of a cupping-glass.

Sect. III.—*Venous Absorption.*

Venous absorption.

(549.) Soon after the discovery of the lymphatic absorbents, a keen controversy arose as to whether absorption was performed exclusively by these vessels: for it was contended by many that the veins assisted in this process, and occasionally acted as absorbing vessels. The arguments and reasonings of Hunter and Monro, founded on numerous experiments, appeared to have completely decided the question, and established the exclusive agency of the lymphatics in the performance of this function. Of late years, however, the ancient opinion has been revived by Magendie and others, who seem to have satisfactorily proved that absorption is occasionally carried on by the veins themselves; and that many of the lesser lymphatic vessels terminate in the small veins, instead of proceeding to the thoracic duct. It has been ascertained, for instance, that where the great lymphatic trunks are tied in animals, substances injected into the stomach quickly find their way into the general mass of circulating blood, and may be detected in the urine. Poison introduced into a portion of intestine, completely isolated from the rest of the body, with the exception only of the artery and the vein, produces its effect upon the system nearly in the same time as if the natural connexions had been preserved. The same result takes place when a limb is separated from the body, by dividing every part excepting the artery and the vein, and the poison is introduced under the skin. It proves fatal in the usual time, although the only medium through which its influence can be supposed to be transmitted is the circulating blood, which must therefore, it is concluded, have received the poison by venous absorption.

(550.) The subject of venous absorption, and of the connexion between the lymphatic and sanguiferous systems, has of late years much occupied the attention of physiologists. Great labour has been bestowed on its investigation by Fohmann, Lauth, and Panizza, on the continent; and recently in this country by Dr. Hodgkin, who was appointed, with others, to form a committee for conducting this inquiry, by the British Association for the advancement of science. A short provisional report by this gentleman is published in the report of the sixth meeting of that association, in vol. v. p. 289, to which we must refer our readers, as containing the latest information on this important branch of physiology. Many facts render it exceedingly probable that the contents, both of the lacteals and of the lymphatics, are intermixed with that of the veins in the lymphatic glands.

Sect. IV.—*Effects of Absorption.*

Effects absorpti

(551.) The absorbents have a powerful influence in modifying the fluid secretions, as well as the solid materials of the body. Their agency in assisting the arteries and capillaries which effect the growth and nutrition of the body is beautifully exemplified in the processes of ossification and of dentition, where the changes can more easily be followed than in the progressive modifications of softer organs. All these facts lead to the conclusion that the absorbent vessels possess very extensive powers in modelling the organization of the body in all its parts. In the progress of life, various changes are effected in the size and form of different parts, either in the natural course, or from the effects of disease. We see various organs diminish in size, sometimes with great rapidity, from the general absorption of their substance, or, as it has been termed, from *interstitial absorption;* and in other instances from causes external to the organ affected, such as pressure or ulceration; in which cases the process is denominated *progressive absorption.* In some structures, especially those which are but scantily furnished with vessels, the renewal of particles is much slower than in more vascular parts; but even these are in a certain degree subject to a constant absorption and renewal of their particles.

Sect. V.—*Function of the Lymphatic Glands.*

Office o the lymphatic glands.

(552.) Of the offices performed by the lymphatic glands, which are so numerously interspersed in the course of the vessels, we are still in profound ignorance; an ignorance which is little to be wondered at, when it is considered that we are but imperfectly acquainted with their structure, and the course which the branches of the absorbents take in the interior of those bodies, and that we are also very much in the dark with regard to the nature of glandular action, and of the changes which it induces on the fluids subjected to its influence. These glands may either be proper secreting organs, intended to prepare a peculiar substance, which is to be mixed with the chyle and lymph, in order to assimilate them more and more to the nature of the blood with which they are to be united; or they may, by their tortuous passages, offer a mechanical obstruction to the progress of these fluids, and thus occasion in them spontaneous changes in the arrangement of their constituent parts. This latter view of the uses of the glands was taken by Mascagni, and he endeavoured to confirm it by pointing out differences in the nature of the lymph before and after it had passed through a gland; but this fact, if established, would be equally explicable on either hypothesis. The greater size and vascularity of these glands in youth, when the growth of the organs is most rapid, would lead to the belief that their functions are of importance in the elaboration of nutritive matter to meet the greater demand for the materials of growth at that period of life.

CHAP. XI.—EXCRETION.

Excreti

(553.) The expulsion from the system of those materials which are useless or noxious, is the office of *excretion;* and the organs or channels by which it is performed are called the *excretory organs.* They consist of the lungs, the skin, the kidneys, and probably also the liver.

Sect. I.—*Excretory Function of the Lungs.*

By the ngs.

(554.) Of the office of the lungs in purifying the blood from its redundant carbonaceous matter, we have already fully treated. Besides carbon, or rather carbonic acid, a large quantity of water is also exhaled by means of the lungs. As, however, there is reason to believe that considerable absorption of water also takes place from the same surface, the amount of loss sustained by the united operation of these two functions is only the excess of the exhalation over the absorption.

Sect. II.—*Excretory Function of the Skin.*

By the in.

(555.) We have already given the results of the chemical analysis of the matter of perspiration, in our account of the aqueous secretions, (§ 514). The chief ingredient is unquestionably water; and the average amount of water which escapes from the body through the channel of the skin, has been very variously estimated by different physiologists; for, indeed, it is hardly possible to arrive at any definite conclusion on this subject, from the great variations that occur even in the same individual at different times, especially according to the variable states of atmospheric temperature and humidity, and also according to differences in the activity of the circulation. The only satisfactory information we can hope to attain is, as to the aggregate loss by exhalation from the skin and the lungs. The daily loss of weight from these two sources taken together is stated by Haller[1] to vary from thirty ounces in the colder climates of Europe, to sixty in the warmer, and is estimated by Lavoisier and Seguin[2] at forty-five ounces in the climate of Paris. But this quantity is, of course, from the causes already mentioned, liable to extreme variation. It has been estimated that, of the whole quantity thus exhaled from the skin and from the lungs, about two-thirds are derived from the former source, and one-third from the latter.

Sect. III.—*Excretory Function of the Kidneys.*

By the neys.

(556.) A considerable proportion of fluid is also carried off from the system by the kidneys; the peculiar office of which, however, appears to be to eliminate more especially the saline materials, which are to be thrown off; and, in particular, the peculiar substance termed *urea*, which, as we have already remarked, partakes much of the character of resinous bodies. As urea contains a very large proportion of nitrogen, it is probable that the kidneys are the channels provided in the economy for the removal of any excess of this element which takes place in the system.

alysis of ne.

(557.) The chemical analysis of the urine has engaged the attention of a great number of physicians and philosophers, not only from its supposed connexion with various states of the body in health and disease, but also from its containing a great multitude of constituents, some of which have very peculiar properties. Above twenty different substances have been detected as entering into its composition; and almost every year is adding to the list of newly discovered ingredients. The existence of phosphorus in this fluid has long been known; and the urine was, till lately, the only source whence this elementary substance could be procured in any quantity. Scheele discovered the uric or lithic acid, which is one of the most remarkable of the animal products. The labours of Fourcroy and Vauquelin led to the knowledge of the exact composition of many of the neutral salts contained in the urine. This analysis was carried still farther by Cruickshank in England, and by Proust in Spain, but has been brought to its present state of perfection chiefly by the labours of Berzelius[3] in Sweden.

(558.) The daily quantity voided, as well as the sensible qualities of this secretion, is greatly modified by circumstances. The former has been estimated at an average as being about two pounds avoirdupois. Its mean specific gravity has been fixed at 1·03. In a healthy state it generally exhibits acid properties, arising from the presence of uncombined phosphoric, lactic, uric, benzoic, and carbonic acids. These acids, together with the muriatic and fluoric acids, also exist in combination with several earthy and alkaline bases, comprising ammonia, lime, magnesia, potass, and soda; the principal compounds thus formed being the phosphates of lime and magnesia, ammonia and soda, the sulphates of potass and of soda, the lactate of ammonia, the muriate of soda, and the fluate of lime. There exist, besides, a large proportion of urea, (composing nearly one-thirteenth of the whole quantity of urine, and about one half of its solid ingredients), mucus, gelatin, albumen, and a small portion of unacidified sulphur. The presence of a minute quantity of silica has also been detected by Berzelius, amounting to about the 220th part of the solid matter contained in the urine. The weight of the solid ingredients obtained by evaporation, is one-fifteenth of the whole fluid, the rest being water. The several ingredients above mentioned may each be rendered evident by the application of appropriate tests.

Urea.

(559.) Urea is a peculiar animal product, which is procured from urine evaporated to the consistence of a syrup and allowed to crystallize; after which alcohol is added, which dissolves the urea, whence that substance is obtained by evaporation. It then appears in the form of crystalline plates, and has a light yellow colour, a smell resembling garlic, and a strong acrid taste. It is chiefly characterised by the bulky flaky compound which it forms with nitric acid. By distillation it yields about two-thirds of its weight of carbonate of ammonia; and by spontaneous decomposition it is resolved into ammonia and acetic acid. It possesses the very remarkable property of changing the form of the crystals of common salt or muriate of soda, which, as is well known, usually crystallize in cubical crystals; but which, when mixed with a small quantity of urea, assume the form of octohedrons. What adds to the singularity of this effect is, that its operation is precisely the reverse on muriate of ammonia, or sal ammoniac; the ordinary form of the crystals of this salt are octohedrons, but when urea is present, they take the form of cubes. Urea contains a much larger proportion of nitrogen than any other animal principle. This substance has been found in the blood, after its separation by the kidneys has been prevented, by the extirpation of those glands. Berzelius has advanced an opinion, that urea is furnished by the animal matter of the serosity of the blood, from the similarity of some of its properties, and also from the circumstance, that after the kidneys have been removed, the animal matter of the serosity is first increased in quantity, and afterwards assumes the character of urea. It appears probable that the principal function of the kidney is the separation from the blood of the excess of nitrogen which it may contain, and its excretion in the form of urea; thus performing an operation with respect to this element analogous to that of the lungs with regard to the superfluous carbon of the blood.[4]

Sect. IV.—*Excretory Function of the Liver.*

4. Excretion by the liver.

(560.) Cholesterine, or the peculiar matter found in the bile, and which composes about eight per cent of that fluid, contains a large proportion of nitrogen. Whatever may be its uses in contributing to the formation of chyle, it is ultimately rejected from the body, and may therefore be classed among the excrementitious substances. We have already noticed the singular circumstance regarding the mode of its preparation, in being formed from venous instead of arterial blood, as is the case with all the other known secretions.

[3] *Annals of Physiology*, ii. 428.

[4] See Berard, *Annales de Chémie et de Physique*, v. 296.

(561.) It is doubtful how far these two peculiar substances, urea and cholesterine, may be considered as pre-existing in the blood, or as formed by the organs which respectively secrete them. It has been ascertained by the experiments of Prévost and Dumas, that in animals in whom the secretion of urine is suppressed by the removal of the kidneys, urea may, after some time, be detected in the blood; and Dr. Bostock ascertained that a similar substance makes its appearance in the human blood, in cases where the secretion of urine had been much obstructed by disease of the kidneys. The secretion from the liver is not liable to so much variation in its amount, as that from the other excernent organs; it is, however, diminished during febrile excitement and inflammatory conditions of the circulation, and increased by moderate exercise, and by external warmth. Both the liver and the kidneys, accordingly, may be ranked among the compensating organs, or those which have their actions occasionally increased in order to supply deficiencies in the functions of others. The excretion of watery fluid from the skin and lungs is evidently made to alternate with that from the kidneys, each of these organs being capable of occasionally supplying the office of the others. The chemical properties of the urine are very much influenced by the condition of the digestive functions. But the necessity of the excretion of urea is apparent from the rapidly fatal consequences which ensue from its accumulation in the system, when the secretion from the kidneys is suppressed, and which would lead to the conclusion, that this substance, when present in sufficient quantity, speedily acts on the nervous system as a virulent poison.

CHAP. XII.—NUTRITION.

Nutrition.

(562.) Nutrition consists in the appropriation of the materials furnished by the blood in the course of circulation, and modified by the processes of secretion, to the purposes of growth, and to the repair of that waste which is continually experienced by the solid structures of the body, in consequence of the exercise of their respective offices. We understand as little what are the particular processes by which these purposes are accomplished as we do respecting those of secretion. No mechanical or chemical hypothesis which can be devised appears at all adequate to the solution of this mysterious problem. The analogy of crystallization, implied in the celebrated definitions of Linnæus, in which the three kingdoms of nature are contrasted, is, in a philosophical point of view, utterly fallacious. According to this great naturalist, " minerals grow, vegetables grow and live, animals grow, live, and feel." It requires no lengthened argument to show that the growth of an animal, or of a plant, is a phenomenon belonging to a class entirely different from the increase of a mineral body. The latter is effected by the successive accretion of new layers of materials, which merely augment the volume of the body, without adding to it any new property; so that the separation of its parts destroys only the form of the aggregate, and not any of its essential qualities. But organized bodies are nourished from internal resources, and the materials which are incorporated with their substance have undergone a slow and gradual elaboration in the organs themselves, and have been assimilated to the qualities of the body of which they are to form a component part. We may consider them as the result of the operation of the organic affinities, to which we have already referred the phenomena of secretion.

Dependent on the circulation.

(563.) The only general fact of importance which has been established with regard to the succession of phenomena in this function, is. that the enlargement of any organ appears to depend essentially on the state of the circulation in that part, and on the supply of blood by its arteries. The increased growth of a part at any period, compared with that of neighbouring parts, is always preceded and accompanied by a marked enlargement of the arteries which furnish it with blood; and this is invariably observed, whether that growth be natural or morbid. A theory has been advanced, that nutrition is effected by the direct union of the red particles of the blood, or of their nuclei, with the tissues. This theory is successfully combated by Müller.[1]

(564.) Although we are unable to trace the exact nature of the processes of nutrition, yet much curious information may be collected by observing the succession of phenomena in the case of the formation of particular structures. Those which we shall select for the purpose of illustration are the bones and the teeth, in which the several stages of growth admit of being observed.

Sect. I.—*Ossification.*

Ossification.

(565.) The process of ossification is particularly interesting, from its exhibiting the operations of nature in the completion of an elaborate structure of such great importance in its mechanical relations to the system, as the osseous fabric. In the early periods of the fœtal state, we can but just trace the figures of some of the larger bones, which appear to be modelled in a soft gelatinous matter contained in a delicate membrane. This substance, as well as its membrane, acquires greater density, and the former assumes more the appearance of cartilage. In process of time, opaque white spots are perceived on different parts of its surface, which, when examined by the microscope, exhibit a fibrous appearance. These lines increase in number and extent; and after a time, red points are seen dispersed throughout the future bone, in consequence of the enlargement of the vessels which now admit the red globules of the blood. Soon after this, we find the earthy matter deposited in great abundance, imparting hardness and rigidity to the structure. In the long bones of the extremities, the osseous substance forms at first a short hollow cylinder, as if it were deposited from the vessels of the investing membrane, or periosteum. In the flat bones of the cranium, ossification commences from a few central points, and spreads on all sides, the fibres taking a radiating direction. In proportion as the bony material extends, the cartilage is removed by the absorbent vessels, in order to make room for the extension of the bone. After a certain time, in the cylindrical bones, a cavity is formed in the middle, in consequence of the absorption of central portions of cartilage and of bone which had occupied that situation. These two opposite processes of absorption and deposition continue during the whole of the future growth of the bone, the interior parts being removed in proportion as fresh bony layers are added at the exterior surface. Thus, when the outer part of the bone is compact and hard, the interior is either formed into a complete cavity, or into the cancellated structure formerly described.

Theorie

(566.) Such are the few well ascertained known facts relative to ossification; but numberless have been the speculations to which they have given rise. Most of the opinions of the ancients on this subject were extremely vague and hypothetical, and have been fully refuted by modern physiologists. Many of the hypotheses of the latter have undergone a similar fate. The one which has acquired most celebrity is that of Duhamel, who, following the analogy of the growth of trees, conceived that the bones were formed of concentric rings, or laminæ, deposited from the periosteum. He endeavoured to adduce in support of his theory the results of experiments in which bones acquired a red tinge, when madder was given with the food. He alleged that when the madder was occasionally intermitted, and again resumed, many times in succession, the bones of the animal exhibited alternate rings of a red and white colour, corresponding to the periods when the animal had taken madder, and had intermitted it. It has since been shown, however, that his imagination in this instance must have misled him; for no such result takes place under the circumstances he describes.

---

[1] *Elements of Physiology*, translated by Baly, p. 359.

(567.) The reparation of fractured bones by the powers of the constitution is a striking instance of the beautiful provisions of nature for remedying injuries accidentally occurring to the body. The fractured ends are quickly united by a bony substance called *callus*, formed in a manner very similar to that by which the bone itself is originally constructed. The arteries near the seat of the injury pour out a kind of lymph, which coagulates, and is either gradually converted into cartilage, or replaced by cartilage after it has itself been absorbed. The deposition of phosphate of lime then takes place within this cartilage, which is either removed or adapted to its reception, and thus the ends of the bone are cemented together, and the limb rendered as firm as before the accident.

2. *Dentition.*

ntition.

(568.) No less curious and interesting is the process employed in the formation of the teeth. The rudiments of every tooth, when examined in the fœtus, consists of a gelatinous pulp, which is extremely vascular, enclosed in a double investment of membrane. The outer membrane is soft and spongy, and is apparently destitute of vessels; while the inner one is firmer, and extremely vascular. The first depositions are those of bony matter, which take place on the exterior surface of the vascular pulp, and chiefly on the upper part, but within the membranous coverings already noticed. The shell of bone thus formed has the shape of the future tooth, and acquires thickness from successive deposits of bone in its inner surface, which are still made by the outer surface of the vascular pulp. When the ossification is sufficiently advanced, the pulp which has thus served as a mould for the tooth, divides itself into two or more parts, corresponding to the intended number of fangs, so that the ossific matter is now deposited in the form of as many tubes round these portions of the pulp, and growing in a direction towards the jaw, forces the tooth in the contrary direction; thus in the lower jaw the tooth rises, and in the upper jaw it descends. The enamel is deposited after the body of the tooth is considerably advanced in its formation. It is the product of a secretion from the inner surface of the outermost of the two membranes, which form the capsule of the tooth, and the materials deposited from it adhere strongly to the bony crown of the tooth which they surround. This secreting capsule has been called the *chorion* by Herissant, who has given an accurate description of the process of dentition. Layer after layer of enamel is thus deposited, till the growth of that part of the tooth has been completed; then the chorion shrivels and is absorbed, and the tooth still continuing to grow at the root, pierces the gum, the resistance of which has been gradually diminishing by the absorption of its substance.

Sect. III.—*Nutrition of the Softer Textures.*

(569.) Greater difficulty exists in following the succession of changes which attend the growth and nutrition of the softer textures, than of those we have now considered, because the materials employed in their construction are less distinguishable by the eye from the other animal substances, and their changes are less easily traced, than those exhibited by the calcareous deposits of the osseous fabric.

A question here presents itself, of great importance with relation to our knowledge of the nature of the vital powers, but of which the solution is attended with the greatest difficulties. It is this: how far, it may be asked, are the powers of secretion exerted in merely separating from the blood those organic products which are already contained as ingredients of that fluid, and how far do they also extend to the actual formation of new proximate elements; and next, what reason is there to believe that the vital powers are capable of producing, from the materials presented to them, originally derived from the food, or the atmosphere, any quantity of those chemical substances, which, never having hitherto been decomposed, must, in the present state of the science, be regarded as elementary?

The consideration of the chemical analysis of the blood, and of the substances prepared from it will suffice to shew that most, if not all the secretions, may very possibly be produced solely by the operation of ordinary chemical affinities. It has been found, indeed, that we are able by certain chemical processes, to form from the blood, out of the body, substances similar to many of the secretions; and we are therefore warranted in the supposition that operations of the same kind are carried on by the secreting organs within the body. It is interesting, however, to trace the origin of many of the products of secretion, from the ingredients contained in the blood itself. On this subject Müller[1] remarks, that some of the proximate elements of the tissues exist in part ready formed in the blood. The albumen which enters into the composition of the brain and glands, and of many other structures, in a more or less modified state, is contained in the blood; the fibrin of the muscles and muscular structures is the coagulable matter dissolved in the lymph and blood; the fatty matter, which contains no nitrogen, exists in a free state in the chyle; the azotised and phosphoretted fatty matter of the brain and nerves exists in the blood combined with the fibrin, albumen, and cruorin. The iron of the hair, pigmentum nigrum, and crystalline lens, is also contained in the blood; the silica and manganese of the hair, and the fluor and calcium of the bones and of the teeth, have not hitherto been detected in the blood, probably from their existing in it in but very small proportion. The matters here enumerated are attracted from the blood by particles of the organs analogous to themselves, partly in the state in which they afterwards exist in the organs; in other instances, their ultimate elements are newly combined in them, so as to form new proximate principles; for the opinion that all the component elements of the organs exist previously in the blood in their perfect state, cannot possibly be adopted; the components of most tissues in fact present, besides many modifications of fibrin, albumen, fat, and osmazome, other perfectly peculiar matters, such as the gelatin of the bones, tendons, and cartilages, nothing analogous to which is contained in the blood. The substance of the vascular tissue, and also the different glandular substances, cannot be referred to any of the simple components of the blood. Even the fibrin of muscle cannot be considered as exactly identical with the fibrin of the liquor sanguinis. Between coagulated fibrin and coagulated albumen, there is scarcely any chemical difference, except in their action on peroxide of hydrogen; the only very important distinction between the fibrin dissolved in the blood and the albumen is, that the former coagulates as soon as it is withdrawn from the animal body, while the latter does not coagulate spontaneously, but requires a heat of from 158° to 167° Fahr., or some chemical agents, such as acids, concentrated solutions of fixed alkali, or metallic salts; and the fibrin of muscle in its chemical characters has scarcely a greater analogy with coagulated fibrin, than with coagulated albumen. In its vital properties the fibrin of muscle differs from both. The comparison of nervous substance, again, with the fatty matter containing nitrogen and phosphorus, is only justified by the present imperfect state of organic chemistry.

---

[1] *Physiology, &c.* p. 361.

The blood, as Dr. Bostock[1] observes, is a substance, the composition of which is peculiarly well adapted to undergo the changes necessary for the processes both of secretion and of nutrition, as it consists of a number of ingredients, which are held together by a weak affinity, liable to be disturbed by a variety even of what might appear the slightest causes. As examples of the facility with which these changes may be effected, we may cite the numerous reagents which have the power of coagulating albumen; the action upon it and upon fibrin of dilute nitric acid, which converts these substances respectively into adipose matter and jelly, changes which are probably the result of the addition of oxygen to the fibrin and to the albumen; and there is some reason to believe that by applying the same reagent to the red particles, we may obtain a substance nearly resembling bile.

With regard to the formation of the saline secretions,[2] and of those substances, the elements of which are not to be found in the blood, or at least not in sufficient quantity to account for the great accumulation that takes place in certain parts of the system, and of which the source is not apparent, we must confess that the present state of the science affords no means of explaining the phenomena. "To suppose," as Dr. Bostock justly remarks, "that we are affording any real explanation by ascribing it to the operation of the vital principle, or to any vital affinities, which is merely a less simple mode of expressing the fact, is one of those delusive attempts to substitute words for ideas, which have so much tended to retard the progress of physiological science."

Sect. IV.—*General Phenomena of Nutrition.*

(570.) The instances we have above given of the processes employed in ossification and dentition, together with the varied operations concerned in the formation and nutrition of all the softer textures of the body, forcibly illustrate the beneficent care displayed in the construction of every part of the frame, and the admirable adjustment of the long series of means which have been provided for the attainment of these diversified and frequently remote objects of the animal economy. Every part undergoes a continued and progressive change of the particles which compose it, even though it remain to all outward appearance the same. The materials which had been united together by the powers of nutrition, and fashioned into the several organs, are themselves severally and successively removed and replaced by others, which again are in their turn discarded, and new ones substituted in their place, until, in process of time, scarcely any portion of the substance originally constituting the organs remains as their component part.

Renewal of materials.

(571.) We see from the examples of the bones, that this continual renovation of the materials of the body takes place in the most solid, as well as in the softest textures; and so great is the total amount of these changes, that doubts may reasonably be entertained as to the identity of any part of the body at different epochs of its existence. The ancients assigned a period of seven years as the time required for the complete renovation of all the materials of the system, but perhaps this entire change may take place during a shorter interval.[3]

Balance of powers.

(572.) The two functions we have been considering, namely, nutrition and absorption, may be regarded as antagonist powers, each continually counteracting the effects of the other. In the early periods of life, though both are in full activity, the former predominates; all the organs enlarging in their dimensions by the addition of fresh materials in greater quantity than the losses by absorption, the whole body is in a state of growth. In the course of time, the frame having attained its prescribed dimensions, these opposite processes of reparation and decay approach nearer to an equality; and at length are exactly balanced. The parts then cease to grow, and the system may be said to have reached its state of maturity. This is the condition of the adult, in which the equilibrium of the functions is maintained for a great number of years. At length, however, the period arrives when the balance, hitherto so evenly kept, begins to incline, the renovating powers of the system are less equal to the demands made upon them, and the waste of the body exceeds the supply. It contracts in its dimensions; it has attained its period of declension, which marks the progress of age, and ultimately leads to decrepitude. The fabric then betrays unequivocal symptoms of decay, the functions are imperfectly performed, the vigour of the circulation flags, the flame flickers in the socket, and is finally extinguished in death. Thus is the whole duration of life, from the first developement of the germ to the period of its dissolution, occupied by a series of actions and reactions, perpetually varying, yet constantly tending to definite and salutary ends.

(573.) We have now concluded the account we proposed to give of the long series of functions which maintain the various organs of the system in that mechanical condition and chemical composition fitting them for the exercise of their several offices in the economy. We have next to enter into the consideration of the higher order of functions connected with the nervous system.

CHAP. XIII.—THE SENSORIAL FUNCTIONS.

Sect. I.—*General Views.*

Objects sensoria function

(574.) The functions we have hitherto considered, however admirably contrived, and beautifully adjusted, are calculated only for the maintenance of a simply vital existence. All that is obtained by their means is a mass of organized materials, which lives, which is nourished, which grows, which declines, and which perishes in a certain definite period, by its mere internal mechanism. But these can never be the real ends of animal existence. Sensation, voluntary motion, pleasure and pain, together with all the intellectual operations to which they lead, these must be the proper objects of animal life; these the purposes for which the animal was created. In man we find the extension of these latter faculties to an extraordinary degree, and the addition of moral attributes which elevate him so far above the brute creation, and place him one step nearer to that divine essence after whose likeness he was made.

(575.) The functions of sensation, of voluntary motion, and of thought, are those which establish our mental connexions with the external world; which enable us to acquire a knowledge of the existence and properties of the material objects that surround us; which awaken in us the operations of our own minds; which bring us in communication with other intellectual and sentient beings, and which enables us to react on matter, to exercise over it the dominion of the will, and to influence the condition of those other beings which like us have received the gift of life, of sensation, and of intellect.

Distinc between matter and mi

(576.) Throughout the whole of the inquiries in which we are about to engage it is important to keep steadily in view the essential and fundamental distinction between mind and matter. Of the existence of our own sensations, ideas, thoughts, and volitions, we have the highest degree of evidence that human knowledge can admit of, that of our own consciousness. Of the existence of matter, that is, of causes foreign to our own mind, but acting on it, and giving rise to sensations, which are strictly mental affections, we have merely a strong presumption; still, however, the belief in the existence of those causes, however irresistibly it may operate in producing in us convictions, and influencing our actions, is yet but an inference from the regularity in the succession of our sensations. We are not justified in saying that it is impossible we can be deceived in this belief; whereas in the consciousness of our mental existence we cannot possibly be mistaken, because that consciousness implies the very fact of our existence.

nexion ween n.

(577.) It is, however, most true, that notwithstanding our ideas of mind and matter are such as wholly to exclude our conceiving any property to belong to both of them in common; yet some inscrutable link of connexion has, in our present state of existence, been established between them, so that each may, under certain circumstances, be affected by the other. External matter acts on our bodily organs, which are still mere matter; but our bodily organs act on our minds; and our minds in turn react on our bodily organs, and occasion movements which enable us to act on extraneous objects. Moreover, it is impossible for us in our present state to carry on any intellectual operation, but by the instrumentality of our material organs; we can neither feel, nor think, nor will, without the healthy condition of the brain, and all the other physical conditions which such a state implies. Disturbance of the physiological functions of the brain is invariably attended by a disturbance of the mental operations connected with those functions. Both are excited by certain states of the circulation in the brain; both are instantly suspended by pressure upon that organ; both are restored by the removal of the pressure, or other disturbing cause.

e ner s sys-

(578.) The *nervous system* is the name given to that assemblage of organs which perform the important functions of which we are now speaking. The primary office of the fibres composing that system appears to be to transmit certain affections, which we may call *impressions*, from one part of that system to another; and more particularly to convey them both to and from that particular part of the brain, the affections of which give rise to sensation, and accompany our mental operations. In the one case, the impression made on one extremity of a nervous fibril, adapted to receive such impression, in a part called an *organ of sense*, is propagated to the part of the brain above described, and to which the name of *sensorium* has been given, and thereby producing a certain physical effect, the nature of which is wholly unknown; *sensation*, which is a mental effect, ensues. In another case, the fibres of the brain are by their action instrumental in retracing, in combining, in modifying these impressions, and forming them into ideas, which are linked together by the laws of association. Again, the mental act we term *volition*, and of which we are always conscious, affects some particular fibres or portion of the sensorium, the impression made upon which is followed by an affection of certain nervous filaments proceeding from those parts of the brain, and conveying an influence, (which for want of a more specific term we may also call *irritation*), to the muscles in which these nerves terminate; and this is immediately followed by the contraction of those muscles. This constitutes *voluntary motion*.

(579.) But the office of the nerves extends yet farther. Various muscles subservient to many of the vital functions, such as the heart, the stomach, and the intestines, act without any interference, or even control of the will. They compose the class of *involuntary muscles;* yet these muscles are supplied with nerves, and have a certain dependence on the nervous system, which is of a very peculiar kind, and will be considered afterwards. These nerves supplying the involuntary muscles, appear to have the office of establishing connexions between the actions of these muscles, and of uniting the various organs of the different functions into one connected harmonious whole.

Series of actions.

(580.) Thus the various phenomena which relate to the nervous system in the performance of the functions we are considering, will arrange themselves under the following heads, according to the natural order of their sequence:

First, the impressions made by external objects on the sentient extremities of the nerves distributed to the organs of sense, through the medium of those organs.

Secondly, the transmission of the impressions so made to the sensorium, through the medium of the nerves of sensation.

Thirdly, the physical changes made on the sensorium.

Fourthly, the mental change consequent on this physical change in the sensorium; which mental change is termed *sensation;* and in experiencing which the mind is wholly passive.

Fifthly, the recurrence, associations, and combinations of the physical changes originally induced in the sensorium, but probably extended through various parts of the substance of the brain, and simultaneous with various mental operations, in exercising which the mind is partly passive and partly active.

Sixthly, the mental act denominated *volition*, which is accompanied with consciousness, and in which the mind is wholly active.

Seventhly, the corresponding change induced by volition on the sensorium, or origin of the nerves of voluntary motion.

Eighthly, the transmission of the impression so received by the nerves of voluntary motion, to the muscles on which they are distributed.

Ninthly, the contractions of these muscles, constituting voluntary motion.

Tenthly, the influence of the nerves on the muscles of involuntary motion, and on various functions apparently depending on involuntary actions.[1]

Sect. II.—*Organization of the Nervous System.*

Division of the nervous system.

(581.) The nervous system comprises organs of a curious and complicated structure, and which are of the highest importance in the animal economy. Their study is exceedingly interesting, whether they be viewed as instruments of sensation, as sources of action, or as the medium of connexion between the body and the mind. This system is composed of a considerable mass of a soft pulpy substance called the *brain*, which occupies the cavity of the skull; a prolongation of this substance filling the canal of the spine, and called the *spinal cord*, or *spinal marrow;* and of various processes in the form of cords, called *nerves*, which extend from the brain and spinal cord, to almost all parts of the body. There are found also interspersed in various parts along the course of the nerves, small rounded or flattened bodies, called *ganglia*, which also belong to this system of organs. All the parts of this system are intimately related to each other, and although they differ considerably in their general appearance, they possess many characters in common. In point of structure they present us with three different modifications; the first comprehending the substance of the central masses, which include the brain and spinal cord; the second, the nerves; and the third, the ganglia. We shall proceed to consider each of these in the above order.

1. *Organization of the Brain and Spinal Cord.*

Structure of the brain.

(582.) *The brain*, or general mass which fills the cavity of the skull, is composed of a number of parts of various shapes, the particular forms and dispositions of which belong properly to descriptive anatomy. It will be sufficient for our present purpose to state, that it is divided into three masses, distinguished by the names of *cerebrum*, which is by far the largest portion, and which occupies the whole of the upper and fore part of the cavity of the skull; the *cerebellum*, or lesser brain, which is situated at the hinder and lower part of the cerebrum; and the *medulla oblongata*, which lies at the central part of the base, or inner surface of the cerebrum, and connects it with the cerebellum, and with the spinal cord. All these parts, as well as the spinal cord itself, are formed of two kinds of substance; the *cineritious*, or ash-coloured substance, which has also been called the *cortical* substance; and the white, or *medullary* substance. These two substances are variously intermixed, sometimes forming strata of different thickness, and sometimes the one enveloping separate portions of the other, in different parts of the whole mass. There is a layer of cortical substance placed on the outside of the cerebrum; it does not, however, form a smooth uniform plane, but is moulded into *convolutions*. In the cerebellum there is a similar superficial stratum formed into concentric laminæ. The convolutions are of considerable depth; and if any of them be cut through, it is seen to consist of both cortical and medullary substance. The cortical forms a layer of considerable thickness; and on looking attentively on its divided edge, a very narrow lamina of medullary substance will be perceived passing through it, and following it through all its windings. This fact has been particularly noticed by Dr. Baillie. The concentric laminæ on the surface of the cerebellum, are composed also of cortical and medullary matter. By this arrangement, the quantity of cortical substance, as well as the extent of its surface on the outer part of the brain, is very much increased.

---

[1] See *Bridgewater Treatise on Animal and Vegetable Physiology*, vol. ii. p. 535, note.

(583.) In the interior of the brain we find cavities of considerable size, termed *ventricles*, and bodies of regular, but various shapes, presenting many different mixtures of two species of matter. Where these bodies appear, from their outside, to be formed of cortical substance only, on cutting into this, there is found a considerable mixture of medullary matter; and where they seem, from their outside, to be formed of medullary matter alone, they are discovered, on dividing them, to contain some cortical substance in the interior. Thus, there is no particular part of the brain composed purely of the one kind of substance or the other; although the proportions of each in the various parts may be very different. A similar intermixture of cortical and medullary matter exists in the spinal cord; but contrary to what takes place in the large mass of the brain, the cortical part is placed in the interior, and is enveloped by the medullary.

(584.) The medullary substance has generally been considered as constituting the most perfect state of nervous matter, or that which more especially exercises the functions of the nervous system. Some physiologists, on the contrary, consider the grey substance as the seat or origin of nervous power; while the fibres of the white substance act merely the part of conductors of nervous influence from one part to another. This medullary portion is obviously of a firmer consistence than the cortical part, and contains fewer blood-vessels interspersed throughout its substance. Both the one and the other are almost perfectly homogeneous in their appearance. Ruysch had fancied that the cortical substance was entirely composed of blood-vessels, connected by cellular membrane; and in this opinion he was for a long time generally followed, although the pulpy consistence it exhibits is scarcely compatible with such a notion. Malpighi supposed that he had detected in it a glandular structure; but this must also be regarded as a mere hypothesis, unsupported by any substantial evidence. The medullary matter presents traces of a fibrous structure; a fact which was first observed by Malpighi, and which is particularly insisted on by Drs. Gall and Spurzheim; and notwithstanding the existence of such a structure is denied by other eminent anatomists, it appears to have been sufficiently established by the elaborate researches of Reil, a detailed account of which has been given by Mr. Mayo.[1]

Microscopic structure.

(585.) Anatomists are far from being agreed as to the minute and ultimate structure of nervous matter. De la Torré asserts that it consists of a mass of innumerable transparent globules immersed in a transparent fluid; and that these globules are larger in the brain than in the spinal marrow. Prochaska describes the same globular structure, which he represents as united by a transparent elastic cellular membrane disposed in fibres. Monro,[2] in his first inquiries, thought that these fibres were convoluted, but afterwards acknowledged that he had been misled by an optical fallacy, incident to the employment of high magnifying powers. The Wenzells[3] also recognised the globular composition of the nervous substance, and considered the globules themselves to be vesicles filled with a material either of a medullary or cineritious appearance, according to the portion examined. Bauer[4] states that the globules are of about the same diameter as the central particles of the globules of the blood, some, however, being still smaller; and that they are of a gelatinous consistence, and soluble in water. The cineritious substance, he finds, is composed chiefly of the smallest globules, surrounded by a large proportion of a gelatinous and serous fluid. The medullary substance, on the other hand, is formed principally by the larger and more distinct globules which adhere together in lines, and have a smaller proportion of fluid, that fluid being more viscid than in the cineritious substance. Dr. Edwards[5] has confirmed by his observations, these results, as far as the general globular composition of nervous matter is concerned. He asserts the diameter of the globules to be one three-hundredth of a millimetre, which is equivalent to the seven thousand six hundred part of an inch; and that these globules are arranged in linear series, constituting the primary linear fibres. Beclard states that he has verified these observations.[6]

2. *The Nerves.*

Nerves.

(586.) The *nerves* are white cords extending from different parts of the brain and spinal cord, to different parts of the body, and more especially to the muscles, the integuments, and other organs of sense, and to the viscera and blood-vessels. Their general form is cylindrical; but they divide, in their course, into a great number of branches, many of which again reunite, or are joined with the branches of other nerves, so as to form in many parts a complicated nervous net-work, or *plexus*, as it has been termed by anatomists. The nerves are usually spoken of as originating in the brain or spinal cord, and as proceeding from thence to their termination in other, and generally distant parts. As the united branches would form a cord of much larger diameter than the trunk from which they arise, it is evident that the total quantity of nervous matter they contain is augmented as they proceed in their course. When examined with the microscope, their surface presents a number of transverse lines or wrinkles, which are evidently for the purpose of admitting of flexion; and thus accommodating them to the different movements of the parts with which they are connected.

Neurilem

(587.) The nerves appear to consist of filaments of medullary substance, enclosed in a tough cellular membrane.

---

[1] In his *Anatomical and Physical Commentaries*.

[2] On the *Nervous System*.

[3] *De Structura Cerebri*.

[4] *Philosophical Transactions* for 1818, and 1821.

[5] *Sur la Structure élémentaire*.

[6] See his *Anatomie Générale*.

At their origin from the central organ, whether it be the brain or the spinal cord, they consist of detached fibrils, sometimes isolated, but in general arranged so as to constitute flat bands. There are two such bands, namely, an anterior and a posterior fasciculus, which unite to form each of the nerves arising from the spinal cord. Some nerves are composed of pure medullary matter, as the optic nerve; but in the greater number this matter is so enveloped in a tough cellular membrane, which has been termed by anatomists the *neurilema*, that it cannot distinctly be perceived. In the olfactory nerves there is an evident junction of cortical with medullary matter, but in most others we find nothing but filaments of medullary matter, each of which is contained in a separate envelope of neurilema, that forms tubes for their reception.

(588.) Many anatomists have attempted the investigation of the minute structure of nervous fibrils by means of the microscope. De la Torré[1] perceived in them globules similar to those of which the matter of the brain is composed. Monro[2] and Fontana describe the nervous filaments as being connected by cellular substance, much in the same way as the muscular fibres, and arranged like them in fasciculi of various sizes. They represent the ultimate fibril as being twelve times greater than the muscular fibre, having a serpentine or tortuous form, and being composed of a cylindrical canal, containing a viscid pulpy matter, evidently different from the substance of the canal itself. Reil has pursued this investigation with still greater care and minuteness, and states that the ultimate filaments differ in thickness from that of a hair to the finest fibre of silk. Their arrangement into larger and larger fasciculi is analogous to what we observe in the structure of muscles, but with this difference, that the nervous fibres in their course along the nerve, frequently divide and subdivide, and are again variously united and conjoined, so as to produce an extensive connexion among all the parts of the same nerve. The membranous neurilema, besides giving support to each individual filament of nerve, and uniting them into fasciculi, furnishes also a general covering to the whole nerve.

(589.) What has now been stated must be understood as applicable to nerves in general. Many differences have been pointed out in the structure of different nerves; but it is not necessary to descend into these minute particulars in the general view we are now giving.

3. *Ganglia.*

glia.

(590.) *Ganglia* are small rounded nodules, which are placed in different situations in the course of nerves, sometimes in the trunk of a single nerve, and sometimes where two nerves unite. They are most numerous on those nerves which are distributed to the viscera, and to the muscles of involuntary motion. Their appearance is very different from that of a mere dilatation of a nerve, being of a reddish-brown colour, having a minute fibrous texture, a firmer consistence, and a greater number of blood-vessels than ordinary nerves. The nerves which pass out from a ganglion are generally of a larger size than those which entered into it, as if they had received, in their passage through it, an additional quantity of matter. It would appear, from numerous observations, that the filaments of the different nerves which join the ganglion proceed through it individually without interruption, but are, at the same time, involved and twisted together in a very complicated manner; the result being, that filaments from many different nerves are united in the formation of a new nerve; so that the parts to which the nerve is distributed receive a supply of filaments from many different sources, and are in very extensive communication with various parts of the brain, spinal cord, and indeed the whole nervous system.

(591.) Besides this junction and intertexture of nervous filaments, the ganglia contain a soft semi-fluid matter, which appears to be analogous to the proper substance of the brain, and like the latter, may be distinguished into cineretious and medullary portions. It would appear, therefore, that the ganglia have some peculiar office with regard to the nerves which traverse them, and that they do not serve the purpose only of a plexus of filaments, establishing mere mechanical connexions between them, as some anatomists have alleged.

CHAP. XIV.—THE EXTERNAL SENSES.

External senses.

(592.) The external senses have usually been reckoned five in number, namely, touch, taste, smell, hearing, and sight; but this arrangement has reference more to the organs by which they are exercised than to the nature of the sensations they excite in the mind. A variety of sensations have been referred to the sense of touch, which are wholly different in their kind, and which are received by means of impressions made on the skin, and also others which are conveyed by nerves in other parts of the body, without any connexion with the skin. These we shall notice after we have considered the sensations more peculiarly belonging to the sense of touch.

SECT. I.—*Touch.*

1. *Sensation of Pressure.*

Touch.

(593.) Every part of the surface of the body is exposed to the contact of foreign bodies; and in most parts of the skin very slight pressure made by those bodies gives occasion to the primary sensation of touch, which is in fact simply that of resistance to the part of the skin on which it presses. This sensation is quite specific, and distinguishable from all other sensations. It may be conveyed, though less perfectly, by several of the internal surfaces of the body, as those of the mouth and pharynx. Certain parts of the skin possess, however, a more peculiar delicacy of nervous sensibility to the impressions of touch, and are therefore to be considered as more especially the organs of this sense. In man the points of the fingers are particularly employed for receiving the finer impressions of touch, and for distinguishing the qualities of external objects, of which this sense is fitted to convey us information. The greater vascularity of the skin of the fingers, and greater developement of its papillary structure, have been assigned as the causes of the apparent increase of sensibility with which they have been endowed. There is no doubt, however, that much depends on the education given to the ends of the fingers, by their constant employment in this office; for we find that the toes and other parts of the body may, by use, be trained to the acquisition of an equal degree of sensibility; of this we see examples in individuals who have been born without hands. Parts where the epidermis is very thin, such as the lips, are also endowed with considerable sensibility to the impressions of touch, and with the power of discriminating differences in those impressions which cannot be felt or appreciated by means of the fingers.

(594) Professor Weber of Leipsig[4] has made a series of very interesting experiments on the relative sensibilities of the skin in different parts of the body, with reference more particularly to its power of conveying to the mind accurate perceptions of mechanical impressions made upon it. He found this power possessed in the highest degree by the tip of the tongue and ends of the fingers, the sensibility of

---

[1] *Philosophical Transactions* for 1769.

[2] *On the Nervous System.*

[3] An account of these researches is contained in the *Edinburgh Medical Journal*, xl. p. 83.

which he estimated at eighty times greater than that of the skin of other parts of the body. He observed, also, that even the skin in different parts of the face, when touched with the points of a pair of compasses opened to a small distance, shewed the greatest diversity in their power of conveying distinct perceptions of touch as to the object in contact being single or double, and as to the distance between the points, when they were perceived to be double.

2. *Sensations of Temperature.*

Sense of heat and cold.

(595.) The same organs which, when pressed by an external body, convey the impression of resistance, communicate also sensations of heat and cold, and nearly in the same relative proportion. Thus the fingers are more sensible to variations of temperature in the bodies they touch than other parts of the skin less accustomed to discriminate them. The lips are still more sensible than the fingers to the differences of temperature in the bodies to which they are applied. This peculiar sensibility affords a ready mode of distinguishing genuine diamonds and other precious stones from such as are counterfeit; for the former, being better conductors of heat, produce a more lasting impression of coldness when applied to the lips or to the tongue.

The sensations of heat and cold are, however, far from being in exact proportion either to the actual temperatures of the bodies which are in contact with the skin, or even to the differences between their temperature and that of the skin. The actual condition of the sensibility of the skin at the time, which depends on a multitude of causes hereafter to be noticed, has a very considerable influence on the sensations. The difference which is observable in the sensibilities of the same part to the impression of resistance, and to that of heat or cold, suggests a doubt whether a different set of nerves may not be employed to transmit to the brain these different kinds of impressions. We find in certain states of disease, that the general sensibility of the surface of the body may be much impaired, and yet it may preserve its sensitiveness with regard to heat and cold; and it is also certain, that differences of temperature produce sensations in parts, the stomach for instance, which are wholly disqualified from communicating the feeling of resistance.

3. *Anomalous Sensations.*

Hunger and thirst.

(596.) Hunger and thirst are sensations referred to the mouth, throat, and stomach, which are also quite specific in their nature, though generally referred to the sense of touch.

Peculiar sensations.

(597.) The same observation applies to a variety of peculiar sensations, many of which are common to the whole surface of the body, and may even be felt in some internal parts, but which it would be difficult to class, or even completely enumerate. The sense of tingling and of itching are examples of this species of sensations. The feeling of nausea is an undefinable sensation referred to the stomach.

4. *Sensation of Pain.*

Pain.

(598.) Every sensation thus referred to the sense of touch, when it rises beyond a certain degree, is accompanied with the additional feeling of pain, which, if considerable, engrosses the whole attention, and effaces all marks of discrimination as to its origin. Pain is generally readily referred to a particular part of the body, as being the origin, or as it is commonly called, the *seat* of pain, especially when the part is external. But in internal parts, this specific reference is often extremely vague and imperfect; and there frequently exists a general feeling of uneasiness, often more intolerable than any other, and to which it is impossible to assign any particular locality. It may also be observed, that in general the actual sensibility bears no relation to the capacity for feeling pain.

(599) A vast number of experiments were made by Haller, with a view to ascertain the comparative sensibilities of the different textures and organs of the body. In general, those which have but a small degree of vascularity, such as the cartilages, tendons, ligaments, fibrous membranes, and bones, and even the simple cellular texture, and serous membranes, in a state of health, have a very obscure degree of sensibility, when cut across, pricked with a pointed instrument, or burned by a hot iron. Yet many of these textures, though deficient in sensibility to these stimuli, are yet extremely sensible to injuries of another kind, namely, forcible stretching, when applied suddenly and in a degree which endangers the integrity of their structure. This is sufficiently illustrated by the acute pain attendant on a sprain. Bones, also, though scarcely communicating any feeling of pain when sawn through in the living body, yet feel acutely the concussion produced by violent blows, as any one may be convinced of who has suffered a blow on the knee. It is also remarkable that all those parts, which are apparently so incapable of sensation under ordinary circumstances, become highly sensible when in a state of inflammation.

(600.) The internal parts of most of the glands and other solid organs, have but little sensibility; and the chief source of pain, when they are attacked with inflammation, arises from the affection spreading to the membranes which invest them. Inflammation of the mucous membranes does not occasion any proportionate degree of pain. Those parts of the body which receive no blood-vessels, as the cuticle and its appendages, the nails and the hair, are absolutely insensible. The cuticle consequently is well adapted to protect the highly sensitive organ which it covers, and to blunt its sensibility.

(601.) Pain often arises from internal causes; from pressure, or distension, or other mechanical or chemical irritation applied to nerves; or from some changes taking place in the texture of the nerve itself. It will appear evident, on a general review of the sensibility allotted to the different organs of the body, that each has received from nature that particular kind and degree which is most needed, and which best accords with the relative importance of its functions, and the dangers to which, in the ordinary course of events, it is exposed.

5. *The Muscular Sense.*

Muscular sense.

(602.) A very important class of sensations has been referred to the sense of touch, which require to be particularly distinguished from the rest; they are those attending the contractions of the voluntary muscles, which render us sensible of the movements of our limbs, and of other parts which are voluntarily moved. These are the feelings which give rise to the idea of extension, and which, combined with the feeling of resistance, communicate to us a knowledge of the forms, magnitudes, and relative positions of external objects. Thus, by moving the hand over the surfaces of bodies, we gain the ideas of their tangible extension together with most of their mechanical properties, such as their roughness, hardness, weight, texture, and dimensions. In these examinations we avail ourselves of the admirable properties of the hand, an instrument which, by the number and variety of its parts, and the motions of which they are capable, is exquisitely fitted for procuring us this useful kind of knowledge. By the perceptions we acquire in infancy from the active employment of the limbs in various kinds of progressive motion, our sphere of knowledge of the material world is prodigiously extended; and these perceptions are an important source of gratification, in consequence of the feelings of pleasure with which, by the beneficent ordination of nature, the active exercise of the voluntary muscles is accompanied.

(603.) The sense of touch, in the comprehensive view which we have now taken of it, is unquestionably the most important of all our external senses, bringing us more immediately acquainted with the essential qualities of the material world, and laying the great foundations of all the knowledge which the other senses supply, by a reference to the ideas derived from touch.

Sect. II.—*Taste.*

ste.

(604.) It was the fashion among the French metaphysicians to resolve all the senses into that of touch; so that in speaking of vision, for instance, they would allege that we see by means of the light which touches the retina. But this is a mere refinement not warranted by facts, and in which the real distinctions existing among the sensations themselves are overlooked.

(605.) If any of the senses could be considered as a finer sense of touch, it would be that of taste, by which we receive impressions of a peculiar kind from the sapid qualities of bodies in contact with the upper surface of the tongue. This sense is manifestly intended to guide us in the choice of our food, and it is accordingly placed at the entrance of the alimentary canal.

1. *Organs of Taste.*

ans of e.

(606.) The principal organ of taste is the *tongue*, but several of the neighbouring organs are auxiliaries in the exercise of this sense. The soft parts of the mouth consist of the lips and cheeks, the gums, the soft palate, the velum, uvula, tongue, the membranous lining of the mouth, and the salivary glands. The osseous parts are the upper and lower maxillary bones, the teeth, and the palate bones.

(607.) The *lips* and *cheeks* are principally composed of muscles; they are covered on the outside by the common integuments, and lined within by the membrane of the mouth, in which are situated numerous mucous glands. The membrane of the mouth is covered with fine villi, which are most conspicuous on the edges of the lips. A small doubling of this membrane is met with in the middle of both the upper and under lips, which fixes them more closely to the jaws. They have been termed the *frœna labiorum.* The union of the lips at the corners of the mouth form what has been called the *commissures* of the lips.

(608.) The *gums*, which surround, and firmly adhere to the collar of the teeth, are very vascular, and composed of a dense and compact cellular substance.

(609.) The *palate* is divided into the *palatum durum*, and *palatum molle.* The former is composed of the palate plates of the upper jaw, covered by periosteum, and by the membrane of the mouth, which here forms numerous rugæ. The *soft palate*, or *velum pendulum palati*, is the name of that membranous curtain which hangs from the posterior edge of the ossa palati, and pterygoid processes, and forms a flexible partition between the mouth and throat. It serves to conduct the fluids of the nose downwards, and at the same time acts as a valve in preventing the passage into the nostrils of what is swallowed. In the middle of the edge of the velum, a conical papilla, termed the *uvula*, is met with, and in the relaxed state hangs pendulous over the root of the tongue.

gue.

(610.) The *tongue* is a complex organ, principally consisting of a mass of muscular fibres, irregularly disposed, and crossing each other in a great variety of directions, and being also intermixed with a soft kind of fat. It is invested by a mucous membrane, being a continuation of that which lines the mouth generally, and which here presents large and numerous *papillæ.* These papillæ are distinguished by anatomists into three kinds, according to their size, form, and situation. The first class of these, called *papillæ maximæ, lenticulares*, or *capitatæ*, are by much the largest, have a lenticular form, with round heads and short stems. They are placed at the base of the tongue, in superficial fossulæ. They have been regarded as auxiliary salivary glands, and have each a perforation in the middle of their convex surface for the excretion of mucus. The second class, or *papillæ mediæ*, or *semi-lenticulares*, are much smaller than the former, and are scattered over the upper surface of the tongue, at some distance from each other; their form is cylindric, while some are terminated by a round, but not dilated extremity. Others are more or less tuberculated at the summit. The third class, or *papillæ minimæ*, which have also been termed *conicæ*, or *villosæ*, are exceedingly numerous, but of very minute size. They cover almost the whole of the upper surface of the tongue, but are most abundant towards the tip, where the sense of taste is most acute.

(611.) The membrane covering the root of the tongue abounds with *mucous follicles.* At the root of the tongue, and behind the papillæ maximæ, there is a hole or deep depression, called the *foramen cœcum Morgagni*, which penetrates only a small way into the substance of the tongue, and receives the mouths of several excretory ducts that open into it. A line is also observable running forwards along the middle of the tongue, from the foramen cœcum; this is the *linea linguæ mediana.* The tongue is somewhat restrained in its motions by the *frænum linguæ*, which is formed by a duplicature of membrane at its under part, connecting it with the jaw.

Salivary glands.

(612.) All sapid substances require, in order to produce an impression of taste, to be applied in a state of solution to the nerves of that sense. Nature has accordingly provided a fluid secretion for the purpose of effecting their solution, and diffusing them over a sufficient extent of the surface of the tongue. This secretion, which is the saliva, is prepared by the *salivary glands*, which consist of three large glands on each side of the face, namely, the *parotid*, the *submaxillary*, and the *sublingual.* The parotid is the largest of the three, and occupies the whole space between the ear and the angle of the lower jaw; its excretory duct, called *Steno's salivary duct*, passes off from the upper and fore part of the gland, and perforates the buccinator muscle, so as to open in the inside of the cheeks, opposite to the second or third molar tooth of the upper jaw. The *submaxillary*, or *inferior maxillary* gland, is situated on the inside of the angle of the lower jaw; its duct is called the *ductus Whartonii*, and it terminates by a small orifice on the surface of a papilla on the side of the frænum linguæ. The *sublingual gland* is still smaller, and is under the anterior portion of the tongue above the duct of Wharton, and its ducts open by several orifices arranged in a line near the gums, a little to the outside of the frænum. The smaller salivary glands of the mouth are very numerous, and are named from their situation, *buccales, labiales, palatinæ*, and *linguales.*

2. *Function of Taste.*

Classification of tastes.

(613.) Attempts have often been made, but with no great success, to establish a classification of tastes. The general characters of the tastes denominated acid, sweet, bitter, saline, alkaline, aromatic, astringent, acrid, and spirituous, are sufficiently known, but their combinations are endless; and there exists besides these, a greater number of other tastes, which it would be impossible to reduce to any of the above classes.

(614.) The principle on which sapid bodies act upon the tongue is probably resolvable in all cases into chemical action. It is observed, accordingly, that substances which are in a solid form, and absolutely insoluble in the saliva, are invariably tasteless; just as in chemistry it is an established axiom that bodies do not act chemically unless they are either in a liquid or gaseous state. Mr. Mayo observes, that the sensations of taste are not perfect until the mouth is closed, and the tongue pressed against the palate, by which means the sapid liquid is brought into more exact contact with the surface of the tongue, and perhaps forced into the texture of its mucous membrane.

Seat of the sense.

(615.) The organ of taste appears to be exclusively the upper and papillated surface of the tongue; for although the impressions of this sense are often referred to the palate, inside of the cheeks and gums, accurate discrimination shows that this reference to the parts against which the sapid body is pressed by the tongue, is deceptive, that the real seat of the sense is confined to the tongue itself, and that its immediate organs are the papillæ, and more particularly those denominated *conicæ* or *villosæ*, which are highly vascular and erectile, being observed to rise above the surface of the tongue when any sapid substance is applied to it. On the other hand, no papillæ are discoverable on the palate.

Some substances, such as peppermint, produce a pungent impression on the back of the fauces; and others, again, such as mezereon, excite in the same part a peculiar sense of irritation, which appears to proceed more from a generally acrimonious property, affecting particularly the nervous surfaces, than from any real sapidity; indeed, if the impressions made on the organs of smell be excluded from consideration, it will be found that the extent of the part of the tongue which really receives impressions of taste, is very limited. Mr. Mayo[1] states that salt, aloes, sugar, or acids, which excite the most acute sensation when applied to the tip or edge of the tongue, produce none at the fore or upper part of the organ, or on the hard palate. But at the back of the tongue they again excite sensation enough to be distinguishable, and they are still more perfectly tasted on the middle of the soft palate and uvula. The participation of the soft palate in the sense of taste has been recently pointed out by MM. Guyot and Admyrauld, and has been carefully verified by Mr. Wheatstone and Mr. Mayo. These latter gentlemen did not find that one taste was perceived more distinctly than another, at any point of the tongue or soft palate.

There is no circumstance more remarkable, with relation to this sense, than its intimate connexion with that of smell, of which we are next to speak.

Sect. III.—*Smell.*

Smell.

(616.) The purpose answered by the sense of smell is apparently to guard against the introduction into the lungs of injurious effluvia, as that of taste is to watch over the qualities of the substances introduced into the stomach. Its seat is the Schneiderian membrane lining the cavity of the nostrils; and more particularly the turbinated bones, which are placed so as to catch the odorous effluvia directly as these enter the nostrils, and which, together with the cavities or sinuses in the contiguous bones, contribute to extend considerably the surfaces on which the impression of these effluvia is made.

1. *Organs of Smell.*

Organs of smell.

(617.) The organ of smell may be divided into the *external* and *internal parts*.

The external part, or *nose*, properly so called, consists principally of an upper bony portion commonly called the *bridge of the nose*, composed of the ossa nasi, supported by a vertical process from the æthmoid bone, together with the vomer, and an inferior cartilaginous portion, of which the middle prominence is called the *dorsum;* the rounded portions below are the *alæ nasi*, or wings; and the cartilage forming the partition between the nostrils is termed the *columna nasi.* These cartilages have a degree of elasticity which preserves the form of the organ.

The internal parts are contained in the cavities of the nostrils, which are divided by the *septum narium* into two lateral passages. In the upper part of each nostril, a spongy bone of a lengthened but irregular shape, the *os turbinatum superius*, which belongs to the æthmoid bone. Below this extends the *inferior turbinated bone*, so that the general cavity is divided by these bones into three passages for the air, running from before backwards; they have been respectively named by Haller the *meatus narium superior, medius, and inferior.*

(618.) The extent of the cavities belonging to the nose is much increased by their communicating with various sinuses, or cavities in the neighbouring bones, namely, the *frontal*, *sphenoidal*, and *maxillary sinuses.* Posteriorly the nostrils open into the pharynx, by two orifices, termed the *posterior nares.* All these cavities, together with the sinuses with which they communicate, are lined with a sensible and delicate mucous membrane, termed the *pituitary membrane*, or sometimes, from the anatomist who first accurately described it, the *membrana Schneideriana.* The lower part of the lacrymal sac becoming somewhat narrower, but without forming any valve, passes into the nose, under the name of *lacrymal duct, canalis nasalis*, or *ductus ad nasum.* At the posterior part of the nares is the opening of the Eustachion tube, leading to the tympanic cavity of the ear.

2. *Function of Smell.*

Connex with tas

(619.) The impressions made on the two senses of taste and smell, have not only a great affinity to each other, but also an intimate connexion; inasmuch as many of those referred to the organ of taste are in reality made on the organ of smell, and are not perceived at all if the nostrils be closed, and the odorous effluvia arising from the substance placed on the tongue be consequently prevented from ascending, and acting on the sentient membrane lining their cavity. When the Schneiderian membrane is inflamed, the taste of all those substances, of which the flavour consists in their scent alone, is altogether lost; and as this is the case with by far the greater number of substances employed as food, the sense of taste appears, under these circumstances, to be very imperfect. Both these senses, but particularly that of smell, are possessed by man in a degree very inferior to that in which they exist in the lower animals.

(620.) It is essential to the exercise of this sense, that the membrane of the nostrils should be in a moist state; for when it happens to be dry from a deficiency of secretion, the extremities of the olfactory nerves are unfitted for the reception of the impression of odours. It is also necessary for smelling that the air charged with the odorous effluvia should impinge with some degree of force against the Schneiderian membrane.

The seat of greatest sensibility to odours is the upper part of the nostrils; and the form of the nose and of its apertures are obviously adapted to direct the stream of air towards those parts. It is found, accordingly, that when the nose has been destroyed by disease, the smell is greatly impaired, if not altogether lost.

Classific tion of odours.

(621.) Odours as well as tastes have been attempted to be classed. Linnæus distributed them into seven classes: 1. *ambrosial*, of which the smell of the rose and musk are examples; 2. *fragrant*, as the smell of the lily, of the jasmin, and of saffron; these are more evanescent than the former; 3d. *aromatic*, as the smell of the laurel; 4. *alliaceous*, partaking of the odour of garlic; 5. *fœtid*, exemplified in valerian and mushrooms; 6. *virous*, or narcotic, as in the smell of opium; 7. *nauseous*, as that of the gourd, melon, and cucumber. But this classification is obviously incomplete, as it omits several very distinct classes of odours, such as that of alcohol, of æther, of camphor, of ammonia, of chlorine, &c.

(622.) Any very acrid or stimulating vapour admitted to the nostrils, instead of producing the sensation of smell, gives rise to mere painful irritation, which excites sneezing, and a copious secretion of mucus.

---

[1] *Outlines of Human Physiology.*

Sect. IV.—*Hearing.*

1. *Acoustic Principles.*

aring.

(623.) The object of the sense of hearing is to convey to us certain impressions made on the nerves of the ear by the vibrations of the air; which vibrations are the result of some mechanical impulse communicated to it by the motion of a body at a distance. Other media besides air are also capable of transmitting sonorous vibrations to the organ of hearing; thus water is known to convey sounds to great distances; and solid bodies possess the same power in a degree proportioned to their molecular elasticity. If the body which is the source of sound be insulated from any such medium, its vibrations cannot be communicated, and no sound is heard. Thus if a bell be placed in the receiver of an air-pump, in proportion as the air is exhausted the sound it produces when struck becomes more and more faint, till at length, when the rarefaction has been carried a certain length, it is quite inaudible. If the same bell be placed in a vessel of condensed air, the sound it gives out will be louder than in air of the ordinary density.

(624.) The velocity with which sound is transmitted in air of the same density is uniform at all distances, and for all sounds whatsoever. As the air of the atmosphere varies in its density, and also in its degrees of humidity, the velocity of sound is not constantly the same. It may be taken at an average as being 1100 feet in a second, or nearly thirteen miles in a minute.

2. *Organ of Hearing.*

ructure
the ear.

(625.) The organ of hearing is divided into the *external* and the *internal ear.*

(626.) The *external ear*, comprehends the *auricula*, or ear, properly so called, and the *meatus auditorius externus.*

ricula.

(627.) The auricula is chiefly composed of an *elastic cartilage* bent into various folds and hollows, and covered with a thin layer of common integuments, the lower fold of which, enlarged by the addition of cellular substance, forms the depending part called the *lobe of the ear.* The cartilaginous portion is termed the *pinna*, or *ala.* Its outer circle, or prominent margin, is called, from its winding direction, the *helix.* The semicircular ridge within this is the *antihelix;* and the small protuberance, in which the helix appears to terminate below at its inner edge, is called the *tragus,* from its being frequently covered with hair. Another eminence, nearly opposite to this, below the anterior extremity of the antihelix, and projecting outwards over the hollow of the ear, is called the *antitragus.* Between the helix and antihelix, is the cavity called the *scaphus*, or *fossa navicularis.*

atus
itorius.

(628.) The *concha* is a large depression under the antihelix, and divided into two parts by the helix. The lower of these leads to the *meatus auditorius*, a passage which at its commencement is composed of cartilage, and farther on is joined to the orifice of the same name in the temporal bone. The cartilaginous tube is lined by a soft membrane, giving rise to hairs, and containing small glands, the *glandulæ ceruminosæ*, which secrete the wax of the ear. This cartilaginous portion of the ear is attached to the temporal bone by several ligaments and muscles; the effects of which in moving the different parts of the external ear are in general very little sensible.

(629.) The membrane lining the meatus is continued along the osseous portion of the canal, which is closed by the *drum* of the ear, or *membrana tympani.* This is a firm, oval, and almost transparent membrane, fixed in an osseous groove at the bottom of the meatus, across which it lies in an oblique position. It is slightly concave on the external side; and is capable of being stretched or relaxed by the action of particular muscles.

Tympanic
cavity.

(630.) The membrane of the tympanum divides the external from the internal ear. Behind it we find an irregular cavity, called the *tympanic cavity*, or *cavity of the tympanum*, which is filled with air; it is about seven or eight lines wide, and about half that space in breadth; and is every where lined by a fine membrane. It has four openings; the first is the small orifice of a passage of communication with the back of the cavity of the nostrils, which is called the *Eustachian tube*, and is shaped like a trumpet, expanding as it approaches the fauces. The second aperture leads to a number of irregular cells, formed in the mastoid process of the temporal bone, and called the *mastoid cells.* At the back part of the tympanum we find an oval opening, called the *fenestra ovalis*, and below this a round perforation, termed the *fenestra rotunda.* Between these fenestræ, is a bony eminence, called the *promontory.*

Ossicula.

(631.) Within the cavity of the tympanum are contained four small bones, the *ossicula auditus*, placed in a series or chain extending across from the membrana tympani to the fenestra ovalis. The *malleus*, or hammer, is the first of these bones; a long pointed process from which, namely, the *processus brevis*, or handle, is fixed to the membrana tympani. It is articulated by its round head with the next bone, the *incus*, or anvil, which much resembles in its shape a molar tooth, having a body and two unequal crura. With the longest of these processes is articulated the *os orbicularis*, of a rounded figure, and smaller than a grain of mustard seed. It forms the medium of connexion between the incus and the *stapes*, which is the last bone in the series, and is so named from its striking resemblance in form to a stirrup. The base of the stapes is fixed to the margin of the fenestra ovalis, which it accurately closes. The articulations of these minute bones are furnished with capsular ligaments, and all the apparatus of the larger joints; appropriate muscles being also provided for their movements. Between the malleus and the incus, there passes a small nervous cord, which crosses the tympanum, and is accordingly named the *chorda tympani.*

Labyrinth.

(632.) The principal cavity of the organ of hearing is situated still more internally, and from the intricacy of its winding sinuosities it has received the general name of *the labyrinth.* All its cavities and passages are lined with a very delicate periosteum, and filled with a watery fluid, and within them is suspended a pulpy membrane of a similar shape, on which are distributed various nervous filaments presently to be described. This saccular-shaped membrane is termed by Breschet the *membranous labyrinth*, in order to distinguish it from the osseous labyrinth, in which it is contained. It forms one continuous closed sac extending within the vestibule and canals, excepting those of the cochlea; and contains a fluid, perfectly similar to the perilymph, and termed by Blainville, *vitrine auditive*, which, intervening between it and the osseous parietes of the labyrinth, surrounds it on all sides, and prevents its coming in contact with those bones.

The central cavity, in which all these passages meet, is termed the *vestibule;* it is of an oval figure, and is situated nearly in the centre of the os petrosum, and at the inner side of the fenestra ovalis. On the side of the vestibule next to the mastoid process, there are five orifices leading to the three *semicircular canals*, as they are called, or passages formed within the substance of the bone. The extremities of two of these canals unite, and terminate by a common opening; hence there appear in the vestibule only five openings, instead of six. These canals are distinguished by the names of the *superior*, or vertical, the *posterior*, or oblique, and the *exterior*, or horizontal. They each form a curvature of more than three-fourths of a circle, and have an enlargement, termed *ampulla*, or *cavitas elliptica*, at one end, the other extremity being nearly of the same size as the rest of the canal.

(633.) The *cochlea*, which is the third division of the labyrinth, has a conical shape, and is situated at the anterior part of the os petrosum, and at the fore-part of the vestibule, with its base towards the meatus auditorius internus, and its apex in the opposite direction; that is, facing outwards. It contains a double spiral passage, winding round like the shell of a snail. This passage begins by a round hole from the vestibule, and after forming two turns and a half, becomes suddenly smaller on arriving at the apex, where it communicates with a similar tube which takes its rise at the base of the cochlea from the fenestra rotunda, formerly noticed as one of the apertures of the cavity of the tympanum; but which is closed by a membrane. The partition which divides these two winding passages is called the *lamina spiralis*, or *septum scalæ;* for the passages themselves are known by the name of the *scalæ cochleæ;* that which communicates with the vestibule being distinguished as the *scala vestibuli*, and the other, from its connexion with the tympanum, the *scala tympani*. The central bony pillar, around which these turns are made has a horizontal direction, and is called the *modiolus*. It has the shape of a cone, at the apex of which is situated another hollow cone in a reverse position termed the *infundibulum*, which, however, is an imperfect funnel, having a common apex with the modiolus, and its base being covered by the apex of the cochlea, which is called the *cupola*.

(634.) It has been supposed that when the fluid in these cavities is in too great a quantity, the superfluous portion is carried off by two minute canals or *aqueducts*, discovered by *Cotunnius*, and bearing his name. One of these opens into the bottom of the vestibule, and the other into the cochlea, near the fenestra rotunda. They bear the names respectively of *aquæductus vestibuli* and *aquæductus cochleæ*. They both pass through the os petrosum, and communicate with the cavity of the cranium.

The form of that part of the membranous labyrinth which occupies the cavity of the vestibule, and which has accordingly received the name of the *membranous vestibule*, though having a general resemblance to that of the cavity itself, yet differs from it in some degree, being composed of two sacs opening into each other. One of these sacs is termed the *utricle;* and the other the *sacculus*. Each sac contains in its interior a small mass of white calcareous matter resembling powdered chalk, and which seems to be suspended in the fluid contents of the sac by means of a number of nervous filaments, derived from the acoustic nerves, and of which they appear to be the ultimate ramifications.[1]

(635.) Through an opening at the base of the modiolus, a branch of the auditory nerve, which has entered by the meatus auditorius internus, passes into the funnel-shaped cavity, and is thence extended through the spiral canals; while another branch passes backwards through the vestibule, and dividing into several branches, enters the orifices of the semicircular canals. The minute branches perforate a part of the bone, which has been termed from its appearance, the *cribriform plate*.

3. *Function of Hearing.*

Functions of the several parts of the ear.

(636.) We thus see that the ear is an organ extremely complicated in its structure, evidently intended to convey the sonorous undulations of the air, after they are collected by the more external parts of the organ, to the branches of the auditory nerve, which are spread over the membranes lining the different cavities of the labyrinth, and the cretaceous bodies suspended within those membranes. We may therefore distinguish the several parts of the apparatus employed for this purpose, according as they are merely designed to collect the aerial undulations, and increase their intensity by concentrating them into a smaller space; or according as they contain the expanded nerves on which the impression is ultimately made. It appears that the medium by which this last effect is produced, is the perilymph, or fluid filling the cavities of the labyrinth, and containing the exquisitely delicate membrane and cretaceous bodies on which the extreme fibrils of the auditory nerve are expanded. This fluid is put in motion by the air in the cavity of the tympanum, and thrown into corresponding undulations.

(637.) The accessory parts of the organ of hearing may therefore be divided into three parts. There is, first, the external ear, which is an elastic cartilaginous appendage to the organ, curiously grooved, so as to form a series of parabolic curves, adapted to receive the undulations of the air, and convey them into the passage of the meatus externus, serving apparently an office similar to that of the expanded part of a trumpet. The sonorous undulations are thus made to strike against the membrane of the tympanum, or ear-drum, which is stretched across, and closes the passage. The cavity behind this membrane is filled with air, which is next thrown into undulations by the medium of the ear-drum, the vibrations of which have been excited by those of the external air. In order to preserve an equilibrium between the air in the cavity of the tympanum and the external air, so that the membrane may not sustain a greater pressure on one side than on the other, a communication is kept open with the back part of the throat by means of the *Eustachian tube*. Hearing is always much impaired, if from any cause the Eustachian tube is obstructed, as it sometimes is by a common cold, which then produces a temporary deafness.

(638.) The cavity of the tympanum is of a very singular form, extending into the mastoid process of the temporal bone, which has a cellular structure. A chain of minute bones, the ossicula auditus, extends, as we have seen, across the cavity, terminating at the fenestra ovalis, or aperture leading to the vestibule; while another aperture, the fenestra rotunda, also closed by membrane, leads to one of the spiral turns of the cochlea. Thus, the fluid in the labyrinth receives from the impulses made on these two membranes, which are situated in two different planes, a double undulation; and these two undulations, the one circulating along the semicircular canals, the other through the spiral turns of the cochlea, probably unite at some focal spot, like the meeting of two tidal waves, and increase the effect produced. These undulations must of course be variously modified, according to their frequency, and the order of their succession, and the impressions made on the nerve must undergo corresponding modifications. But we are so completely in the dark as to the real office of the several parts of this elaborately constructed organ, that it is exceedingly difficult to prosecute the physiology of this sense with such imperfect data. We are unable even to form a rational conjecture as to the offices of the delicate muscles provided for directing the movements of those ossicula, which are articulated with such great nicety, and which seem calculated to alter the tension of the membrana tympani, and bring it into a state capable of vibrating in unison with the sonorous undulations that impinge upon it. What adds in no small degree to our embarrassment, is the knowledge we have acquired of the power of hearing being retained, without apparent diminution, when the greater part of this apparatus of bones, with their joints and muscles, and even the ear-drum itself, has been destroyed by accident or disease.[2] It should be observed, however, as Mr. Mayo[3] remarks, that the stapes is so strictly applied to the membrane of the fenestra ovalis, that the loss of this bone necessarily produces incurable deafness, by the attendant injury of the labyrinth.

---

[1] The most accurate and complete description of the anatomy of the ear, is that given by Breschet, *Sur les Organes de l'Ouie*, which first appeared in the *Annales des Sciences Naturelles*, xxix. 129. A compendious account is contained in *Dr. Roget's Bridgewater Treatise*, ii. 420.

[2] See two papers by Sir Astley Cooper, in the *Philosophical Transactions* for 1800, p. 151; and for 1801, p. 437.

[3] *Outlines of Human Physiology*, 3d edition, p. 221, note.

(639.) Sir Everard Home imagined that the muscular structure of the membrana tympani, enabling it to contract or relax according to circumstances, so as to vibrate in unison with the musical notes which reached the ear, conferred the power of distinguishing musical tones. But this ingenious hypothesis is completely overturned by the fact above stated, of the integrity of the membrane of the tympanum not being necessary for the perfect accuracy of the sense of hearing, even with relation to the distinction of musical sounds. Dr. Young thinks it probable that the semicircular canals which are disposed in a remarkable manner in three orthogonal planes, corresponding to the three dimensions of space, enable us to estimate the acuteness or pitch of a sound; and that the cochlea serves the office of a micrometer of sound.[1] But the grounds of these opinions are too vague and conjectural to inspire us with any confidence in their solidity. When the external passages are totally obstructed, sonorous vibrations may still be transmitted to the auditory nerves by means of the bones of the head. Thus, the sound of a tuning fork applied to the teeth, or even to other parts of the head, is perfectly audible under these circumstances. We thus possess a criterion for determining, in cases of deafness, whether the disease consists in the insensibility of the nerves to these impressions, or is seated in the passages leading to the labyrinth.

SECT. V.—*Vision.*

ision.

(640.) The physiology of the eye is more interesting than that of any of the other organs of the senses; because, from the knowledge we possess of the laws of optics, to which it is so admirably adapted, we can understand the offices of its several parts, and the mode in which they concur in the production of the resulting effect. The study of the eye has been said to be the best cure for atheism; and it furnishes, indeed, the most striking and unequivocal proofs of the existence of design and intelligence in the construction of the animal fabric. These proofs have accordingly been always among those most prominently adduced by philosophers in support of the arguments of natural theology.

(641.) The organs subservient to vision are lodged securely in the bony cavities of the orbits, where the surrounding bones protect them on every side, excepting in front. They may be divided into the internal and the external parts; the former consisting of the spherical bodies denominated the *globes of the eye*, or *eye-balls;* and the latter comprising parts which give motion to the globe, and otherwise assist it in its functions.

1. *Internal parts of the Eye.*

e-ball.

(642.) The eye-ball is composed of segments of two unequal spheres; one of which, constituting about four-fifths of the whole, forms the portion which is within the orbit; while the other fifth is that part which is seen in front, and which, being a portion of a smaller sphere, is more protuberant. The diameter of the eye-ball, from behind forwards, is accordingly longer than its transverse diameter; the proportion being that of twenty-five to twenty-three.

(643.) The eye-ball is made up of coats and humors. The former consist of the *sclerotica*, *cornea*, *choroides*, and *retina*, together with the *conjunctiva*. Of the latter there are three, viz. the *vitreous*, *crystalline*, and *aqueous humors*.

ats.

(644.) The *sclerotica*, which is the exterior coat, is, from its compact fibrous texture, the densest and strongest, as well as the thickest of the tunics of the eye, and the one from which the other parts of the eye-ball derive their principal support. It covers all that portion of the globe of the eye, which has already been pointed out as constituting its largest segment. At its anterior edge it is joined to the more convex tunic, which completes the figure, and is named the *cornea*, from its being composed of a great number of concentric laminæ, of a horny elastic texture. Some authors have given it the name of the *cornea lucida*, from its perfect transparency, and by way of contrast to the sclerotica, which they had named the *cornea opaca*.

(645.) The *choroid coat*, or *tunica choroides*, lies immediately within the sclerotica, and is composed of a congeries of blood-vessels connected together by membrane. It has been distinguished into two layers, the innermost of which has been termed the *tunica Ruyschiana*. At the middle of the choroid coat are observed numerous vessels convoluted into a spiral form. These have been termed the *venæ vorticosæ*. The internal surface of the tunica Ruyschiana, or *tapetum*, as it has been called, seems, from its villous or fleecy appearance, to be a secreting surface. It is everywhere lined with a black or deep-brown mucous substance, included in a fine cellular tissue. This is the *pigmentum nigrum*, which forms a layer, separating the choroides from the next coat, or *retina*. This latter tunic is an expansion of the pulpy substance of the optic nerve, spread over a fine membrane. The optic nerve, from which this medullary matter is derived, enters the eye at its back part, at a point nearer to the nose than the centre, or axis of the eye, and perforates the sclerotic and choroid coats.

(646.) From the inner margin of the junction of the cornea and sclerotica, there extends across the fore part of the globe of the eye a membranous partition, called, from the variety of its colour, the *iris;* it is perforated in the centre by an aperture, called the *pupil*, because, as it is said, it represents objects no larger than a pupilla, or puppet. The structure of the iris is exceedingly peculiar; it appears to be made up of a number of fibres, which pass from the inner to the outer margin in a radiated direction, together with others which run circularly. These fibres have been presumed to be of a muscular structure; but doubts are still entertained with regard to this point. The posterior surface of the iris is lined with a pigment similar to that which is found within the choroid coat. It has been called the *uvea*, from its fancied resemblance in colour to the grape.

(647.) The iris is connected with the choroid coat by an intermediate structure, called the *ciliary ligament*, *ciliary circle*, or *orbiculus ciliaris*, which is a circular belt, more than a line in breadth, made up of a soft and pulpy tissue, and of a whitish colour. It is also at this part that the choroides adheres firmly to the sclerotica. From this part, also, there extends inwards a dark coloured ring, which is a continuation of the choroides, and is termed the *corpus ciliare*. It is about the sixth part of an inch in breadth towards the temple, but somewhat narrower towards the nose. It is covered in every part by the pigmentum nigrum. It is marked by radiated striæ at its inner part, but they are somewhat obscured by the pigmentum nigrum. At the outer part these striæ become gradually broader and more elevated, and appear like folds, only the intervals between them being covered with the pigment. These folds are termed the *ciliary processes*. Each of these processes is of an irregular triangular figure, with the base outwards, or at the ciliary circle, and its apex inwards, or towards the axis of the eye. Their number is generally about sixty, and they are alternately longer and shorter.

Humors.

(648.) About three-fourths of the globe of the eye, within these several tunics, is filled by a very transparent and gelatinous humor, which, from its supposed resemblance to melted glass, has been termed the *vitreous humor*. It is nearly of the consistence of the white of an egg, and consists of a fluid substance contained in the cells of a very fine and delicate cellular tissue, called the hyaloid membrane. It is invested by a transparent membrane, termed the *tunica vitrea*, or *capsule* of the vitreous humor. The anterior surface of the vitreous humour is depressed, for the lodgment of the *crystalline lens*, or *humor*, which is a dense body, perfectly transparent, and has the shape of a double convex lens, of which the posterior surface has a greater convexity than the anterior surface. The lens is composed of a great number of concentric laminæ, which become more and more dense towards the centre, and each lamina is made up of very distinct parallel fibres. It is enclosed in its own peculiar *capsule*, in which it appears to float loosely, a watery fluid, called the *liquor Morgagni*, being interposed.

---

[1] *Medical Literature*, p. 98; and *Lectures*, vol. i. p. 387.

(649.) The fore part of the eye-ball, between the crystalline lens and the cornea, is filled by a watery fluid, called the *aqueous humor*, in the middle of which the iris is suspended, thus dividing the space into what are called the *anterior* and *posterior chambers* of the aqueous humor. The aqueous humor, like the other humors, is contained within a delicate membrane, which lines the inside of the cornea, and passes over the crystalline lens and the convex margin of the vitreous humor.

(650.) The capsule of the lens adheres closely to the tunica vitrea. Behind the edge of the former, and between the margin of the ciliary zone and capsule of the vitreous humor, a triangular passage is formed, called from its discoverer, the *circle of Petit*, or *canalis Petitianus*. When air is blown into this passage, it passes freely round the edge of the lens.

(651.) At that part of the retina which is situated in the axis of the eye, there is a small circle, where the retina is transparent, giving rise to the appearance of a hole, as if the retina were deficient in that part. It was discovered by Soemmerring, and bears the name of the *foramen centrale of Soemmerring*. It is surrounded by a yellow circle, about a line in diameter. The fibres of the optic nerve, in passing to form the retina, perforate a thin plate of membrane which is extended from the sclerotica, and which is termed the *lamina cribrosa*. The centre of the optic nerve is perforated by the *arteria centralis retinæ*, forming an aperture which has been called the *porus opticus*.

2. *External parts of the Eye.*

Appendages to the eye-ball.

(652.) The orbit is a conical cavity, in the fore part of which the globe of the eye is situated, the remaining space behind the globe being chiefly filled with fat, which surrounds the optic nerve, and intervenes between it and the straight muscles that extend between the margin of the foramen opticum, through which the optic nerve passes out of the skull and the fore part of the sclerotic coat, where they are inserted by broad and flat tendons. These tendinous expansions have been improperly considered as composing one of the tunics of the eye, which being of a white colour, has received the name of *tunica albuginea*.

(653.) The globe of the eye is covered at the fore part by two eye-lids, or *palpebræ*, which are composed of muscular fibres, covered by the common integuments, supported at their edge by a cartilage called the *tarsus*, and furnished with a row of hairs, termed *cilia*, or eye-lashes. At the roots of the eye-lashes are sebaceous follicles, named from the anatomist who first observed them, the *glandulæ Meibomii*, and which secrete a glutinous liniment. The eye-lids are lined on their interior surface by a very fine and smooth serous membrane, which is reflected over the anterior part of the globe of the eye, and even over the surface of the cornea. This membrane is called the *tunica conjunctiva*.

Lacrymal apparatus.

(654.) Between the ball of the eye and the upper vault of the orbit, on the temporal side, lies the *lacrymal gland*, which secretes the tears. It is composed of a number of small, whitish, granular bodies, which are collected together into two lobes. There is also a chain of smaller glands lying between the principal gland and upper eye-lid, and connecting them together. The excretory ducts from all these glands are exceedingly minute, and terminate in the inner surface of the upper eye-lid, near the outer angle of the eye. After moistening the surface of the eye, the tears are again collected by two small orifices, called the *puncta lacrymalia*, placed on a small eminence in each eye-lid, near the inner angle of the eye, at the extremity of the tarsus. They are the beginnings of two small canals that run in the direction of the edges of the eye-lids, towards the side of the nose, where they approach each other, and terminate together in the *lacrymal sac*, which is a membranous bag situated on the os unguis, and leading to a passage into the cavity of the nostrils. The puncta are kept separate by the interposition of a small reddish body, called the *caruncula lacrymalis*, situated between the inner angle of the eye-lids and the ball of the eye. Minute hairs are found upon the surface of this body, which serve to entangle small objects which might otherwise get into the eye. There is also a reduplication of the tunica conjunctiva, shaped like a crescent, and hence termed the *valvula semilunaris*, the points of which are directed towards the puncta, and which assists the caruncle in directing the tears to the puncta.

Having thus described the apparatus for vision, we shall now proceed to consider the mode in which that function is performed.

3. *Optical Principles.*

Laws of light.

(655.) The object of this sense is to convey to us a knowledge of the existence and visible qualities of distant objects, by means of the light which they send to the eye. This is accomplished by altering the natural direct course of these rays, so that they may form a distinct image of these objects on the retina. That such images are actually formed on the retina may be easily shewn in the eye of an animal recently killed, by carefully removing the opaque sclerotic and choroid coats, together with the black pigment from the back of the eye, so as to expose the retina. The objects on the other side, in front of the cornea, will then be seen beautifully depicted on the retina, their images being inverted; precisely in the same way, and on the same principles as they are seen in a simple camera obscura.

(656.) In order to understand and trace the operation of the principles concerned in these phenomena, it will be necessary to refer to the laws of optics.

Refracti

The rays of light in traversing any medium of uniform density, move always in straight lines; but when the density changes they deviate somewhat from this rectilinear course, according to the direction of the ray with respect to the planes in which the change of density occurs. Thus a ray from the sun, or other celestial body, traversing obliquely through our atmosphere, the different strata of which are of increasing density as they come nearer to the earth, is gradually bent in its course, and arrives at the surface of the earth in a direction somewhat nearer to a perpendicular line than if there had been no atmosphere. This deflexion from a straight line is termed *refraction*. Refraction takes place suddenly, if the ray passes abruptly from one medium to another, which sensibly differs from it in its density; the direction of the deflexion being always towards the denser medium; or, to speak more accurately, towards a line drawn perpendicular to the surface common to the two media, and situated in the denser medium.

Reflexio

(657.) In the case of the passage of a ray through the surface of a new medium of very different density from the first, another phenomenon takes place; the ray is decomposed, part being transmitted and refracted, while another portion is turned completely back into the medium it was already traversing. This is termed *reflexion*. Objects which are not luminous in their own nature are rendered visible only by the reflexion from their surfaces of the light which they receive from other bodies. The law in this case is, that the angle of reflexion, by which is meant the angle which the course of the reflected ray makes with a line perpendicular to the surface, is equal to the angle of incidence, or the angle which the incident ray makes with that same perpendicular; and also, that it is in the same plane with the incident ray, and the perpendicular line.

(658.) The law of refraction is, that the course of the refracted ray is deflected towards that part of the perpendicular which is situated in the denser medium, and that the sine of the angle of refraction, (or the angle it makes with the perpendicular) has to the sine of the angle of incidence the same constant ratio. This ratio increases in proportion to the difference there is between the two media in respect of density.

4. *Formation of Images in the Eye.*

rmation
images.

(659.) It follows as a consequence of the above laws, that a pencil of rays proceeding through the air, and falling on the convex spherical surface of a medium of greater density than the air, (as is the case with the cornea of the eye,) is so refracted as to be collected, after proceeding a certain distance, into one and the same point. This will readily appear when we consider that those rays fall with more obliquity on the cornea, according as they are more distant from the central ray of the pencil, or that which may be conceived to fall perpendicularly on its surface. These more oblique rays are consequently more refracted; that is, more bent from their original course; and this law being observed throughout the whole pencil, all the rays will tend after refraction to the same point, which point is called the *focus* of that pencil of rays.

(660.) The same process taking place with regard to all the other pencils of rays proceeding respectively from the several points of the objects viewed, and each being collected into separate points in different parts of the retina which receives them, images of those objects will be delineated on that membrane; for it is evident that all the focal points will have, with respect to one another, the same relative positions as the points of the external objects from which each pencil of rays proceeds, when referred to the sphere of vision. The impression thus made on each respective point of the retina, is transmitted to the sensorium, where it makes a distinct impression, and gives rise to the sensation of light and colour; and in conjunction with the experience gradually gathered from the sense of touch, imparts to us a knowledge of the existence, relative situation, form, magnitude, distance, and colour of the objects before us. This, then, is vision.

ust-
ts.

(661.) Such is the general outline of the mode in which vision is accomplished; but there are a thousand beautiful contrivances and adjustments provided for ensuring the accuracy with which this picture of the surrounding scene is portrayed on the retina. The perfection of vision is entirely dependent on the distinctness, the vividness, and the fidelity of this picture; and the whole apparatus of the eye is calculated to obtain these qualities.

(662.) The purposes served by the apparatus external to the globe of the eye, are sufficiently obvious. The effectual protection given to the eye by the arched form of the bones which compose the orbit,—the provision of a soft cushion in the fat which occupies the bottom of the cavity,—the beautiful contrivance of the eye-lids, which, on the least appearance of danger, are ever ready to close upon the organs they are appointed to guard,—and even the direction of the eyebrows, intended to divert the course of the perspiration from the forehead, are all calculated to call forth our admiration, because the end to be answered being obvious, we can judge of the fitness of the means for the accomplishment of those ends. A still further proof of exquisite design offers itself in the lacrymal apparatus, which provides the means of preserving the surface of the cornea always clean and transparent, and fitted for its office of regularly refracting the rays of light.

Function
of the iris.

(663.) The humors of the eye, through which the light passes before arriving at the retina, have different degrees of density, and consequently have different degrees of refractive power. The first and greatest refraction of the rays takes place at the outer surface of the cornea; the next is at the inner surface, where the rays meet with the aqueous humor. Now this humor is rather less dense than the cornea, and consequently the rays already refracted, and rendered convergent by the cornea, have their convergence slightly diminished, when they traverse the aqueous humor. These, in fact, are converging towards points at some distance beyond the retina. The iris is interposed in the course of the rays while they are passing through the aqueous humor; the circular aperture of this membrane, the pupil, admitting only the more central portion of each pencil of rays. By intercepting the extreme rays, which, in consequence of a peculiarity in the law of spherical refraction, hereafter to be explained, would, if allowed to reach the retina, somewhat confuse the image, greater clearness of that image is obtained, at the sacrifice, indeed, of a portion of brightness. It serves, accordingly, the same purpose with regard to the eye, which the circular ring, placed in the interior of a telescope, effects in contracting the aperture of the instrument; rendering the image more distinct, though less illuminated than it would otherwise be. But the iris has this great superiority over the circle in the telescope, inasmuch as it is capable by its contractile power of enlarging or diminishing the aperture of the pupil, as occasion requires. Thus, when the object viewed is but faintly illuminated, the pupil is enlarged, and admits more light, thus giving greater brightness to the picture; an advantage which more than compensates for the slight indistinctness of the fainter images composing that picture. When, on the contrary, an object is too bright, so that its image would produce too vivid an impression on the retina, the pupil immediately contracts, so as to reduce the quantity of light admitted into the interior of the eye, and to prevent any injurious effect upon the retina.

5. *Adjustments for the Correction of Aberration.*

Aberration
of sphericity.

(664.) That part of the converging pencil of rays, which is admitted through the pupil, falls upon the anterior convex surface of the crystalline lens, which being denser than the aqueous humor, occasions a new refraction of the rays, and gives them an increased degree of convergence, so that they now tend to foci nearer to the retina than before, though still somewhat beyond it.

(665.) An exquisite provision is found in the peculiar structure of the lens for correcting what is termed the *spherical aberration.* It is a necessary consequence of the mathematical law of refraction, that in a pencil of rays falling on the convex spherical surface of a denser medium, those rays which are farthest from the central ray, will be bent somewhat more than is requisite to bring them to the same focal point as the rays which are nearer to the centre of the pencil; hence all the rays can never be collected accurately into the same point; although in ordinary optical instruments, such as common telescopes, and camera obscura, the aberration thus resulting is confined within such narrow limits as not to produce any very great inconvenience. But in the eye even this minute defect of ordinary optical instruments is remedied. The lens is composed of successive laminæ, increasing in their density and refractive power, in proportion as they approach the centre; that central part being the hardest and densest of the whole. The central rays of each pencil, therefore, are subjected to a greater refractive action than the more exterior rays, and the whole are brought accurately to convergence at the same focal point.

(666.) After passing through the crystalline lens, the rays enter the vitreous humor, where, again, there is a change of density in the medium. The density of the vitreous humor is less than that of the lens; and were its surface convex, the convergence of the rays would be diminished by the refraction they would then experience; but the surface being concave, the refraction contributes still farther to increase the convergence of the rays, which now traverse the aqueous humor, and are collected accuratcly into their respective foci on the retina itself.

Aberration of parallax.

(667.) Rays proceeding from objects at different distances from the eye, will arrive at the cornea with different degrees of divergence, and the same refractive powers of the humors would cause them to converge at different distances; in order, therefore, to obtain distinct images of these objects on the retina, either the distance of that membrane from the cornea must be altered, or the refractive power of the humors must be changed. Thus, if the power of the eye at any one time be suited to distinct vision of distant objects, near objects will appear confused, from the indistinctness of their images on the retina; because the focus of convergence of the rays proceeding from those objects is farther back than the situation of the retina. If, either by elongating the axis of the eyc, the retina could be removed to this new focal distance, or else by increasing the refractive power of the humors, the rays could be made more convergent than before, we should again obtain distinct images of those near objects on the retina; but then the images of distant objects would, at the same time, and from the contrary cause, be indistinct; and in order to give distinctness to these, the contrary changes are required to be made in the eye to those already mentioned. Now, it is found that the eye really possesses the power of accommodation here described, adapting itself, by some internal changes, to the vision of both near and remote objects, according as the attention is directed respectively either to the one or to the other.

(668.) The effort by which the eye changes its intcrnal state, so as to accommodate its powers to the vision of near objects, after having viewed those more distant, is always attended with a contraction of the pupil; and the exclusion of the remoter rays, consequent upon this diminution of aperture, must partly contribute to the greater distinctness of the images, by excluding the rays near the circumference of each pencil. But it is certain that the refractive powers of the eye are also increased; and it is a question of considerable difficulty to determine the manner in which this increase is effected. Sir Everard Home[1] supposed that it was accomplished by the joint actions of the straight muscles which surround the ball of the eye, and which, by compressing it all round its sides, might elongate its axis and increase the distance of the retina from the cornea, while they at the same time would make the cornea more convex, by drawing back its circumference, and thus rendering its central part more protuberant. This plausible theory is overturned by the fact discovered by Dr. Young,[2] that when the effect of any change in the curvature of the cornea is removed by placing the eye under water, the eye still retains its power of accommodation to the vision of objects at different distances, by changes which take place in its refractive powers.

(669.) The most probable supposition relative to this operation is, that the ciliary ligament has the power of contracting at the same time with the sphincter of the iris; a change which will be attended with the effect of bringing the lens somewhat forwards, and of increasing the convexity of its surfaces, while the convexity of the cornea will also be increased. Any cause which produces the contraction of the pupil, such as a bright light, enables the eye to adjust itself more rapidly to vision at a shorter distance; and on the contrary, the suspension of this power of contraction of the circular fibres of the iris, occasioned by belladonna, is accompanied by the total but temporary loss of this power of adjustment. Those who, by frequent practice in experimenting on their own eyes, have acquired a considerable voluntary power of changing the refracting condition of the eye, even although there be no object before the field of vision requiring such change, when they exert this power, also contract the pupil, which by this means indirectly acquires the character of a voluntary muscle; although in other respects, and with other persons, it is strictly to be ranked in the class of the involuntary muscles. The writer of this treatise possesses this power, and has given an account of the circumstances attending its exertion in a letter to Mr. Travers.[3]

Chrom aberrat

(670.) The same gradation of density in the successive laminæ of the crystalline lens, and the consequent successive refractions of the rays effected by the several humors of the eye, have also the effect of correcting the dispersion of light, arising from the difference in refrangibility of the differently coloured rays. The eye, in addition to its other perfections, has the properties of an achromatic optical instrument, correcting the confusion of colour in the images it forms on the retina.

(671.) All extraneous light, which might be reflected from one part of the eye to another, and might be mixed with the rays which should exclusively form the image on the retina, is absorbed by means of the *pigmentum nigrum*, which is placed immediately behind the retina, which lines every part of the interior of the eye, and which extends over the ciliary circle, and over the posterior surface of the iris.

(672.) Different parts of the retina possess different degrees of sensibility; the centre, or that situated in the axis of the eye as it is called, immediately oppositc to the pupil, being by far the most sensible part. We accordingly see most distinctly those objects, the images of which are formed on that spot. Hence, whenever we pay attention to an object, we immediately direct both eyes towards it in such a manner as that the centre of both retinæ may receivc its image. It is very remarkable that there is a minute circular space situated exactly in the axis of the eye, where the retina seems to be deficient, so as to produce the appearance of a perforation at the very point where vision is most distinct. No satisfactory explanation of this curious circumstance has yet been given.

(673.) When the eye is at rest, the field of distinct vision is very limited; it extends, however, according to Dr. Young, to a space formed by a radius of about 60 or 70 degrees; it extends to a greater distance outwards than inwards, being 90 degrees in the former direction, and only 60 degrees in the latter. It extends downwards 70 degrees, and only 50 degrees upwards.

Insensi spot in retina.

(674.) Mariottc[4] of the French Academy of Sciences, made the curious discovery that there is a part of the retina situated at the termination of thc optic nerve which is insensible to light; so that when the image of any object falls upon that precise spot, it is no longer seen. The conclusion which he drew from this fact was, that the scat of vision is not the retina, but the choroid coat; for at this spot the choroid coat is wanting, being perforated to admit of the passage of the optic nerve. But the phenomena is better accounted for by the consideration that there is present at that spot the central artery of the retina, which here divides itself into a number of radiating branches, and excludes the presence of nervous matter, in which, judging from the analogy of all the other senses, the power of communicating sensation exclusively resides. This defect in vision, if we may so term it, is seldom perceived when both eyes are used, because the optic nerve enters each eye obliquely, and on different sides of the centre of the retina; so that they can never both receive the image of the same object at the same time.

yopia and esbyopia.

(675.) The defects of the eyes of some persons with respect to their refractive powers produce what is called *long-sightedness*, when these powers are deficient; and *short-sightedness*, when too great. The source of former imperfection, which constitutes the *presbyopic eye*, may often be traced to the effects of age, which produces a flattening of the cornea; and probably also impairs that voluntary power by which the refractions may be increased when near objects are viewed. The short-sighted, or *myopic* eye, has generally an excessive convexity of the cornea, which may be diminished, but is very seldom materially so, by the progress of age. The remedies for these defects are obvious; namely, the use of convex spectacles for the presbyopic, and of concave spectacles for the myopic eye; the former supplying the deficiency in the power of refraction; the latter correcting its excess.

(676.) Such then are the means employed for producing certain impressions on each retina, which it is the office of the optic nerves to transmit to the sensorium, where these give rise to corresponding sensations. The inquiry into the perceptions arising in the mind in consequence of these sensations belongs to another branch of the subject hereafter to be considered. It will be sufficient in this place to point out the general fact relating to the physiology of the eye, that the impression made upon each point of the retina, produces in the sensorium a distinct impression, suggesting to the mind a distinct sensation.

CHAP. XV.—PHYSIOLOGICAL LAWS OF SENSATION.

Sect. I.—*Phenomena of Sensation.*

(677.) Having examined the different modes in which impressions are made upon the extremities of the nerves situated in the respective organs of sense, we have next to direct our attention to the physiological phenomena which ensue on those impressions being received.

1. *Specific Endowments of the Nerves of Sensation.*

cificen- ments erves.

(678.) The extremities of the nerves intended to receive these impressions appear in general to be expanded over a certain extent of surface, and to be of a softer texture than the nerves themselves. This difference appears to arise from their being divested of the membranous covering which closely binds together the filaments composing the nerves, while they are pursuing their course from one part to another. Such expansions are noticed in the optic, auditory, and olfactory nerves, and probably also in those distributed to the papillæ of the tongue, and the cutis. The nerve of each particular sense appears to have different specific endowments. Thus the optic nerve and retina are peculiarly adapted to be affected by the impressions of light; and are not fitted to convey any other impressions. There are experiments recorded which tend to shew that irritation of these nerves do not communicate pain, as is the case with that of nerves sent to other parts of the body. On the other hand no other nerve in the body is capable of exciting, by any change that can be induced upon it, the sensation of light, as was pretended in the case in the celebrated imposture of Miss M'Avoy of Liverpool, who endeavoured to persuade people that she could see with the tips of her fingers: or in the more elaborate delusions of animal magnetism, in which persons are stated to be able to read a piece of writing applied to the pit of the stomach, or nape of the neck, by optical impressions made on different parts of the skin.[1]

(679.) That the optic nerves are incapable of exciting by their action any other sensations than those of light, is farther rendered probable by the circumstance that these sensations may be produced by other causes than those which usually give rise to them; such as impressions of a mechanical nature. A blow in the eye, producing sudden pressure on the retina, excites the sensation of a flash of light. The appearance of brilliant spangles in the field of vision is often the result of too active a state of circulation in the vessels of the retina, which excites in the fibres of the nerves actions similar to those produced by the presence of light. The galvanic influence affecting the same, or even neighbouring nerves, produces, in like manner, the sensation of a flash of light. Analogous facts have been noticed with regard to other senses. The well-known sensations of singing in the ears is the consequence of an action of the auditory nerves, excited by the state of the circulation in the organ of hearing, and is probably totally unconnected with any real sonorous vibrations communicated to that organ.

2. *Modifications of Impressions.*

Duration of impressions.

(680.) In order that an impression made upon the sentient extremity of a nerve may excite sensation, it must be applied for a certain time; for if it be of too transient a duration, no effect, as far as regards sensation, is produced. This is well exemplified in the case of vision; we lose sight of an object in very rapid motion, because the impression made by its image on the different points of the retina on which it is successively formed, is of too transient a nature to excite those actions which produce sensation.

Visual illusions.

(681.) On the other hand, when a distinct impression has been made on the nerve, that impression has a certain duration, independently of the continuance of the cause which excited it; for the sensation produced is, to a certain extent, permanent. This is also shewn, in the case of vision, by several experiments familiar to all, such as whirling rapidly with a circular motion, an object brightly illuminated, which gives rise, as is well known, to the appearance of a continuous circle of light. Many optical deceptions are founded on the same principle, such as that of the *Thaumatrope*, of the *Phantascope*, or *Phenikisticope*, and the curved appearance of the spokes of a revolving wheel when viewed through parallel bars, of which last phenomena the theory has been elsewhere given by the writer of this treatise;[2] and also the appearance of a similar kind noticed by Mr. Faraday.[3]

Coalescences of impressions.

(682.) One of the consequences of the law of the permanence of sensations is, that impressions which rapidly succeed one another in the same nerve, are not distinguishable as separate impressions, but produce a blending together, or coalescence into one sensation. Thus if a circle painted in different parts of the circumference with different colours, be rapidly whirled round its centre, the colours are blended together into one tint; and if the different prismatic colours of the spectrum be properly adjusted as to their relative proportions, the effect of this coalescence of the sensations excited by the whole is that of a white colour. The thaumatrope may also be made to illustrate this principle; for the pictures on the two sides of the card appear, by the rapid revolution of the card, to coalesce into one.

[2] *Philosophical Transactions for* 1815.

[3] *Journal of the Royal Institution*, vol. i. p. 205. See also Dr. Roget's *Bridgewater Treatise*, vol. ii. p. 524.

(683.) The most remarkable and complete illustration of the same principle is afforded by musical sounds, which, though they appear continuous, are, in fact, composed of separate impulses, repeated at very short, but regular intervals of time.

Modifications of sensibility by previous impressions.

(684.) Another law of sensation, is that when a nerve has received a strong impression, that nerve is proportionally weakened for a certain time after, and is less susceptible of a similar impression from the application of the same cause. The eye, after being dazzled by a strong light, has its sensibility diminished to the impressions of a weaker light. Different parts of the retina thus acquire different degrees of susceptibility of being affected by the same quantities of light. Thus, if the eyes be directed steadily to a bright object for a certain length of time, and be then transferred to a white sheet of paper, a dark spot, having the figure of that object will be seen on the paper, in consequence of that portion of the retina, on which the luminous image had been impressed, being fatigued, and rendered less excitable than those parts of the retina which did not receive that image. The light from the paper which arrives at that part of the retina which had received the impressions of the bright object, will produce less effect on that part, than the light of equal intensity from other parts of the paper does on the other parts of the retina. Those parts of the paper which are situated so as to have their image on the exhausted part of the retina appear darker, therefore, than the rest; and hence arises the appearance of a dark image. The experiment may be reversed by fixing the eyes attentively for some time on a dark object on a white ground, and then transferring it to some other part of the white ground; when immediately a brighter spot, corresponding in size and figure to the dark object, will be seen.

Ocular spectra.

(685.) These appearances, which imitate those of real objects, have been called *ocular spectra*. The susceptibility of the retina to receive impressions of particular colours is also found to be affected in the same manner, when any one of them has been strongly impressed. Thus the spectrum of a coloured object, while it has the same dimensions and figures as the object, will at the same time have an opposite colour, when the eye is transferred to a white ground. It will have what is called the *complementary colour* to that of the object itself; that is, it will have that tint which results from the admixture of all the colours composing white light, when the latter colour is left out. Thus red and green, yellow and purple, blue and orange, being complementary colours respectively to each other, the ocular spectrum of a red object will be green, that of a green object red, and so with all the others.[1]

(686.) We may here observe, that the appearances of spectra above described, are merely temporary; for the several parts of the retina soon regain their natural state of equable sensibility.

(687.) Illustrations of this law readily present themselves when we search for its application with regard to all the other senses. Sounds which are too loud produce temporary deafness, or at least impair for a time the sensibility of the ear to weaker sounds. Similar phenomena are observed as to odours and tastes, with reference to their appropriate senses. The sensibility of the skin to different temperatures varies considerably according to the previous impressions which have been made upon it. Thus the same body may appear either hot or cold, according to the previous temperature of the hand which is applied to it.

SECT. II.—*Conditions necessary for Sensation.*

Conditions for sensation.

(688.) The sensibility of the sentient extremities of nerves, or their capability of receiving such impressions as lead to their appropriate sensations, is dependent on certain conditions of the organ. These conditions are principally the following. First, it is necessary that the organ receive a proper supply of arterial blood by the vessels circulating through it, and particularly through that part on which the nerves are distributed. Secondly, it is required that the expansion of the nerve belonging to the organ should be exempt from excessive pressure. Compression of a nerve in any part of its course immediately puts a stop to all its functions; and consequently its power of receiving and conveying impressions is suspended as long as the pressure is continued. On the removal of the pressure, provided it has not been too violent, or too long continued, the nerve after a certain time, generally recovers its powers. Thirdly, a certain temperature is requisite for the maintenance of sensibility in the nerves. The benumbing effect of cold is well known, and extends generally to all the functions of the nervous system. It is very probable that this operation of cold is referable to its retarding or arresting the circulation in the capillary vessels; and it might, therefore, perhaps, be included in the causes which influence the first of the conditions here enumerated. Lastly, the office of every nerve being to transmit impressions from one of their extremities to the other, it is necessary for the due performance of this function, that an uninterrupted continuity of their filaments should be preserved throughout their whole course. The complete division of a nerve in any part, necessarily prevents this transmission, and destroys the function of the nerve.

(689.) Irritations applied to the nerve in any part of its course, produce sensation, provided the communication of that part with the brain be uninterrupted by any of the causes above specified. Thus, if a nerve be tied or divided at any point, irritations applied below the ligature or division will produce no effect as to sensation; but when applied above that point, sensation immediately follows. What is here said applies more particularly to the nerves distributed to various parts of the body, and especially to the integuments; the irritation of which nerves gives rise to a sense of pain. The nerves of the senses of sight, of hearing, of smell, and of taste, are so situated as hardly to admit of being the subjects of experiments which might decide the question as to what kinds of sensation would be excited by irritations directly applied to them; and whether these sensations would be similar to those they usually convey from impressions made upon their extremities. Analogy would undoubtedly be in favour of such similarity. Persons who have lost a limb by amputation, experience sensations not only of pain, but also of touch, and of muscular motion, exactly similar to those which they formerly derived from the parts of the limb which they have lost. These sensations arise from imitations taking place, either in the lower extremities of the nerves which have been divided, and which remain in the stump, or in the brain itself.

(690.) The most remarkable circumstance attending the communication of irritations along the nerves of sensation, is the celerity of the transmission. It appears, indeed, to be instantaneous, and can be compared only to the rapidity of the electric fluid passing along a conducting body.

SECT. III.—*Theories of Sensation.*

Theori of sensati

(691.) We are completely ignorant of the nature of that power by which the nerves effect this rapid communication along the lines of their fibres, and even of the changes which take place in the nerve while it is performing this function. Several hypotheses have been proposed with a view to supply this chasm in our knowledge. The oldest of these, and that which maintained its ground for many centuries, is, that the brain and nerves are furnished with a certain fluid, which was called the *animal spirits*, and was the medium of communication between the different parts of the nervous system. Traces of this theory may be found in the writings of Hippocrates; but it derived its principal support from Descartes, who reduced it to a regular form, and powerfully recommended it by the force of his authority. According to the views of those who espouse this theory, the brain is considered as an organ whose principal office it is to secrete the animal spirits, which are of a very subtile and ethereal nature, and to supply them to the nerves, which were considered to be the natural excretory ducts of the brain. The existence of this fluid was, for a very long period, universally admitted by physiologists, and the doctrines founded upon it were more or less mixed up with all the reasonings of physicians respecting the causes and phenomena of diseases, and the effects of remedies. Traces of the influence of this doctrine may be found in the popular language of medicine even in the present day, when the hypothesis from which it is derived is deservedly exploded as perfectly gratuitous, and devoid of any just foundation.

---

[1] For more ample details on this subject, the reader may be referred to an Essay on Ocular Spectra, by Dr. Charles Darwin, published in the 76th volume of the *Philosophical Transactions*, and reprinted in Dr. Darwin's *Zoonomia*.

pothesis ibra- s.

(692.) Another hypothesis invented to account for the propagation of impressions along the fibres of nerves, was that of their depending on vibrations or periodical oscillations of their particles, analogous to those of the strings of a harpsichord when producing musical notes. The great champion of this doctrine was Hartley,[1] who embellished it by his beautiful applications to a great variety of phenomena relating to sensations, and even to the intellectual operations. It afforded a happy explanation of many of the phenomena of ocular spectra, and of those depending on the permanence of sensations. It is needless to remark, that this hypothesis is equally visionary and destitute of any solid basis as the former.

trical ry.

(693.) All these mechanical theories are overturned by the fact that no tabular structure can be discovered, on the minutest anatomical scrutiny, to exist in the filaments which compose the nerves; nor can the slightest motion be detected in any of their parts, while they are actively transmitting the impressions of sensation.

(694.) The latest hypothesis as to the nature of nervous power is, that it is identical with electricity. It is supported principally by the experiments we have already mentioned, in which, after the par vagum was divided, so as entirely to intercept its action in promoting the secretion of the gastric fluid, secretion was restored by transmitting the galvanic fluid along the lower portion of the nerve. The experiment, indeed, applies only to a particular office of the nervous power, namely, that of promoting secretion; but the hypothesis it suggested has been extended to all the other functions of the nerves, and of course to their power of transmitting those impressions which give rise to sensation.

CHAP. XVI.—FUNCTIONS OF THE SENSORIUM.

SECT. I.—*Locality of the Sensorium.*

ity ium.

(695.) If we except the nerves appropriated to the organs of the special senses of sight, hearing, smell, and taste, and those distributed on the face, and other neighbouring parts, all the nerves subservient to sensation appear to terminate in the spinal cord. We are then, in the first place, to determine whether the impressions which these nerves convey to that organ, are transmitted to any other part of the nervous system, previously to sensation being produced.

(696.) Experiments in all the animals whose structure, as far as regards this part of the nervous system, is analogous to the human, have established the general fact, that sensation does not take place, unless the part of the spinal cord to which the nerve is connected, communicates by an uninterrupted continuity of substance with the brain. The division of the spinal cord near the foramen magnum, instantly renders the whole body insensible; but it does not appear so immediately to deprive the parts about the face of sensibility, for some degree of it appears to be retained as long as the circulation continues. The injury, indeed, soon becomes fatal, by the circulation ceasing in consequence of the interruption to the function of respiration. The effects of injuries to the spinal cord occurring to men from accidents of various kinds, afford ample confirmation of the fact that the brain is the general centre to which all impressions made upon the nerves must ultimately be brought before they can excite sensation.

(697.) Admitting the brain to be the immediate organ of sensation, it next becomes a question, whether any particular part of the brain is more especially appropriated to the exercise of this function. It is to such a part, supposing it to exist, that the name of *sensorium* has been applied. There are two modes of conducting this inquiry; the first is by tracing very carefully, the filaments of all the nerves which are immediately connected with the brain, and endeavouring to discover if they unite in any central part of that organ, which may accordingly be supposed to be the seat of sensation; or, in other words, the sensorium. The second mode of investigating the subject, is to ascertain if any one part of the brain can be discovered, on which impressions directly made, are invariably productive of sensation.

(698.) The fibrous substance of the spinal cord, being directly continuous with the medulla oblongata, may be supposed to terminate in that part of the brain; so that, viewing the spinal cord as a collection of all the fibres of the nerves of sensation continued along its whole length, these nerves themselves may be considered as following this course, and having this termination. These fibres are found more particularly to converge towards the corpora quadrigemina, and crura cerebri. Now, it happens that this is also the very spot with which the nerves of the senses, whose organs are in the head, namely, the fifth, seventh, and eighth pairs, are more particularly connected. It appears also, from the late investigations of the French physiologists, that no part of the brain higher than the corpora quadrigemina, and no part whatever of the cerebellum, is essentially concerned in sensation; for it is found that in animals the power of sensation remains, even after the removal of all the parts of the brain, or of the cerebellum, higher than this spot. The conclusion which has been deduced from these experiments is, that the medulla oblongata, and more particularly that segment of it to which the nerves of the head are united, is the organ most essentially connected with the mental change constituting sensation. But it is not probable that these corporeal changes immediately connected with sensation, are confined to a *single point* in the brain, which might emphatically be termed *the seat of the soul*, as Descartes expressed it, when he boldly pronounced the pineal gland to be that spot.

SECT. II.—*Requisite conditions of the Sensorium.*

Conditions of the sensorium.

(699.) A multitude of facts tend to confirm the view of the subject which has here been taken. The same conditions as those which are required for the exercise of the functions of the nerves in every part of their course, are equally necessary for the performance of those of the brain. It is indispensable that the circulation in the brain should be in a healthy state, and that arterial blood be supplied by its vessels. It is indispensable that a proper temperature be preserved; and it is likewise indispensable that the brain be not compressed by any considerable force. A failure in any one of these conditions, produces total deprivation of the power of sensation, as well as of all the other functions of the brain. This effect is found to result more particularly when pressure is made in the direction of the medulla oblongata; for in that case complete insensibility takes place; and on the removal of the pressure, the faculty of sensation slowly returns; but if any considerable injury has been inflicted on that part, the power of sensation is irrecoverably lost.

---

[1] *On Man.* A full account of Hartley's theory is given by Dr. Priestley in a separate work bearing that title.

(700.) It is probable that most of the laws which regulate the functions of the nerves with respect to sensation, apply with equal truth to the sensorium itself; but with regard to several of the phenomena, it is difficult to determine whether they depend on affections of the sensorium, or of the extremities of the nerves, situated in the organ of sense. We must despair of being able to resolve this question, because the changes which take place in both these parts, appear to be simultaneous. The impaired power, for example, which is the result of a strong impression from an object of sense, may arise equally from the exhaustion of that part of the sensorium to which the impression is communicated, as of that of the sentient extremity of the nerve; and we have no means of discriminating between them.

(701.) Another point of resemblance is, that irritations applied to the sensorium, from other sources than the nerves themselves, give rise to the same train of sensations as impressions communicated through the nerves. These irritations may be given by the pressure of blood circulating in the arteries of the sensorium; and this is probably the source of many of those sensations generally ascribed to affections of the nerves, or of the organs of sense. Pains, and other sensations in various parts of the body, arise from affections of the brain. The same origin may often be assigned to sensations which arise in dreams, and likewise to various spectral illusions which affect persons who are awake, and aware of their being deceptions of the sense. In delirium and insanity, the sensations from this cause assume a fearful degree of intensity, and are accompanied by a fixed belief in their reality.

Sect. III.—*Laws of Recurrence, and of the Association of Impressions.*

Law of recurrence.

(702.) With regard to all the subsequent changes and operations which take place when sensation has been excited, it is extremely difficult to pronounce how much of the phenomena are purely mental, and how much are strictly the result of corporeal changes connected and associated together by physical laws. In other words, it is difficult to determine what are the operations in which the mind is purely passive, and dependent on the actions of its bodily organs, and what are those in which it exerts a spontaneous power of action, and thereby reacts upon those organs, and produces in them a series of changes which lead to the most important results. The distinction we are attempting to draw, is founded upon this essential difference in the order of sequence of the phenomena, that in the one the organic change precedes the mental change, and in the other succeeds to it.

Law of spontaneous recurrence.

(703.) The two principal physiological laws relating to the former of these physical changes, namely, those which precede the mental affections, are, first, the *law of spontaneous recurrence.* Whenever an impression of a certain intensity has been made upon the organs of sense, the sensation which is produced by it, after disappearing for a certain time, recurs without the presence of the cause which originally excited it; and this happens repeatedly, and without any corresponding effort of the mind, and often in opposition to any effort which can be made to counteract the tendency. This spontaneous recurrence of sensations is probably the result of the repetition of those changes in the sensorium which originally gave rise to them. In the language of metaphysics, the corresponding mental affections are termed *ideas*, in order to distinguish them from the similar and more vivid affection excited by the primitive impression, and to which the term *sensation* is more particularly appropriated.

Law of association.

(704.) The second law which regulates the unknown affections of the brain connected with the passive phenomena of mind, is that of *association*, or the law by which impressions, and consequently the corresponding ideas, recur in the same order of sequence as that in which they were originally excited. The phenomena of disease, and the operation of different agents which modify the state of circulation in the brain, and the conditions of the nervous powers, afford ample evidence that the modes of association, and of the sequence of impressions and ideas, are dependent on the physical condition of the brain, and result from certain changes taking place in that organ.

(705.) The views here presented, far from being favourable to the doctrine of materialism, are directly opposed to it; since they necessarily imply the existence of an essential distinction between mind and matter, and aim only at tracing the connexions which have been established between them by the divine Author of our existence.

(706.) Such, then, being the physiological connexions which exist between the physical changes taking place in the brain, and the passive phenomena of the mind, it is not an unreasonable supposition, that the voluminous mass of cerebral substance which, in the human brain especially, has been superadded to the medulla oblongata, or to the immediate physical seat of sensation, is in some way subservient to that astonishing range of intellect and combination of mental faculties which are found in man. We may conjecture also, with much appearance of probability, that in the lower animals, the intellectual endowments which mark several of the more intelligent races are connected with similar, though inferior, expansions of cerebral substance.

(707.) All the mental phenomena in which the mind is passive have been referred by metaphysicians to the principle of association, and consequently may, in as far as this principle is concerned, be connected with the physical changes above noticed. Hence we find the memory, which is the direct result of that law, is more especially liable to be impaired by certain physical states of the brain, such as those induced by severe concussion, by fevers, and by the progress of age.

(708.) As scarcely any thing is known with regard to the physical changes which take place in the brain in the relations which they bear to mental phenomena, the further consideration of these phenomena belongs properly to psychology rather than to the subject of this treatise. The inquiry must here be taken up by the metaphysician, whose province it becomes not the physiologist to invade.

Sect. IV.—*Volition and Voluntary Motion.*

Phenomena consequent on volition.

(709.) Leaving, therefore, to the metaphysician the analysis of those mental phenomena, which, however dependent they may be for their existence on the healthy actions of the brain, require modes of investigation different from those of physiology, and lead to results very remote from any conceivable laws of material agency; we may resume the subject at the point when, in consequence of the mental acts of *volition*, by which term we here mean to express the endeavour to produce certain specific movements of the body, new changes are again produced in the cerebral organs, and new trains of physical phenomena succeed. That this mental effort of volition constitutes a distinct step in the series of phenomena, is proved by the instances of paralysis, in which the patient is conscious of making the effort to move the palsied limb, yet no motion, or even sensation of motion, ensues. Another illustration of the same distinction is derivable from a different disease affecting the limbs, namely, *anæsthesia*, which consists of the loss of sensation only, while the power of voluntary motion remains; and in which the voluntary act so exerted produces the intended muscular contractions, unattended, however, with the feelings which usually accompany them. The same complete ignorance in which we are with regard to the changes which take place in sensation, pervades our notions of those which attend volition, in as far as they occur in the brain. A few facts, indeed, have been collected with regard to those parts of the brain which are impressed, if such a term may be used, antecedently to the voluntary motions of the limbs. They appear to be chiefly the crura of the cerebellum, and the adjacent parts of the medulla oblongata.

(710.) All the physical conditions which are necessary in order that sensations may be felt, are equally necessary for rendering the cerebral organs capable of receiving from the mind those impressions which lead to voluntary motion. The mental stimulus of volition produces a certain effect on the origin of the nerves, leading to the muscles employed in these motions, which impression, being propagated along the course of those nerves, excites these muscles to contraction. The transmission of those impressions is made with the same celerity, and probably by the same agency, as those which produce sensation; but they are made in the contrary direction, namely, *from* the brain, instead of *towards* it. The same conditions of perfect continuity of fibres, of freedom from pressure, and of healthy circulation, are essential requisites in both cases; and every thing that has been said with regard to the former, is also applicable to the latter. Mechanical irritations, applied either at those parts of the brain which adjoin the origin of the nerves, or to the nerves themselves, either at their origin, or in any part of their course, whether that portion of the nerve situated between the point to which the irritation is applied be entire or divided, or compressed by a ligature, are found to produce the same muscular contractions as those which are the result of volition.

scles of
untary
tion.

(711.) Mr. Mayo[1] ascertained, that after any nerve which supplies a voluntary muscle is cut through, either in a living animal, or immediately after death, mechanical irritation of the part of the nerve disconnected with the brain, as for instance the pinching it with a forceps, causes a single sudden action of the muscle or muscles it supplies. On the other hand, a like effect cannot be produced by irritating mechanically the nerves distributed to those muscles over which the will has indisputably no influence. "It must be admitted, however," he remarks, "that this phenomenon is not exclusively confined to those muscles which are allowed on all hands to be voluntary; nor, indeed, is it shewn in all the muscles which seem at first sight to be directly under the controul of the will." But it is not easy, in various instances, to determine whether muscular actions are voluntary or not; while the point of distinction proposed by Mr. Mayo has the recommendation of being easily verifiable. Setting aside, therefore, in the first instance, the question of the influence of the will, let us be satisfied with observing what muscles act when a divided nerve that enters their substance is mechanically irritated, and what do not. We may afterwards trace the collateral differences of the two classes of muscles which are thus distinguished.

(712.) The parts which are susceptible of this mode of excitement, are the muscles of the trunk, head, and limbs, of the tongue, of the soft palate, of the larynx, of the pharynx, and œsophagus, and of the lower outlet of the pelvis. The opposite class comprehends the heart, the stomach, the small and great intestines, and the bladder.

(713.) The collateral differences which characterize either class are, with exceptions afterwards to be adverted to, the following:—

Of the muscles which act when a nerve distributed through them is mechanically irritated, it may be remarked:

1. That they admit of being thrown into action by an effort of the will.

2. That with sufficient attention and resolution, their action may be refrained from.

3. That their action is attended with a conscious effort, and is guided by sensation.

4. That if divided, the separate parts retract instantaneously to a certain distance, and subsequently undergo no farther permanent shortening.

5. That when mechanically irritated, a single and momentary action of their fibres alone ensues.

6. That they remain relaxed, unless excited by special impressions, both in the living body, and before the loss of irritability after death.

7. That their action in the living body habitually results from an influence transmitted from the brain or spinal cord through the nerves.

(714.) The exceptions to be made against this statement, if applied generally, are, that the three first affections are not easily brought home to the muscular fibres of the œsophagus, or of the lower part of the pharynx; but it deserves at the same time to be considered, that the lower part of the pharynx and the œsophagus are in the peculiar situation of parts employed on one object alone, instinctively and habitually, on the recurrence of one impression; a condition which would soon reduce a strictly voluntary muscle to a state apparently removed from the control of the will.

(715.) Muscles of the preceding class, if we except the fasciculi belonging to the pharynx, and œsophagus, and urethra, are so disposed as to extend from one piece to another of the solid frame-work of the body; they enlarge or straighten the cavities of the trunk; they produce the phenomena of the voice; they close the excretory passages; the greater number are employed to move the limbs on the trunk and the frame on the ground. Muscles of the second class are used, like the exceptions in the preceding, as tunics to the hollow viscera, the cavities of which they diminish in their action, and thus serve to give motion to their contents. The œsophagus, indeed, appears to partake of the nature of both classes of muscles; when the nervi vagi are pinched, one sudden action ensues in its fibres, and presently after a second of a slower character may be observed to take place.

(716.) Of the muscles which do not act on the mechanical irritation of any nerve distributed through them, it may be remarked,

1. That the will cannot instantaneously or directly produce action in them.

2. That the resolution to abstain from their action is insufficient to repress it.

3. That their action is not attended with a conscious effort, and seldom has reference to sensation.

4. That if divided, the retraction which follows is in most instances slow and gradual.

5. That if they are mechanically irritated, not one, but a series of actions ensues.

6. That their natural state, in the absence of external impressions, is not continued relaxation. When the heart and bowels are removed from the body of an animal immediately after death, they continue for a time alternately to contract and to dilate.

7. That an impression transmitted through the nerves does not appear the usual stimulus to their action.

(717.) From the experiments of the French physiologists it would appear, that in an animal deprived of all the upper portions of the brain, but in which the medulla oblongata is preserved, all indications of the more complex operations of thought disappear, but the animal still remains capable of executing such voluntary motions as are of an instinctive character, as, for example, swallowing. Animals deprived of the cerebellum, provided the medulla oblongata remains, and is free from compression, not only appear to be capable of sensation, but give all the usual indications of intelligence, and evidently exert volitions, which occasion the action of many voluntary muscles. But they have lost the power of regulating the contractions of those muscles so as to execute any definite voluntary action, excepting those which are instinctive. All the other voluntary movements of the body and limbs are performed in so irregular a manner, that they are generally ineffective for the purposes for which they are intended; and most of the usual complex movements required for progressive motion cannot be performed at all. This has been explained by the supposition that the animal has lost all recollection or association of those trains of muscular sensations which used to accompany and to guide these movements, in consequence of the loss of the cerebral organs which are instrumental in furnishing those associations. One of the inferences drawn from these facts (which themselves require more ample confirmation before they can be regarded as established) is, that the recollection of those associations connected with voluntary motion depends on the cerebellum, in the same way in which the associations of sensations and ideas depend on the hemispheres of the brain.

[1] *Outlines of Human Physiology*, third edition, p. 39 to 42.

Decussation of nerves.

(718.) It is a remarkable circumstance that injuries or diseases occurring in the hemispheres either of the cerebrum or cerebellum produce paralysis, that is, destroy the power of voluntary motion, of the muscles situated on the opposite side of the body. This has been endeavoured to be explained by the alleged decussation or crossing of the nervous fibres of the lower part of the corpora pyramidalia on each side. But in order to account for all the phenomena of this kind, we must suppose the decussation to take place between the fibres which compose the posterior and the anterior columns of the spinal cord.

Nerves of sense and of motion.

(719.) Although the function of the nerves in transmitting impressions from the organs of sense to the brain, which give rise to sensation, and in transmitting impressions of volition from the brain to the muscles of voluntary motion, which give rise to the contraction of those muscles, appear to be of the same kind, and to differ only in the direction in which the impression is transmitted, the question has often been asked, whether the same nervous filaments which transmit the one class of impressions are employed to transmit the other likewise; or whether different portions of the nerve are appropriated to these different offices. The truth of the last of these propositions may now be considered as being firmly established.

(720.) The observations which first suggested the idea of there being two sets of nervous filaments, the one subservient to sensation, and the other to volition, were those in which a limb was only partially paralysed, the power of motion being retained, while that of feeling was lost. Experiments had also been made in which nerves that had been divided, and had afterwards spontaneously united, were found to have recovered the power of placing the muscles to which they were distributed under the command of the will, but yet had no power of conveying sensitive impressions. Erasistratus and Herophilus had long ago taught the doctrine of there being two species of nerves respectively appropriated to these opposite functions; and Galen was inclined to the same opinion from observing that both the tongue and the eye are supplied with two separate sets of nerves, the one apparently subservient to sensation, the other to motion. But it is to Sir Charles Bell and to Magendie that the merit belongs of bringing forward decisive proofs of the reality of this distinction between nerves for sensation and nerves for motion, the idea having before been only loosely thrown out by speculative physiologists as a plausible conjecture.

(721.) It results from this discovery that the transmission of impressions in opposite directions, that is, in the one case from the extremities to the brain, and in the other from the brain to the muscles, is effected by different nerves, or at least by different sets of nervous filaments, and that no filament is capable of transmitting impressions both ways indiscriminately, but always in one particular direction. These two kinds of filaments are, it is true, conjoined together into one nerve; but the object of this union is not community of function, but convenience of distribution, the two kinds of filaments still remaining distinct in their functions as they are likewise distinct in their origins. We know that all the nerves connected with the spinal cord have a double origin; that is, are composed of two nerves, the one proceeding from the anterior, and the other from the posterior columns of the spinal cord. It is found that an injury done to the anterior roots of those nerves excites convulsions in the muscles which they supply, but does not appear to excite any sensation of pain in the animal on which the experiment is made; and the division of those nerves is followed by the immediate paralysis of those muscles, that is, by their incapability of being excited to contract by any voluntary efforts. On the contrary, the irritation of the posterior roots of the same nerve is attended with no contractions of muscles, but calls forth expressions of violent pain. The section of these nerves is followed by insensibility of the parts which those nerves supply, while the power of voluntary muscular contraction remains.

Symmetr cal system of nerves.

(722.) From the symmetrical situation of these nerves with regard to the spinal cord, Sir Charles Bell has given them the name of the *original*, or *symmetrical nerves.* They comprehend, of course, all the spinal nerves which arise by double roots, the posterior of which has invariably a ganglion near its origin, while the anterior branch has no such appendage. These spinal nerves are distributed laterally to the two halves of the body; those of the one side having no connexion with those of the other. Sir Charles Bell ranks the fifth pair of the cranial nerves in the same class as the spinal nerves; considering its two roots as composed of filaments, appropriated the one to sensation, the other to motion; the former being provided with a ganglion near its origin, and the latter having no ganglion. He regards the third, probably the fourth, the anterior branch of the fifth, the sixth, the portio dura of the seventh, and the ninth, as being exclusively motor nerves, distributed to the muscles of the eye-ball, lower jaw, face, and tongue, and placing these muscles under the control of the will. The ganglionic portion of the fifth pair, on the other hand, he regards as the great sentient nerve of the head; which gives exclusively sensibility to the face, eye-ball, mucous membrane of the nose, mouth, and tongue. This nerve is in communication with the posterior column of the spinal cord; whilst the motor nerves, above enumerated, appear to communicate with the anterior column. An exception to this rule, however, occurs in the case of the fourth pair, which has never been proved to communicate with the anterior column of the spinal cord. It would appear also that the larger portions of the eighth pair, which seem to be more connected with the posterior than with the anterior columns, are nerves both of sensation and of motion; so that the exclusive appropriation of the nervous filaments, originating from the different surfaces of the spinal cord, to motion or to sensation, is perhaps not yet rigidly demonstrated.

(723.) It is remarkable that the peculiar sensations conveyed by the optic, the olfactory, and the auditory nerves, have been found by Magendie to be much impaired, or even entirely lost, by injuring the branches of the fifth pair of nerves, which also supply the respective organs to which the above nerves appear to be particularly appropriated. The cause of this anomaly has not yet been satisfactorily explained.

piratory ves.

(724.) Sir Charles Bell has distinguished another class of nerves, which he conceives to be altogether subservient to the function of respiration, and to be distributed to the muscles concerned in that function. These he terms the *irregular*, or the *superadded*, or the *respiratory nerves*. They arise by single roots; they pass from one organ to another in various directions, and pursue a very irregular and intricate course, passing across the nerves belonging to the symmetric system, occasionally uniting with them, and connecting together the two halves of the body. These nerves, according to Sir Charles Bell, are not under the control of the will, and are not capable of exciting sensations; their only office being that of transmitting impressions from one part to the other. The nerves which strictly belong to this class are the eighth pair, the spinial accessory nerves, the phrenic, the external respiratory nerve of Sir Charles Bell, and the great sympathetics.

(725.) The first pair, or the olfactory nerves, the second, or the optic, and the portio mollis of the seventh pair, are wholly nerves of sensation; and from the special nature of the impression they convey, may be considered as forming a separate class of nerves.

nglia.

(726.) Most nerves pass through *ganglia*, or are interwoven with others in *plexuses* before they reach their destination. The purposes answered by this intermixture of filaments, which, in either case, appears to take place, is to provide extensive connexions between the parts supplied with nerves and different portions of the spinal cord, or medulla oblongata, from which the several fibres originate. Thus the sensative and the motory filaments are intimately united in the same nervous cord, which is thus rendered capable of performing all the functions of nerves. Many hypothetical uses have been assigned to the ganglia, which appear to be unsupported by facts. Drs. Gall and Spurzheim suppose that they contribute to increase the nervous power in those nerves on which they are placed; but there does not seem to be any solid foundation for this opinion.

ssifica- of scular ion.

(727.) Muscular contractions, then, may be distinguished, with reference to the nervous power which excites them, into four classes; namely, 1. The purely voluntary motions; 2. The automatic motions; 3. The instinctive motions; 4. The involuntary motions. We have now fully considered the first of these classes, the purely voluntary motions, which may be defined to be those consequent on an effort of volition of which the mind is conscious, and which is accompanied by a distinct idea of the end intended to be accomplished. No examples or illustrations are necessary of motions belonging to this class, as they are those with which we are most familiar. We pass on then to the other classes in the order in which we have enumerated them.

Sect. V.—*Automatic Motions.*

tomatic ions.

(728.) Automatic motions are those which consist of a series of actions, each of which was originally the object of a distinct volition; but which by habit, that is, by repeated association, have become linked together in such a manner, that a simple act of volition is sufficient, apparently, to renew the whole series, without requiring any separate effort of attention to each. Most of the actions which we daily perform, such as walking, speaking, writing, or playing upon a musical instrument, afford examples of automatic motions, being linked together by associations which, far from requiring any conscious acts of volition, follow one another in a regular order of sequence that cannot be broken unless by the exertion of a separate effort of atttention. All these movements, however, are still voluntary, inasmuch as they remain under the control of the will, which commands their commencement, can regulate their course, and can stop them at pleasure.

(729.) The muscular actions required for respiration may probably be classed under this head. The immediate exciting cause of the act of inspiration is a sensation felt in the chest from the presence of venous blood in the capillary vessels of the lungs; and this sensation, if not speedily relieved, increases rapidly to one of extreme distress, and even agony. The influence of this sensation in exciting the very complicated actions which are necessary to relieve it by drawing air into the lungs, and which, indeed, are continued during sleep, and even when sensibility to all other impressions appear suspended, as in the state of apoplexy, is rendered manifest by the increased frequency and energy with which these actions are performed whenever any cause exists obstructing the free acces of air into the lungs, and thus augmenting the intensity of the sensation.

(730.) Since the actions of respiration are caused, in the first instance, by sensations, they must be dependent on the sentient nerves of the lungs, and especially on those that establish the most direct communication between them and the medulla oblongata, namely, the eighth pair of nerves. We find, accordingly, that after the section of those nerves the actions of respiration are performed more slowly and less perfectly than when entire. They, nevertheless, continue, probably by means of the other communications which the lungs have with the brain, through the branches of the great sympathetic proceeding from the spinal cord. When the part of the medulla oblongata from which these nerves originate is injured, all attempts at inspiration are finally arrested, because a final stop is put to the sensation which prompts them. The section of the phrenic nerves, or an injury to the spinal cord at any part above the origin of those nerves, paralyses all the respiratory movements of the chest, and thus occasions asphyxia and sudden death.

(731.) When the sensation which prompts inspiration, is intense and long continued, all the muscles performing movements auxiliary to this act, such as those which assist the intercostals in elevating the ribs, which hold the glottis open, which raise the velum pendulum, which open the mouth, and which expand the nostrils, are called into simultaneous action, and the movements themselves are performed in concert, and with perfect precision. These actions are under the control of the will, as respects their force, their rapidity, and their frequency, and they may even be performed at pleasure, either separately or in conjunction; unless, indeed, the sensation which prompts them be unusually intense; in which case they cease to be voluntary and automatic, and pass into the class of instinctive motions we are next to describe. Sir Charles Bell supposes that the nerves of all the muscles employed in these auxiliary actions have peculiar connexions among themselves at their origin from the lateral columns of the spinal cord, from which the eighth pair, which is the great sentient nerve of the lungs, also arises; and that these connexions are the principal cause of their conjunction of action, whenever the sensation imperiously demands that they should act in concert. Yet, on other occasions, we find that all the muscles concerned in these actions, are strictly voluntary muscles, and are perfectly obedient to the will.

Sect. VI.—*Instinctive Motions.*

Instinctive motions.

(732.) It is the essential character of motions which are strictly voluntary, that they are accompanied not only by a consciousness of their being performed, but also by a conviction that we may, or may not perform them, as we please; or, to speak more philosophically, according as there exists or not, a sufficient *motive* for their performance. But there are also, in the healthy state, many muscles, of the actions of which we are always conscious, and which, under ordinary circumstances, are perfectly obedient to the will, but whose actions we have, on other occasions, no direct power of controlling by any effort of the will. They occasionally seem even to be rebellious to its authority, and as if they were transferred to the agency of some other power. They are always preceded by some sensation, as in the case of coughing, sneezing, and vomiting; or some internal affection of the mind, which has been termed *emotion*, as in the case of laughing and weeping; and they take place without any previous conception of the object they are calculated to attain, and therefore without the previous existence or operation of a motive. A very large proportion of the actions of brute animals appear to belong to this class; being characterized by the absence of that train of mental operations, which imply the agency of motives, and the previous knowledge of the consequences resulting from such actions; operations which are comprehended under the term *reason*, as contradistinguished from *instinct*, or blind and inexplicable impulse derived from other sources.

(733.) Instinctive motions are distinguished by Dr. Alison into two kinds, the one comprising such as are not only prompted by an act of which we are conscious, but are also directed without our being aware of it at the time, to an end which we desire; the other, those in which our actions are consequent indeed on a sensation, but are prompted by a blind impulse, the consequences which are to flow from the action being either unknown or disregarded; as, for instance, in gratifying the appetites, guarding the eyes from danger by closing the eyelids, or the body from falling by throwing out the hands. Dr. Alison, in his *Outlines of Physiology*, to which we are indebted for several of the preceding remarks and illustrations, has very clearly treated of the whole subject of the functions relating to muscular motion. He farther remarks that the instinctive actions are closely connected with the motions which proceed directly from sensations on the one hand, and with the strictly voluntary motions on the other. In the adult human being, it is hardly possible to distinguish them from movements which have been prompted by reason, and become habitual; but in the infant, and in the lower animals, they are easily recognised, being distinguishable by two marks; first, that they are always performed in the very same way; whereas actions which are strictly voluntary, and prompted by reason, although directed to the same ends, vary considerably in different individuals; and, secondly, that, however complicated the movements may be, the truly instinctive actions are performed equally well the first time as the last; whereas even the simplest of the strictly voluntary movements require education. The complex acts of sucking and deglutition performed by a new-born infant, may be given as examples of strictly instinctive motions.

(734.) It is important, however, in the consideration of this subject, that we bear in mind, that these actions, although in themselves instinctive, are yet performed by muscles which are at other times voluntary, and whose nervous connexions with the sensorium, render it necessary for the performance of these actions, that the muscles themselves should communicate by their respective nerves with the sensorium. We may fairly presume, therefore, that such actions are immediately dependent on a change taking place in the sensorium, through the medium of which alone the impression which is the occasion of the actions, becomes effective in their production.

Sympathetic actions.

(735.) The same remark applies also to those sensations which arise from *sympathy*, as it is termed; that is, which are referred to a part of the body very different to that to which the actual irritation is applied. Of this kind is the pain of the shoulder accompanying inflammation of the liver; pain of the knee from disease of the hip-joint; and itching of the nose from irritations in the bowels. These sympathetic sensations may perhaps be explained by the nerves of those corresponding parts having their origins from the same parts of the brain; but much yet remains to be done towards establishing the truth of this hypothesis.

Sect. VII.—*Involuntary Motions.*

(736.) Under the head of the involuntary motions, we mean to comprehend all those muscular contractions which are performed without the intervention of any change in the sensorium, and consequently without being attended with either sensation, consciousness, or any other mental change. The most unequivocal examples of this class of motions are those in which muscular actions are excited by irritations applied directly to the motor nerves which are sent to the muscles themselves; for although, in the living body, such irritations are usually accompanied with the sensation of pain, that sensation must be regarded as an accidental concomitant, and not a necessary part of the phenomenon; as is proved by the absence of all sensation, when the nerve has been divided between the brain and the part to which the irritation is applied, and yet the muscles in which the nerve terminates, exhibit the same involuntary contractions as before. The same phenomenon, indeed, may be reproduced after the death of the animal, or when the brain or head has been removed.

(737.) Other cases are met with of a more complex and dubious character; namely, those in which muscles usually under the influence of the will, exhibit contractions in consequence of irritations applied, not to their own nerves, but to some more distant part, which receives other nerves. It is manifest that in these instances, the irritation of these latter nerves produces an impression which is propagated along their course towards the central parts of the nervous system, and is from thence again transmitted along the course of the nerves supplying the muscles, in which they excite contractions of the same kind as those originating in volition. Yet these motions may take place wholly independently of the sensorium, and are found to occur, indeed, when all communication with the brain is intercepted. For if, a few seconds after an animal has been deprived of life, the spinal cord be divided in the middle of the neck, and also in the middle of the back, upon irritating either by a mechanical or chemical stimulus, or by the application of heat, any sensitive portion of the body connected by nerves with either of these isolated segments, the muscles of that portion of the limb, so connected with the spine, are thrown into action. If, for instance, the sole of the foot be pricked, the foot is suddenly retracted, with the same gesture as it would have been during life, and of course with the same apparent indication of suffering.[1] It is evident that here an irritation applied to a nerve, the usual office of which during life was to transmit impressions to the sensorium productive of sensations of pain, has now produced an impression which is conveyed to the spinal cord only; but which yet is followed by the contractions of those very same muscles, which, during life, obeyed the determinations of the will, and produced a motion of the limb directed to its removal from the cause of injury.

(738.) Phenomena of this description may be observed more readily, and are exhibited in a manner still more marked, according as the animal on which the experiment is made, occupies a lower place in the scale. Among vertebrated animals, the motions just described, and others of a similar character, indicative of sensation and volition, are most easily produced in reptiles, as in the turtle, the serpent, and the frog; in which we find that isolated portions of the spinal cord perform functions analogous to those of the brain, as far as relates to the receiving of impressions from a certain set of nervous filaments, and the transmit-

---

[1] See *Mayo's Outlines of Human Physiology*, p. 231.

ting of impressions to other nervous filaments, which proceed from the same part of the spinal cord, and are distributed to the muscles. These two sets of nerves correspond in their functions to the sensory and motor nerves by which sensorial phenomena are produced, (see § 721.) In articulated animals, whose spinal cord consists of a series of nodules of nervous matter, resembling ganglia, connected by two longitudinal cords, and severally giving origin to their respective bundles of nerves, which radiate on each side from these ganglia, as from so many centres, the capability of each ganglion to perform this double function is still more susceptible of demonstration; and each segment of a worm or an insect, for example, appears, in consequence, to enjoy a separate life, and exhibits the semblance of possessing powers of sensation and voluntary motion independently of the rest.

(739.) The question now arises whether these indications of sensorial powers actually proceed from the exercise of those faculties; that is, whether they are accompanied by actual feeling and actual volition, of both of which consciousness is the essence; or whether they exist in appearance only, and without any real consciousness on the part of the individual percipient being. This question, taken in all its generality, it is extremely difficult, perhaps impossible, to decide; and its solution involves that of another problem, equally obscure, which is presently to come under our notice: namely, as to the locality and extent of the sensorium in all the classes of the animal kingdom. The plan of structure, and the vital constitution of articulated animals, are so different from what occurs in the system of animals of the vertebrate type, that whatever may be the conclusions we may form with regard to the sensorial powers and the organs which exercise them in the former class, we are not warranted in extending the same conclusions to the latter class of beings, in all of which we cannot fail to recognise the most decided character of individuality. It is hardly possible to conceive the co-existence of two separate centres of sensation and volition in any vertebrate animal, because we find it impossible to understand how consciousness can be subdivided into portions corresponding to the different segments into which the spinal cord may be divided. If, therefore, we regard the sensorium as occupying any portion of the brain, or rather of the encephalon, such as the medulla oblongata, we cannot admit the existence of a separate or accessary sensorium, situate in any part of the spinal cord, and capable of exercising the sensorial functions independently, when all nervous communication with the principal sensorium is cut off. If the power of sensation could ever be retained, even for a second, after the head has been severed from the body, we must suppose that the seat of that faculty is still in the head, and not in the trunk, the movements of which, when excited by galvanism, however they may resemble those which were performed during life in obedience to volition, in conformity to the design, and prompted by motives arising from bodily sensations, must be regarded as purely mechanical, or rather as the result of mere nervous irritation, and without the existence of either sensation or volition of any kind. We have decisive proofs that in the human system phenomena of this kind occur without any participation of the mind, that is, without either sensation, perception, or volition, in cases where, from accident, the spinal cord has been divided or compressed in the neck, or back, and where the muscles of the trunk that receive their nerves from that part of the spinal cord, which is situated below the injury, are affected with involuntary movements. We are therefore fairly entitled to extend the analogy to other animals whose construction does not materially differ from that of man, however appearances may seem to countenance the hypothesis of the sensibility of the trunk, after its communication with the brain has been intercepted.

(740.) Great confusion has been introduced into this subject by the inaccurate language employed by physiologists in theorizing on these phenomena; and in using which language they have lost sight of the essential distinction which should ever be kept in view between psychological and physical phenomena. The term *sensibility* should be strictly confined to such properties as are immediately connected with the mental changes which are denominated sensations, and which are characterized by attendant consciousness: all other corporeal properties or phenomena which do not produce these mental changes, are simply of a physical nature, and belong to another class to which the same appellation ought never to be applied. Bichat has committed this great error in employing the term *organic sensibility* to denote phenomena of this latter kind; and the introduction of this term has led to an interminable confusion of ideas among those who have adopted his system, and who have been thereby led, from this misapplication of terms, to some vague notion of a peculiar but obscure kind of actual sensation, which they attributed to portions of the nervous system unconnected with the sensorium, independent of all percipience, and partaking of the mystical doctrines of Stahl and Von Helmont as to the operations of their supposed *anima* and *archæus*. (See § 101.)

For the dissipation of these clouds which have too long obscured the ideas and perplexed the reasonings of physiologists, we need only direct on the subject the searching light of philosophical analysis, which will render its outlines clear and distinct, and enable us to follow their various flexures and crossings, and obtain more correct views of the landscape in all its details.

(741.) The power exercised in the instances we have described by the central parts of the nervous system, independently of all sensorial phenomena, is that power which we have already distinguished by the term *nervous power*, in contradistinction to the *sensorial power* exercised by the same system. (See § 96, 536, 537.) To Dr. Wilson Philip belongs the merit of having first clearly pointed out the distinction between these two orders of functions, and of having given them specific appellations. Dr. Marshal Hall has lately introduced a new term, that of *reflex function*, to designate the series of phenomena consisting of the transmission of impressions by certain nerves to the central parts of the nervous system, (which he limits to the spinal cord,) and the consequent transmission of an action by the muscular nerves, which is followed by the contractions of muscles. To the whole system concerned in this function he gives the name of the *excito-motory system;* the nerves receiving the impression he calls the *incident* nerves; and those conveying it to the muscles, the *reflex nerves.*

(742.) It would appear from what has been already noticed, (§ 711,) that every muscle the action of which is capable of being brought under the dominion of the will, and which is therefore entitled to be classed among the voluntary muscles, may occasionally be made to act by other causes, applied either directly to their own fibres, to the nerves distributed to them, or to other parts connected with them only by the medium of portions of the brain, spinal cord, or the ganglia of the sympathetic: and it has been conjectured that the sets of nervous fibrils which are instrumental in the performance of these latter functions, are different from those which are employed to transmit the impressions of sensation and volition. This latter view is the one adopted by Dr. W. Philip, who observes that, " however blended the organs of the sensorial and nervous powers may appear to be, we are assured that they are distinct organs by the fact, that while the organs of the nervous power evidently reside equally in the brain and spinal marrow, those of the sensorial power appear to be almost wholly in man, and chiefly in all the more perfect animals, confined to the former."[1] It does not, however, appear that we as yet possess any direct means of either establishing or disproving the truth of this supposition.

Involuntary motion.

(743.) There yet exists another class of muscles, comprehending those which never, under any circumstances, become voluntary. To this class belong the heart and blood-vessels; the muscular fibres of the excretory ducts, and other parts of the organs of secretion; and the coats of the stomach and of the intestines. As the influence of the nervous system on those muscles is of a very pecular kind, and as their motions are governed by different laws from those which regulate the voluntary muscles, it will be necessarv to bestow on them a separate consideration.

(744.) M. Le Gallois, in a work entitled, *Expériences sur le Principe de la Vie, notamment sur celui des Mouvemens du Cœur, et sur le Siège de ce Principe*, thought he had proved that the muscular power of the heart is derived altogether from the spinal cord, and not from the brain. He found that on injuring the spinal cord, the heart is so enfeebled as no longer to be capable of propelling the blood; but that the contractility of the heart may continue unimpaired when the brain, and even the whole head, is removed, provided respiration be kept up by artificial inflation of the lungs. He conceived, therefore, that the use of the cardiac nerves is to establish the connexion between the spinal cord and the heart; and that whenever the heart is affected by passions and emotions of the mind, which produce their first changes on the brain, it is influenced through the medium of the spinal cord, which is itself affected by the brain. Dr. Wilson Philip has shewn the fallacy of this conclusion; and has completely established, by direct experiment, that under similar circumstances, the brain has just as much influence on the motions of the heart as the spinal cord. The motion of the heart is no more affected by the removal of the spinal cord than by that of the brain, if the same precautions be taken in either case, of effecting the removal slowly, and with as little disturbance to the remaining parts of the system as possible. If, on the other hand, either the brain or the spinal cord be suddenly crushed by a blow, which at once destroys its texture, the heart is instantly paralysed, and its motions cease. Although the muscular fibres of these organs are not excited to contraction by irritations of any kind applied to their nerves, nor their contractions arrested by the section of those nerves, yet these actions are immediately accelerated by the application of chemical stimulants, such as alcohol, either to the brain or to the spinal cord; and retarded by the application of opium, tobacco, or other narcotic agents, to the same parts.

(745.) It would appear, therefore, that although there is no essential difference between the real nature of the irritability of the involuntary, and that of the voluntary muscles, yet that each is influenced by different kinds of stimuli, and by stimuli applied through a different medium. Mechanical stimuli, such as punctures or partial divisions of the fibres of the muscles of voluntary motion, act on them only through the medium of their nerves; and if applied to the parts of the brain whence these nerves originate, will throw those muscles into the most violent spasmodic contractions. The heart, on the contrary, is but slightly disturbed in its movements by the same kind of injury done to the brain or spinal cord, provided the injury be confined to a small portion of those organs. That important organ appears to be affected only in proportion to the extent of the parts that have suffered injury, and to the suddenness with which that injury has been inflicted; as is exemplified by wounding the brain rapidly in many directions. Chemical stimuli, on the contrary, applied to any part of the brain or spinal cord, produce considerable and immediate increase of the action of the heart; while the voluntary muscles continue all the while unaffected; and the animal betrays no sense of pain. Accordingly the heart, having no direct dependence on any part of the nervous system, may continue its action when the brain and spinal cord are destroyed, and even when it is itself removed from the body. The nerves with which it is supplied, however, render it capable of being influenced through those causes, as, for example, by the passions, and by various poisons, which affect a considerable portion of the nervous system.

Ganglion system.

(746.) The contractile powers of the other parts of the vascular system, and most of the secreting organs, as well as the irritability of the stomach and intestines, are, like those of the heart, independent of the nervous system, yet capable of receiving an influence through the medium of the nerves; and the same law appears to extend generally to all the involuntary muscles. The extensive nervous communications which are naturally established between the whole system of involuntary muscles, and the organs in which they enter, seem to be necessary in order that any one set of these organs should be subjected to the influence of all the others. This purpose is effected by that complex arrangement of nerves, which has been termed the *ganglionic system*, from the great number of ganglia annexed to them. The great sympathetic nerve forms the principal connecting nerve in this system between all the muscles of involuntary motion; which, through the medium of filaments from the extensive chain of ganglia belonging to this nerve, are placed in connexion with every part of the brain and spinal cord. Each ganglion belonging to the sympathetic system has been considered as a secondary centre of nervous influenee, receiving supplies from all the latter parts, and conveying to the former organs the united influence of the nervous system in general. The muscles of voluntary motion, on the other hand, are subjected to the influence of only small portions of these central parts of the nervous system, and receive their nerves directly from these parts; and usually without the intervention of ganglia, and with comparatively few intermixtures of nervous filaments; such intermixtures being designed for the purpose of effecting combinations with the nerves of sensation, and especially with those which convey impressions relative to muscular motion.

(747.) The ganglia of the sympathetic system have, accordingly, been considered by many physiologists as performing functions similar to those of the portions of the spinal cord exercising mere nervous power; that is, in the language of Dr. Marshall Hall, performing reflex functions, and belonging, together with the branches of the sympathetic nerve, to the excito-motory system.[2]

SECT. VIII.—*Psychological relations of the Sensorium.*

Psycholo gical rela tions.

(748.) In treating of the functions of the nervous system which involve operations both of the body and of the mind, it is very difficult to draw the strict line of distinction between them, and avoid treating of subjects which properly belong to metaphysics. We have endeavoured, in the preceding account of the physiology of man, to confine ourselves strictly to the consideration of the corporeal changes which accompany the different mental affections, and to avoid, as much as possible, encroaching upon the province of the metaphysician. That certain physical changes take place in some portion or other of the cerebral mass in connexion with various mental changes, we have the clearest evidence: but of the nature of these physical changes we are wholly ignorant; nor does the present state of our information afford a shadow of hope that we shall ever gain any more precise knowledge of them. The mental changes, on the other hand, constitute a distinct and separate branch of science; to the knowledge of which we arrive by channels totally different from those which instruct us relatively to the former; namely, by consciousness, and by reflexion on the series of phenomena furnished to us by consciousness. These two subjects of study, the material and the immaterial, however numerous may be the subtle and inscrutable links that connect them, constitute two worlds, which in our conception must for ever remain totally distinct; nor is it even possible for us to conceive how any knowledge which we can obtain with relation to any physical changes in our corporeal frame, or any physiological laws that may regulate the succession of those changes, can in the smallest degree assist us in understanding the phenomena of intellect, and the affections of the soul.

unctions the brain.

(749.) The brain has been very justly regarded as the organ of the mind; that is, the corporeal instrument invariably employed in the operations of the mind. This is a necessary corollary from the proposition that no mental operation can take place without the co-existence of some physical change in the brain. But a second proposition, the converse of the former, has been advanced; namely, that the mental operations are the "functions of the brain." But this latter proposition would be true only on the supposition that the physical change in the brain, and the corresponding mental change of which we are conscious, are one and the same thing. Until this fundamental doctrine of materialism, namely, the identity of matter and mind, be proved, we cannot include under the functions of the brain, both the mental changes and the corporeal changes. The physiological office, or function of the brain is the production of certain corporeal changes, connected in some inexplicable manner with certain mental changes; which two classes of changes are in their nature, as far as we are capable of forming any conceptions of them, radically and essentially different from each other.

(750.) The ambiguity of ordinary language is, indeed, a frequent source of confusion of ideas on this subject. We speak correctly when we say that the eye is the organ of vision, because it is an instrument without which vision could not be exercised; but were we to regard vision as the function of the eye alone, we should evidently be guilty of inaccuracy in extending too far the purpose of that instrument. The function of the eye is to produce certain impressions upon the retina, which impressions are but links in the series of changes, of which only the last constitutes vision. These impressions made on the retina are followed by changes in the course of the optic nerves, and these again by changes in the sensorium. The function of the optic nerves, and of that part of the sensorium in which they terminate, is the production of these physical changes. Vision, an affection of the mind, is undoubtedly the effect of these physical changes, but is not properly the function of any of these organs, except the term function be used in that loose and popular sense, in which it is made to embrace all the remote consequences of the phenomena, in the production of which the organ in question is concerned. In this sense, indeed, vision, and all the mental affections consequent upon vision, might certainly be said to be functions of the eye; but in the strict philosophical sense, the function of the eye is limited to the formation of images on the retina, and the impressions thereby received by the retina; and, in like manner, the proper function of the brain is the production of certain physical changes in the fabric of the brain, consequent upon certain impressions made on the nerves by external causes, and consequent also upon certain internal affections of the mind, which are capable of exerting on it this influence.

(751.) The affections of the mind are very various and complicated; a great multitude of ideas and associations are treasured up in it, and constitute a variety of powers, of faculties, of propensities, of instincts, and of passions. The conformation of the brain, which is the organ of the mind, is also very complex, and appears to consist of an assemblage of different parts, constructed evidently with extreme refinement, and arranged with great care, and with very elaborate design. The idea naturally suggests itself, that these different portions recognised by the anatomist may, perhaps, have some correspondence with the several faculties into which the phenomena of the mind have been analyzed by the metaphysician. This question has indeed been often started, and is quite distinct from that of the materiality or immateriality of the soul; for it is perfectly conceivable that if the immaterial soul acts by means of material organs, and receives impressions from those organs, its different operations may require different organs. But this subject, together with the theories to which it has given rise, having been already amply discussed under the Treatise on PHRENOLOGY, we need pursue the subject no farther in this place.

SECT. IX.—*Sleep.*

Sleep.

(752.) Whilst the functions which have for their object the reparation of the state of the body, and which include assimilation, absorption, circulation, respiration, secretion and nutrition, continue in constant activity, all those connected with sensation and volition require intervals of repose, and cannot be maintained beyond a certain time without great exhaustion of the nervous power. These periodical intermissions in the activity of the animal functions, so necessary for the renovation of the power on which they are dependent, constitute *sleep*. The eye-lids close to protect the eye from injury, and the eye-ball is turned upwards; the external senses and all the active intellectual operations are suspended; the voluntary muscles are relaxed; and we become insensible to all external impressions. The movement of the involuntary muscles continue, though with somewhat less energy than during our waking hours. The heart beats with diminished force and frequency, and the muscles of respiration act more slowly; but the inspirations are more full and deep, and the secretions are in general less abundant; but digestion and absorption are carried on with great activity. The power of sensation, though blunted, is not altogether lost during sleep, as is proved by the continuance of that part of the movements of the muscles of respiration, which depend on sensation. Instinctive movements of the limbs, producing a change of posture, frequently take place from an obscure sensation of constraint at their continuing long in the same position. Any unusual impressions made on the organs of the senses are felt during sleep, and even remembered; and, if the impression be sufficiently vivid, will interrupt sleep.

Dreaming.

753. Neither is the mind wholly inactive during sleep; it is still occupied with a succession of ideas, which is often more rapid than when we are awake; the imagination is even more vividly exerted, and the images that pass before the mind are considered as realities. This constitutes *dreaming*, a state which is characterized also by the peculiar circumstance of the want of all voluntary power of directing the succession of ideas. Trains of ideas and images commence and follow one another, being indissolubly linked together by those laws of association which are independent of volition.

Somnambulism.

(754.) An extraordinary modification of dreaming occurs in what is called *somnambulism*, or sleep-walking; where the will recovers a certain degree of power over the mental operations, and over the voluntary muscles both of speech and of motion, while the body is still less capable of receiving external impressions than in ordinary sleep. In this peculiar kind of sleep, the insensibility to most external impressions is so profound, that it is scarcely possible to awaken the person without employing a considerable degree of violence. When at length he does awake, which often happens as suddenly as from natural sleep, he usually retains little or no recollection of what happened to him, or of what he did while in this singular state.

(755.) A state very similar to that of natural somnambulism, is induced in some nervous constitutions, especially those of young females, by certain manipulations which produce a long-continued reiteration of impressions made on the senses, and which probably act through the medium of the mind. These have been ascribed to a special agency, termed *animal magnetism*, or *mesmerism*. For an account of these effects, we must refer our readers to the article MAGNETISM, ANIMAL.

CHAP. XVII.—THE VOICE.

The voice.

(756.) The function of the voice, and of its modulation into articulated sounds, by which it is rendered subservient to speech, has been already pointed out as an important part of the animal economy of a being designed, as man evidently is, to hold extensive communion with his fellow creatures, and effect the rapid interchange of ideas and feelings, through the medium of the sense of hearing, (§ 24.)

Acoustic principles.

(757.) In order to understand the mode in which articulate sounds are produced, it will be necessary again to advert to the principles of acoustics, of which a brief account was given in introducing the subject of the physiology of hearing, (§ 623.) The object to be accomplished in the function of the voice is the production, not so much of single sounds, (such as those which result from single impulses given to the air,) but of continued sounds, composed of reiterated vibrations, repeated at short and equal intervals, and constituting a *musical note*. There are two principal modes in which such sounds are produced; the one, that which is practised in stringed musical instruments, in which the impulses are given to the air by the vibrations of solid bodies, which are generally chords having different degrees of tension; and the other, such as is adopted in wind instruments, where the air is thrown into undulations at regular intervals, by alternations of expansion and condensation, generally taking placing during the passage of a stream of air through a cavity in which it suffers certain reflexions and reverberations, alternately impeding and promoting its progress. In many cases the effect is obtained by a combination of both these means, as in a hautboy, where an elastic plate, or *reed*, is placed in the course of the air which is passing along a tube, capable by its form of producing a musical note, independently of such addition.

Organs of the voice

(758.) In the construction of the vocal organs of man, nature has resorted to combinations of this kind. Advantage is taken of the function of respiration to convert the passages through which the air is admitted to, and expelled from the lungs, into a sounding instrument; by adapting to the upper part of the trachea, a curious mechanism, consisting of a frame-work of elastic cartilages, with an apparatus of ligaments, muscles, membranes, and mucous glands, the assemblage of which is termed the *larynx*. The aperture through which the air passes is denominated the *glottis*. Here it is that the breath is *vocalised*; that is, rendered not only sonorous, but also modulated in its pitch, so as to give rise to a musical sound. Modifications are subsequently impressed on these sounds, by the changes which the undulations are made to undergo in the cavities of the pharynx, of the nostrils, and of the mouth, according to the various forms and dimensions given to those cavities by the motions of the muscles of the pharynx, the velum pendulum, the uvula, the tongue, the cheeks, and the lips; and according to the obstacles placed in the way of the passage of the air by the movements of these parts, and the application, in particular, of the tongue and of the lips to the palate and to the teeth.

(759.) The cartilages of the larynx are five in number, namely, the *thyroid*, the *cricoid*, the two *artenoid*, and the *epiglottis*. The *thyroid*, which is also called the *scutiform*, or shield-like cartilage, is placed at the upper and fore-part of the larynx, and is the largest of the whole. It consists of two lateral wings of a quadrangular form, uniting in front in a longitudinal angle, which is felt projecting in the fore-part of the throat, and has obtained the name of the *pomum adami*. From the posterior corners, four processes project, called its *cornua*, distinguished into two *superior*, and two *inferior*. The *cricoid*, *annular*, or *ring-like* cartilage, is placed below and behind the former; and it has four articular surfaces, two below, for its connexion with the inferior cornua of the thyroid cartilage, and two above, for the articulation of the *arytenoid* cartilages, which are bodies of a pyramidal shape, much smaller than the rest, and placed one on each side, upon the upper posterior and lateral parts of the cricoid cartilages. They give attachment to ligaments, and compose a part of the sides of the opening called the *glottis*. The whole passage is lined internally by a delicate mucous membrane.

(760.) The *epiglottis* is a cartilaginous lid, which has a pointed shape, resembling the leaf of an artichoke. It is fixed at its base to the os hyoides, to the thyroid cartilage, and to the root of the tongue; and hangs obliquely backwards over the opening of the glottis, which extends in a line from behind forwards, and is formed by the approximation of the vocal ligaments, or *chordæ vocales*. These ligaments, which consist of fibres endowed with a high degree of elasticity, are covered with the fine membrane which invests the whole of this delicate apparatus, and extends down the trachea into the lungs, and above to the posterior fauces. These are attached together in front to the thyroid cartilage, and behind to the arytenoid cartilages, where, in the relaxed condition of the organ, they are at some distance from each other, so as to leave a triangular opening for the passage of the air. The effort to speak, or to utter a vocal sound, commences with the action of certain muscles, more particularly the *crico-thyroidæi*, which stretch the vocal ligaments, and the *crico-arytænoidei laterales*, and the *arytænoidei transversi and obliqui*, which conspire to make the arytenoid cartilages approximate. By these combined actions, the vocal ligaments are brought near to each other, in parallel directions, so that the interval between them or *rima glottidis*, as it is called, is reduced to a mere narrow linear fissure.

Formation of vocal sounds.

(761.) When, therefore, the air is forcibly propelled from the lungs through the glottis, while the vocal chords are in this approximated position, different vocal sounds will be produced, according to the degree of tension which is given to the chordæ vocales. The greater the tension of these ligaments, the more frequent will be their vibrations, and the higher the pitch of the note they produce. The loudness of the sound emitted is proportioned, not to the frequency of the vibrations, but to their extent, or the magnitude of the excursions made by the vocal chords in vibrating. The varied degrees of tension which can be imparted at will, and instantaneously, to the vibrating ligament of the larynx, by the finely regulated actions of their different muscles, constitute the chief source of superiority in the vocal organ to any instrument of human invention.

(762.) The muscles above enumerated as giving tension to the vocal ligaments, and clossing the glottis by the approximation of the arytenoid cartilages, are opposed by their antagonists the *thyreo-arytænoidei*, which relax the vocal ligaments, and place them in the vocalizing position, and by the *crico-arytænoidei postici*, which separate the arytænoid cartilages, and thereby open the glottis. Thus the instrument we are considering is capable of an infinite number of changes of form, and susceptible of the finest modulation.

(763.) It should be stated, however, that many physiologists have maintained that the musical tones of the voice depend, not merely on the tension of the vocal ligaments, but also on the size and form of the aperture through which the stream of air is propelled, and that the larynx partakes as much of the properties of a wind as of a stringed instrument. The principal advocate of this opinion was Dodart, whose first paper[1] contains a historical account of the views on this subject taken by the earlier physiologists. His chief antagonist in this controversy was Ferrein,[2] who compares the larynx to a violin, or harpsichord, and conceives that the voice is produced by the vibrations of the edges of the ligaments of the glottis; and compares the action of the air to that of a bow setting these parts into vibration. The hypothesis of Dodart has been adopted by Blumenbach, who conceives the action of the larynx to be analogous to that of the flute. But the generality of physiologists consider the action of the ligaments of the glottis to be vibration, and similar to that of strings resounding by their tension alone. Such is the view taken of the subject by Dr. Young,[3] Soemmerring,[4] Magendie,[5] Willis,[6] and Mayo,[7] who all maintain that the voice depends on the vibrations of the chords; the frequency of which must, according to all acoustic principles, be regulated solely by the tension of the chords.

(764.) Dr. Willis observes that, for the production of laryngeal sounds, something more is requisite than a definite tension of the vocal ligaments. He has shown, by experiment, that in order that the edges of two membranes, such as those made of leather or of Indian rubber, opposed to each other with a narrow interval, may vibrate, the parts of the membrane near their edges must be brought parallel to each other. Comparing this disposition of membrane in his experiment with the parts of the larynx, he supposes that the latter will not vocalize, unless some change, independent of, and superadded to, the tension of the ligaments, be produced in their relative position.

(765.) The experimental proof on which Mr. Willis founds his conclusion that some change in the relative position of the vocal chords is necessary to produce an audible vocal sound, is the following. If the finger be placed upon the membrane which intervenes between the thyroid and cricoid cartilages, their approximation or increased remoteness may readily be felt. Now their approximation being produced by the action of the crico-thyroid muscles, involves an increased tension of the ligaments. But it is possible by an effort to keep these cartilages approximated, while something is still wanting in the internal arrangement of the larynx, to fit it for the production of sound. When the thyroid and cricoid cartilages are thus approximated, and the ligaments thus shewn to be in a state of tension, if air be impelled through the larynx, sound does not necessarily follow; the ligaments have still, Mr. Willis concludes, to be placed in the vocalizing position.[8]

uence of trachea.

(766.) There are still other parts of the vocal apparatus connected with the sounds produced at the larynx, which require to be adverted to. Among these the varying conditions of the trachea appear to have the greatest influence on those sounds, and of this influence Mr. Wheatstone proposes the following theory:[9]

"Such a vibrating apparatus as we have described the ligaments of the glottis to compose, is by itself capable, from the varying tension of those ligaments, of producing all those sounds of which we find the voice to be susceptible. But the intervention of a tube between the lungs and the larynx, must necessarily exercise an important influence on the voice, though it has never yet been taken into consideration. For, if we unite such an apparatus, or a free reed, which may serve as a substitute for it, with a tube (supposing it for the moment fixed to a determinate degree of pitch), it is found, that, unless the column of air in the tube is of such a length as to be separately capable of producing the same number of vibrations, the sound cannot be obtained in its greatest force and purity, and that when the tube is half this length, the discordance between the tube and the reed is so great, as to prevent the production of the sound: between these limits the sound is intermediate in intensity and quality. This influence of the tube is by experiment found to be the same, whether the tube be placed after the reed, as in several wind instruments, or before it, as in the vocal organ. We will now suppose the tube to be unalterable in its length, and the reed necessarily to undergo all its varying modifications of pitch; the sounds, instead of being of even quality, will be irregular in intensity, and require different degrees of effort to produce them, while, in some parts of the scale, they will be totally extinguished. All this may be prevented, and the utmost regularity obtained, by shortening the tube, in proportion as the vibrations of the reed increase in frequency. The trachea is obviously incapable of changing its length within limits sufficiently considerable to serve this purpose; but Savart's experiments have shown, that a tube of constant length may be made to produce a great range of sounds, by making it of elastic sides susceptible of variable tension. The analogy between such a tube and the trachea is perfect."

(767.) One mode of giving increased tension to the windpipe is the action of the transverse muscular fibres which bind the ends of its cartilages together. Another is the elevation of the larynx, which follows in so remarkable a degree the elevation of the pitch of the voice. Practice in singing improves the voice, partly by giving us a more ready command over the tension of the trachea, and partly by enabling us to regulate and vary the opening of the glottis while we preserve the tension of the vocal chords.

Formation of articulate sounds.

(768.) Such being the mode in which vocal sounds are produced in the larynx, the next step in the inquiry will relate to modifications they receive from the shape of the cavities of the pharynx and mouth, through which the expired air has yet to pass. When thus modified they become not merely vocal, but *articulate* sounds, and constitute the elements of speech.

(769.) This branch of the subject has been ably investigated by Sir Charles Bell,[10] who has traced the influence which the changes produced by the muscular actions of the tongue and fauces, on the shape of the cavities of the mouth and pharynx, have on the resulting articulate sounds. He has examined the succession of actions which must be performed before a word can be uttered, and which he finds to consist in the compression of the thorax, as well as the adjustment of the glottis, the elevation and depression of the larynx, and the contraction of the pharynx.

Pronunciation of vowels

(770.) The elementary articulate sounds of a language consist of vowels and consonants. Vowels are continued sounds, produced when the passage of the air through the fauces is uninterrupted, the fauces being only more or less narrowed. Each vowel requires a different elevation of the tongue or contraction of the lips. Thus the sound of the broadest pronunciation of the letter *a*, which occurs in the word *awe*, results from the lowest position of the tongue, giving its greatest depth to the cavity of the mouth. The ordinary sound of *a*, as in the word *age*, is produced by a certain elevation of the tongue, reducing considerably the capacity of the mouth. The vowel *e*, pronounced as in *eve*, is sounded by raising the tongue still more, so as to leave a more contracted channel for the exit of the air. The positions for *o* and *oo*, are obtained by placing the fauces in the position first described, namely, that for *au*, and then approximating the lips.

[9] Ibid. p. 252.

[10] *Philosophical Transactions* for 1832, p. 299.

Of consonants.

(771.) The pronunciation of consonants is effected by interruptions to the passage of the air in some part of the cavity of the mouth, by various motions of the tongue and lips, which, when applied to the palate or the teeth, narrow or close the channel for its exit.

(772.) The following experiment is mentioned by Mr. Mayo[1] as having been made by M. Deleau, demonstrating that the articulation of vocal sounds takes place in the fauces. He introduced through the nostrils into the pharynx a flexible tube, and, by means of a gum bottle, impelled air through it into the fauces; then, closing the larynx, he threw the fauces into the different positions requisite for producing articulate sounds, when the air impelled from the gum bottle became an audible whisper. Dr. Bennati repeated this experiment, allowing at the same time laryngeal sounds to pass into the fauces, when each articulated letter was heard double, in a voice at once, and in a whisper.

(773.) Consonantal sounds may be divided, first, into *aspirates* and *sonants*, or, secondly, into *continuous* and *explosive*.

(774.) The aspirates are those which may be rendered audible without a vocal sound, as is the case with *p*, *t*, *k*, *h*, *f*, *th*, *s*, and *sh*. The sonants are those which, without any appreciable difference in the shape of the fauces from the form required for the pronunciation of the preceding to which they are allied, are not heard without a vowel sound, either previously uttered, as in *b*, *d*, *g*, *v*, *z*, and *l*, or subsequently, as in *g*, or in conjunction with it, as in *r*.

(775.) Continuous consonants are pronounced when the vocalized air passes through some part of the organ, previously rendered very narrow. Explosive consonants are those which are produced by the interruption to the current of air occasioned by the entire closing of the passage, and its being allowed to burst out with some force by the sudden opening of the same passage.

(776.) The nasal consonants, *m*, *n*, and *g*, are distinguished from the rest by the peculiar character of their articulation arising from the breath being allowed to pass through the nostrils; while in the pronunciation of the others, the soft palate being raised closes the posterior nostrils, and prevents the sound from diffusing itself in that direction.

(777.) We refrain from entering into any further details with regard to the position of the fauces, tongue, and lips, in the pronunciation of the different consonants, having already treated of this subject at some length, in the article Deaf and Dumb, to which we shall therefore refer our readers.[2]

Pitch of the voice.

(778.) The low pitch of the voices of men compared with those of women and boys, arises both from the greater general size of the larynx, and also the greater length of the chordæ vocales, which has been found to measure nearly double that of the latter. In attempting to utter high notes, voices, naturally grave, assume the character of the *falsetto*. This, Mr. Willis supposes, may result from the shortening of the vocal chords; but Mr. Wheatstone is disposed to ascribe it to the tension given to the windpipe being such as to reinforce the laryngeal sounds by subdivisions.

(779.) Some curious observations on the mechanism of the voice during singing have lately been given by Dr. Bennati,[3] who states, that the compass of his own voice extends to three octaves. He concludes from his inquiries, that it is not merely the muscles of the larynx which modulate the sounds, but those also of the os hyoides, and the other neighbouring parts. He mentions that, on removing part of the tonsils, the operation was followed by the raising of the voice half an octave, without altering its compass. Mr. Mayo supposes this effect to result from the cicatrix stretching the mucous membrane of the larynx, and thus giving increased tension to its inner surface.

CHAP. XVIII.—GENERATION.

Sect. I.—*General Views.*

Generatio

(780.) As far as we are permitted to scan the designs of the Almighty Creator in the formation of organized beings, they appear destined to a mode of existence characterized by perpetual mutation. Their living state is made to consist of a perpetual series of actions and reactions, in which nothing is intended to be permanent, not even the materials of which the combinations constitute the substance and organs of the body. All is subject to displacement, alteration, renewal, and renovation, during a certain definite period, which varies in each species, according to the primordial law of its constitution; and all must bend, when that period is exceeded, to the imperative law of mortality, to which every individual endowed with life is subjected.

(781.) But the same counsels which prescribed these limits, and decreed the extinction of life, and the dissolution of the frame in which it had resided, have providently ordained most ample means for the continuance of the race, and the indefinite multiplication of its numbers. Individuals perish, but the species is preserved in endless perpetuity by means of Generation; a function of paramount importance in the economy of nature, and for which the most ample provision has been made, and the greatest solicitude manifested to secure the accomplishment of its purposes. Nutrition and generation, indeed, constitute the only functions which can be said to be universally exercised by all organized beings, whether belonging to the vegetable or the animal kingdom, or whatever rank, from the lowest to the highest, they may occupy in the scale of nature.

(782.) But although the purpose is thus manifest, and the provisions for its execution thus effective and even exuberant, the immediate agency by which one living being is rendered capable of giving rise to another similar to itself, is enveloped in the most profound and most hopeless obscurity. No means within the compass of our understanding, no combination of the powers of matter which we can possibly conceive, no process of which the utmost stretch of human imagination can give us the most remote idea, has ever made the least approach towards the solution of this most inexplicable of all enigmas,—the production, nay, the apparent creation, of a living plant or animal by powers inherent in the organization of a similar being. We must content ourselves, in studying this inscrutable mystery, to observe and generalize the phenomena, in silent astonishment at the marvellous manifestation of design and of power exhibited in this department of the wonderful works of the Almighty.

Plans of productio

(783.) Various plans of reproduction are exhibited in the different classes of animals, but they are all reducible to three general heads, which may be designated by the titles of *fissiparous*, *gemmiparous*, and *sexual* reproduction. Many physiologists, however, have been disposed to admit the existence of a fourth mode of reproduction, which they have termed *spontaneous*, or *equivocal generation*. It is contended by the advocates of this hypothesis, that in many of the lower tribes, instances occur of the formation of animals without the intervention of any parents, and produced by the spontaneous union of certain elements, which might fortuitously be found in juxtaposition, in collections of the decomposing materials of other organized structures, after the extinction of their life. Although this opinion was at one period the generally prevailing doctrine, it is now, in consequence of the more extensive knowledge which has been obtained of the procedure of nature in the multiplication of animals, very generally exploded. The principal arguments in its favour were, in the first place, those drawn from the existence of intestinal worms, and other parasitic entozoa, in the bodies of animals, the germs of which appear neither to be introduced into the system from without, nor to have any assignable origin from within; secondly, those derived from the rapid appearance of infusory animalcules in all infusions of decaying animal or vegetable matter that are exposed for a short time to the air. But the analogy of every other department of the animal and vegetable kingdoms is directly opposed to the supposition that any living being can arise, unless it has originally sprung from an individual of the same species as itself, and of which it once formed a part. The difficulty which the hypothesis of the spontaneous production of infusory animalcules professes to remove, consists in our inability to trace the pre-existence of the germs in the fluid where these animalcules are found to arise, and to follow the operations of nature in these regions of infinite minuteness. But the recent discoveries of Ehrenberg relative to the complete organization of these beings, in which he in many instances detected the presence of generative organs, has very much diminished the difficulty of conceiving the possibility of their ova, so minute as to be wholly imperceptible, existing in great numbers in the fluid, or even in the atmosphere, and giving rise to all the observed phenomena.[1]

issipa- us generation.

(784.) *Fissiparous generation*, the simplest of all possible modes in which the species can be multiplied, consists in the spontaneous and gradual division of the body of an individual animal into two or more parts, which, when the division is completed, separate, and each soon assumes the form, and grows to the size of the parent, and becomes capable of performing all the functions which originally belonged to the undivided animal. The most common form of this mode of generation is met with in some of the simpler of the infusoria, as the monas, the gonium, the cyclidium, the vorticellæ, and the volvox. In the instance of the volvox, however, we find an approach to the next order; for the young are seen forming within the body of the parent, which is, in course of time, reduced to a mere membranous vesicle, and then bursts, and is torn into shreds, setting free the enclosed young, each of which immediately begins to execute its independent movements in the fluid.

emmipa- us generation.

(785.) *Gemmiparous generation* occurs when a new individual grows from the parent as a bud or sprout; at first exhibiting but little resemblance in shape or structure to the parent animal, but gradually assuming that form while still adhering to it, and being afterwards detached to commence an independent existence. Numerous examples occur of this mode of reproduction among the lower orders of zoophytes, such as animals belonging to the tribe of polypi, of which the hydra viridis, rendered celebrated by the researches of Trembley, may be taken as the type. Sometimes, as happens in the sponge, the actinia, and some of the lower orders of mollusca, the young are formed from small detached masses after they are separated from the body of the parent. These bodies, which are called *spores*, *sporules*, or *gemmules*, are generally of a rounded form and homogeneous structure; and the whole substance of which they are composed is converted during their developement into the new animal. Hence they may be regarded as buds formed in the parent body, but detached from it before the evolution of the new animal begins. In some species these gemmules are formed in all parts of the body indiscriminately; but in most others there is a particular generative organ provided for their formation.

Sexual generation.

(786.) In by far the greater number of organized beings no reproduction takes place except by the co-operation of two kinds of generative organs; laying the foundation of the distinctions of sex, and constituting *sexual generation*. As characterising the female, there is, in the first place, an organ, termed the *ovary*, of which the office is to form the *ova*, or eggs. These are organized bodies of a determinate shape, within which we first find the earliest rudiments, or *germ*, of the future animal contained in a fluid, which is itself enclosed in a vesicle. But the ovum, or, more properly speaking, the *ovulum*, thus formed exclusively by the female organs, never advances in its developement beyond this stage, and can never give rise to a new animal, unless it receive a certain vivifying impression given to it by the contact of a peculiar fluid, denominated the *semen*, which has been prepared by a totally distinct apparatus, constituting the male organs.

Fecundation.

(787.) The nature of the impression thus made by the seminal fluid on the ovulum, or immature ovum, and which constitutes its *fecundation*, and awakening in it a power of reproduction, which had before remained dormant, is wholly unknown; nor is it accompanied with any immediate alteration in its appearance or structure. None of the parts of the new animal can yet be discerned in the fluid contents of the ovulum, the great mass of which consists of a fluid holding in suspension granules of albuminous or oily matter; and a certain time must elapse, even in the most favourable circumstances, before the formative process exhibits its effects. The form of the egg is given by the external coverings, and there is in every egg a determinate part, at which the minute rudimental germ of the embryo is first visible. It is to this germ that the power of independent life and developement appears more immediately to belong, the granular fluid serving only as nutriment laid up in store for the supply of materials for growth.

Essential processes.

(788.) Thus the processes essential to sexual reproduction consist, first, in the formation of an ovulum by the female organs; second, in the secretion of the seminal fluid by the male apparatus; third, in the application of the seminal fluid to the ovulum so as to confer on it fecundity.

Varieties.

(789.) The mode in which this application is made differs according as the male and female organs are both contained in the system of the same individual, (as occurs in *monœcious* plants and hermaphrodite animals,) or exist separately in different individuals, (as in *diœcious* plants, and all the higher classes of animals.) In the former case, self-impregnation may take place, either by the required seminal access being effected internally in each individual independently of any other; or, in other cases, by the concurrence of two individuals in sexual union which reciprocally impregnate one another, (as is exemplified in the leech, the earth-worm, and the snail.) In the second division, where the male, or fertilizing organs, are possessed exclusively by one individual, and the female organs, or those producing the germ, by another, impregnation of the ova may take place either after their exclusion from the body of the female parent, by their contact with the male semen ejected on them when thus excluded, (as happens in the case of fishes and batrachian reptiles,) or within the body of the female; for which latter purpose, a new function, that of *copulation*, becomes necessary. This last mode of procedure is had recourse to by nature in by far the largest portion of the animal kingdom, including all the tribes of insects, nearly all the mollusca, and all warm-blooded vertebrated animals.

Modes of developement.

(790.) All the subsequent phenomena relate to the developement of the embryo thus brought into existence; to the supply of nourishment for its growth; and to the advantages of situation, of warmth, and of protection, which are necessary for the favourable procedure of the vital powers in the progress of this developement.

---

[1] See Bridgewater Treatise, *on Animal and Vegetable Physiology*, vol. ii. p. 591, note.

Oviparous.

(791.) Various plans are resorted to for conducting these processes of developement of the fecundated ovum. In that which is termed *oviparous generation*, the ovum, during its passage through the oviduct, receives the addition of a considerable quantity of nutritious matter, sufficient for the supply of all the materials requisite for its growth, until the period when it is capable of procuring food for itself; and it also acquires a capsule, or substantial covering, frequently of a calcareous nature, fitted for its protection under the circumstances in which it is to be placed. When thus formed it constitutes an *egg*, or complete ovum; and in this form it is either excluded from the body of the female parent, and hatched, if already fecundated, by the influence of external warmth; or if not previously fecundated, this change is accomplished by the seminal fluid of the male being shed upon it. The former case, which implies sexual congress, is exemplified in all insects and birds: the latter, which requires no such congress, obtains in fishes, and many of the reptilia. Both are comprehended under the term *oviparous animals.*

(792.) In a few instances the eggs, previously fecundated within the body of the female, instead of being expelled, remain in the oviducts until they are spontaneously hatched, and the young are then brought forth alive. This phenomenon, which is exhibited by many cartilaginous, and a few osseous fishes, by several reptiles, and by some gasteropodous mollusca, insects, annelida, and entozoa, has been called *ovo-viviparous generation.*

Mammiferous.

(793.) In *mammiferous generation*, on the other hand, the ovum, which is not perfected in the same degree as in the two former cases, remains within the female, and is attached, by the medium of a substance called *the placenta*, to the inner surface of an organ termed the *uterus*, where it receives nourishment from the maternal system, and where it remains until it is capable of independent life, and it is then brought forth. This retention during growth in the uterus is termed *utero-gestation*, and its subsequent exclusion is termed *parturition.* The young of mammalia after birth, although they cease to be organically connected with the mother, continue to derive from her a certain quantity of sustenance in the form of milk, which is a secretion from certain glands termed *mammæ*, the possession of which is the characteristic feature of this class of animals. An exception occurs in the case of marsupiate animals, in whom the young leaves the uterus at a very early period of its formation, while it is yet of a very small size, and its organs are comparatively imperfectly formed. On being born it is introduced by the mother into a pouch, termed the *marsupium*, formed by a folding of the integuments of the lower part of the belly; and a short time after it has been deposited there, it is found attached by its mouth to one of the nipples of the mammæ, which are concealed within the marsupium, and there receives its nourishment until it has acquired sufficient size and strength to quit its habitation. *Monotrematous generation*, which is peculiar to the ornithorynchus and echidna, is not yet perfectly understood. The generative organs, and the ova within the ovaries, in these animals, partake in a great degree of the oviparous type; but they are also combined with the presence of mammary glands, which perform the office of lactation, as in the strictly viviparous class of animals.

(794.) The following table, which is nearly that given by Dr. Allen Thomson,[1] exhibits a synoptical view of the various forms of the reproductive process occurring in different classes of animals:—

Modes of Reproduction.	Non-Sexual,	*Fispasirous,* .	A. The parent splits into two or more parts, each part becoming a new animal. 1. By transverse fissure. 2. By longitudinal fissure. 3. Irregularly. B. The parent bursts, and the included young are discharged.
		Gemmiparous, .	A. *Buds* sprouting from the parent stock. B. *Gemmæ.* or Sporules, formed— 1. In all the parts of the body. 2. In one part only.
	Sexual,	*Monœcious,* or Hermaphrodite,	Both sexual organs contained in the same individual. 1. By self-impregnation. 2. By mutual impregnation.
		Diœcious, .	A. *Oviparous;* eggs laid, and afterwards hatched. 1. Eggs fecundated externally. 2. Eggs fecundated internally. B. *Ovo-viviparous;* eggs hatched within the maternal body. *Mammiferous;* the parent suckling the young by mammæ. 1. *Monotrematous.* 2. *Marsupial.* 3. *Placental,* or strictly *viviparous.*

(795.) A wide range of inquiry is here opened to us, comprehending, if we were to include in its field the whole of the animal kingdom, an immense multitude of facts, to the complete study of which the labours of a whole life would be inadequate. We are, however, to confine ourselves, at present, to the view of human physiology; but even here the great extent of the subject obliges us to reduce within a narrow compass the account we have to give of this important and interesting department of the science. For this purpose, after a short description of the circumstances relating to the unimpregnated ovum, we shall proceed to the physiology of the male and female systems respectively, bringing its history to the period of the fecundation of the ovum. This latter subject will lead us to consider some of the most celebrated theories of generation; after which we shall briefly consider the phenomena of utero-gestation and parturition, which are functions belonging exclusively to the female parent, but which accompany and are accommodated to the successive changes attending the developement of the fœtus. Of these latter changes, relating to the system of the new individual, it will be more convenient to give the history separately.

Sect. II.—*Unimpregnated Ovum.*

(796.) Much difficulty is necessarily experienced in obtaining direct evidence of the early changes occurring in the process of human generation, from the scanty opportunities allowed us of direct observation of those changes, and from our being precluded from resorting to the most instructive fountain of knowledge, namely, experimental research. While, therefore, we obtain occasional views of the actual phenomena which occur in man, we must content ourselves with filling up the chasms in the continuous history of his generation, by the observation of those which are presented in the lower animals that most resemble him in the mode in which this function is conducted, and by remoter analogies derived from other classes.

Structure and functions of the ovarium. Graafian vesicles.

(797.) It is well established, from these combined sources of information, that the essential part of the female system concerned in generation is the *oviary*, or *ovarium*, of which there is one, situated on each side, in the cavity of the pelvis. The ovaries are small capsular bodies, of an oblong, or oval, and somewhat flattened shape, which are enveloped in the fold of the peritoneum, forming the broad ligaments of the uterus. They are composed of a white and loose cellular texture, in which we discover several minute vesicles, or cysts, filled with a transparent fluid, and termed, from the name of De Graaf, who first observed them, the *Graafian vesicles.* Their number is generally from fifteen to twenty in each ovarium, and they vary in size, the largest being about one-third of an inch in its longest diameter. The fluid which is contained in these vesicles is slightly viscid and albuminous, inclining to a yellow colour in the most turgid vesicles, containing numerous granules of an irregular shape, and a few globules of oil, but being otherwise pellucid.

---

[1] *Cyclopædia of Anatomy and Physiology*, by Dr. Todd, article Generation, p. 438, to which article we are largely indebted in the compilation of this chapter.

(799.) Besides the peritoneal covering already described, the ovarium has a cellular coat proper to itself. Each of the Graafian vesicles has a double investment; the outer coat consisting of a close filamentous texture; and the internal layer being thicker, softer, and more opaque than the outer, from which it is readily separable after maceration, and having a slightly villous inner surface. The membrane immediately containing the granular fluid above described, also exhibits the appearance of being studded with granules, and is on that account styled the *membrana granulosa.* Within the granular fluid is found a body, composed of closely coherent granules, which has been denominated by its discoverer, Baer, the *discus proligerus,* and which he represented as having a flattened or discoid form. and as forming the bed in which is placed the minute vesicle of the *ovulum,* or germ of the unimpregnated *ovum.* The later researches of Dr. Martin Barry, of which he has given an account in a paper communicated to the Royal Society of London, have thrown further light on this branch of Zoology. The following is a summary of the principal conclusions at which he has arrived on this subject.

ulum.

(800.) The ovulum of all vertebrated animals, and of many of the invertebrata also, is contained in a vesicle, called by some authors the *chorion,* but which Dr. Barry thinks it desirable, wherever found, to call an *ovisac.* He considers the Graafian vesicle of the mammalia, and also the capsule, or *calyx* of oviparous vertebrata, as an ovisac which has acquired a covering; which covering is the "*couche externe*" of the "*capsule de la vesicule de Graaf*" of Baer. The *perfect* Graafian vesicle of the mammalia has been shewn by preceding physiologists to be analogous to the perfect capsula, or calyx of the bird; but the analogy is found by Dr. Barry to be much more remarkable between the ovisacs of these two classes of animals, before these additional coverings have been acquired; and this analogy may also be extended to those of amphibia and fishes, so that, in fact, the surfaces of all the vertebrata are in their original structure essentially the same; a conclusion which Dr. Barry is disposed to extend also to the ovisacs of many of the invertebrata.

(801.) The ovisac, being originally an independent structure, can be better studied in this state than at a later period, when it has become the lining membrane of the Graafian vesicle or calyx. Thus, while the perfect Graafian vesicle of the mammal, and the perfect capsule of the bird, are obviously corresponding structures, there yet exists this difference, that there is a space, filled with a large quantity of fluid in the former, not present in the latter; a difference which does not exist in the early stages of formation, when ovisacs in general appear in this respect to be essentially the same. The structure of the ovisac may be examined, in some mammalia, when it does not exceed in length the 600th, or even 1200th part of an inch; so that in the latter case, a cubic inch would contain 1728,000,000.

(802.) The ovisac of the vertebrata, and perhaps of other animals, is at first of an elliptical form. In the mammalia and birds, myriads of ovisacs and ovula are formed, which never reach maturity. Many of these are formed in the substance of the proper membrane of larger ovisacs, and are therefore termed by Dr. Barry *parasitic ovisacs.*

(803.) The ovisac is formed in a cavity proper to itself, with which it does not appear to have any organic connexion. The granules found in the fluid of the ovisac are very characteristic in their appearance, and imply the presence of albumen in a concentrated form. A stratum of these granules, found on the internal surface of the proper membrane of the ovisac, constitutes, as Baer remarks, a distinct membrane. But the mass of granules described by that anatomist as being discoid, is believed by Dr. Barry to be of a spherical form. This latter observer finds that the ovulum of vertebrated animals is, when first formed, situated in the centre of the fluid of the ovisac, and more or less obviously held there by a flake of granules; and has at first no proper envelope of granules. In the mammalia, there forms around the ovulum a granulous covering of a spherical form, which Dr. Barry terms the *tunica granulosa*; but it has no discoid mass of granules proper to it. At a certain period, the ovulum of the mammalia passes from the centre of the ovum to the periphery; and there, while invested by its granulous tunic, it penetrates the membrana granulosa, leaving behind it a flake of granules. Here it lies quite in contact with the proper membrane of the ovisac, is more or less imbedded in the membrana granulosa, and is supported behind by a mass of granules, sometimes presenting the appearance denominated by Baer the *cumulus.* But this cumulus does not belong to the proper granulous covering, or tunica granulosa, of the ovulum; for it may in some animals be separated from this covering, in the form of what Dr Barry calls the *petasiolus granulosus.*

(804.) After the ovulum has reached the periphery, its tunica granulosa may, at least in some animals, by contact with the membrane of the ovisac, become attenuated, or may even disappear at one side; which circumstance, together with the great transparency of this tunic, may have been the cause of Baer's assigning to it a discoid form. This approximation of the ovulum to the exterior surface of the ovisac, is doubtless for the purpose of exposing it to the action of the fecundating seminal fluid, which reaches it while it is in this situation, and still in the ovary. The next step being now the application of this fluid, we are brought to the next stage of our inquiry, namely, into the series of apparatus and of functions provided for the preparation of the semen, its introduction into the female organs, and its transmission to the surface of the ovulum.

SECT. III.—*The Male System.*

Male organs of generation.

(805.) The preparation of the seminal fluid is the office of the two glandular bodies called the testicles, or *testes.* They are suspended in a portion of common integument having the form of a sac, termed the *scrotum,* by a round band, called the spermatic cord, which pursues a very serpentine course; a plexus of veins, the assemblage of which has received the name of *corpus pampyriforme;* consisting of the spermatic artery, a plexus of absorbents, a plexus of nerves; and lastly, the *vas deferens,* or excretory duct; and they are farther supported by a sub-cutaneous layer of muscular fibres, termed the *dartos.* The scrotum is divided into two chambers, one testis being lodged in each, by a membranous partition, or *septum.* Each testicle is loosely contained in a sac, formed by an external serous membrane, the *tunica vaginalis,* derived from the peritoneum, which forms a cavity for its reception similar to that of other serous membranes. This tunic is reflected, like those of other cavities, over the body of the organ; and the reflected portion, which is called, from its white colour, the *tunica albuginea,* forms the proper capsule of the testis. When this latter tunic is divided, the testis is found to consist of a flattened oval substance, to the upper, outer, and back part of which a narrow and flat slip of substance, called the *epididymis,* is found adherent.

(806.) The substance of the testicle is extremely vascular, and the ultimate branches of its spermatic arteries are collected into small bundles of fine convoluted vessels, separated from one another by *septulæ*, or membranous partitions. From these the *vasa seminifera*, or beginnings of the excretory ducts, take their rise, and gradually unite to form a smaller number of canals of larger diameter, but exceedingly tortuous in their course. On arriving at the surface and back part of the testicle, they suddenly become straight, assuming the name of the *vasa recta;* they, however, again subdivide, and their branches have very numerous communications with one another, composing the net-work of tubes called the *corpus highmorianum*, or the *rete testis.* From the rete testis arise the ducts denominated the *vasa efferentia*, which, after being again contorted into numerous convolutions, form the conical bodies called *coni vasculosi;* these again, alternately join to form the epididymis, already mentioned, and which consists of one slender tube, of enormous length, coiled upon itself into a small compass.[1] The epididymis at length emerges, in the form of a tube of larger diameter, which is the *vas deferens*, and which ascends along the spermatic cord towards the abdomen. On tracing these ducts into the pelvis, we find them passing up by a circuitous route through the spermatic passage, and on reaching the pelvis, again descending by the lower side of the bladder, to the under part of its cervix. Each duct is here connected with an oblong membranous bag, called the *vesicula seminalis;* which is a long blind sac, folded many times upon itself; its open extremity entering the vas deferens at an acute angle. These sacs are supposed to be receptacles for the retention and accumulation of semen, until the time when it is required to be expelled. But Hunter remarked that the fluid contained in them is somewhat different from that obtained from the seminal ducts of the testicle itself; and he therefore supposed that these vesicles secrete a peculiar fluid which may perhaps dilute and add to the bulk of the semen. He even contended that the proper office of these cavities is not that of reservoirs of semen; supporting his opinion by arguments derived from comparative anatomy, which furnishes many examples where no direct communication exists between them and the vas deferens, and others where these vesicles are entirely absent. Notwithstanding these analogies, the prevailing opinion is in favour of the vesiculæ seminales in man being reservoirs of the seminal secretion.

(807.) From the vesiculæ seminales and the vas deferens, the semen is occasionally discharged through a duct common to both, and about half an inch in length, which perforates a body called the *prostate gland*, and then opens on each side into a canal, termed the *urethra*, which is continued from the urinary bladder, close to a small eminence in that canal, termed the *verumontanum*, or *caput gallinaginis*. The prostate gland is of the size of a small chesnut; in shape it resembles a heart, with the apex directed forwards. Its texture is firm and tough; it is divided into two lateral lobes, and one anterior lobe, and contains a great number of follicles, into which a white opaque viscid fluid is secreted. This secretion is discharged by ten or twelve excretory ducts opening obliquely into the urethra, in a furrow at the side of the verumontanum.

(808.) The urethra is a canal, lined by a mucous membrane, serving the double purpose of discharging the urine and the semen. As it proceeds forwards from the neck of the bladder, it passes through the prostate gland, on emerging from which it becomes more contracted in its diameter, and passes under the symphysis pubis. At this part, for the length of about an inch, it is supported only by firm cellular and ligamentous membranes; this part of the canal is termed the *membranous portion* of the urethra. It is then dilated into what is called the *bulb*, or *sinus* of the urethra; and it afterwards receives the ducts of several mucous glands, which have been denominated the *glands of Cowper*, and which are generally very minute, but sometimes have the size of peas. One of these is placed on each side of the membranous portion of the urethra, below which they are united by an isthmus; and the duct of each, about three inches in length, opens by perforating the mucous membrane lining the spongy body of the penis. Mucus is also furnished to various parts of the canal by *lacunæ* provided for that purpose. At its bulbous part, the urethra takes a considerable curve forwards, and is surrounded in the rest of its course by a peculiar erectile texture, denominated the *corpus spongiosum urethræ.* This substance is expanded, at the extremity of the penis, into what is termed the *glans*, which is covered by a fold of the skin called the *prepuce.* The *corpora cavernosæ* are the cylindrical bodies which compose the chief bulk of the penis. They arise by two *crura*, one from each ascending ramus of the os ischii, and are chiefly composed of the peculiar structure, termed the *erectile tissue*, (see § 434.) At its extremity, the urethra is considerably narrower than where it passes along the corpus spongiosum.

(809.) These parts, namely, the glans and corpora cavernosa penis, and the corpus spongiosum urethræ, consist principally of large convoluted veins, which in the last named part are particularly dilated and branched, and are bound together and crossed in various directions by ligamentous bands and fibres. This arrangement, by obscuring the connexions which the veins have with one another, as well as their tortuous course, has led to the mistake that has so long prevailed among anatomists, of ascribing to these bodies a cellular structure. These bands appear to be provided for the purpose of limiting the distention of the vessels, and adding to the rigidity occasioned by the accumulation of blood in the venous convolutions during erection. The means by which the blood is made to pass from the small arteries into these convoluted veins, is not clearly understood. Professer Müller[2] has lately discovered a remarkable set of minute dilated and ramified branches, which he terms *arteriæ helicinæ*, and which are appended to the terminal twigs of the arteries distributed on the sides and interspaces of the venous cavities in the penis of man and several animals, and which he represents as projecting into the interior of the veins, and pouring their blood into them; a mechanism which must doubtless have some direct relation with the process of erection. Dr. Houston[3] has described some muscles, under the name of *compressores venæ dorsalis penis*, to the contraction of which, and the consequent impediment to the return of the blood from the penis, he attributes the erection of that organ. It is more probable, however, that this effect is produced principally by an altered action of the blood-vessels themselves, and is analogous to the turgid state of the vessels which occurs in blushing, than is owing to any mechanical cause. The purpose served by the dilatation, elongation, and rigidity of the male organ, effected by this vascular action, is obviously that of enabling it to penetrate to a sufficient distance into the female organs during coition, for the conveyance of the semen to those parts of the latter whose office it is to carry it on to the ovulum which it is intended to fecundate. With this view, the secretions from the testes, vesiculæ seminales, prostate gland, and the glands of Cowper, are poured together into the bulb of the urethra, and thence expelled with force by the action of the muscles called the *ejaculatores seminis.*

---

[1] The whole length of the excretory vessels of the testes is very extraordinary. Their diameter has been stated to be no greater than the 200th part of an inch; and it has been estimated that the total length of the vessels which compose one of the testes amounts to more than 500 feet.

[2] *Archiv. für Physiol. &c.* 1835. pp. 27 and 220.

[3] *Dublin Hospital Reports*, vol. v.

ıe semen, d its ani- lcules.

(810.) The seminal fluid, which acts so important a part in the process of generation, has at all times attracted much attention. It is found to be considerably heavier than water, to have a peculiar odour, which increases on keeping; to exhibit alkaline properties, and to give off ammonia when heated. From the analysis of Vauquelin, it appears that human semen contains six per cent. of animal mucus, three of phosphate of lime, and one of uncombined soda; the rest being water. The phosphate of lime is deposited in crystals when the fluid is at rest. But the most remarkable circumstance in its composition is, the constant presence of an immense number of microscopic animalcules, the form, appearances, and size of which are different in almost every different animal; but in each species of the more perfect animals, the kind of animalcules, like that of the entozoa, is constant and determinate. Leeuwenhoek claims the merit of having first discovered them; but the priority of this discovery is assigned by Haller to Ludwig Hamm, who, when a student at Leyden, is said to have observed them in the year 1677. Another claimant of the discovery is Hartsoeker,[1] but apparently on no good grounds. An account of the controversy that arose on this subject, is given by Dr. Bostock.[2] Doubts were at one time entertained of the fidelity of the representations of these singular beings given by Leeuwenhoek; but they have been wholly removed by the later researches of Spallanzani, and the still more recent inquiries of Prevost and Dumas. These animalcules have a definite figure, consisting of a flattish rounded head, from which proceeds a long tail, exhibiting constant undulatory movements. They are accordingly classed by naturalists under the title of *spermatozoa*, as a species of the genus *cercaria*, among the infusoria.

(811.) It would appear from the elaborate researches of Prevost and Dumas, that these spermatic animalcules are found, at one time or other, in the semen of almost all the animals in which they have been sought for; but at that period of their life, and in that season of the year only, when the animals in which they exist are fit for procreation. They are almost always present in the fluid secreted by the testicles, and very often in that of the vesiculæ seminales, into which they have doubtless been introduced along with the fluid derived from the testicles. Hence it has been concluded, that their presence is intimately connected with the power of propagation; and may even be essential to that process. Wagner infers from his observations, that these animalcules are subject to remarkable changes of form at different periods, and that they even go through a regular gradation of developement; and phenomena leading to the same conclusion have been observed by Dr. Allen Thomson.[3]

ıberty in male.

(812.) It is not until the period of puberty that the generative organs are fully developed, and become capable in either sex, of exercising their proper functions. Prior to this period, the physical character of the two sexes is nearly the same: there is the same delicacy of complexion, the same high pitch of the voice, and the same slightness of figure. But the developement of the sexual organs appears to exercise a peculiar and specific influence over the system at large, affecting the growth of the rest of the frame, and modifying both its physical and mental powers. The attainment of this condition is more tardy, by two or three years, in the male than in the female; and the age at which it takes place, differs in different climates, and in persons of different temperaments, modes of life, and circumstances of physical and moral education. It occurs at an earlier age in southern than in northern climates; in this country generally appearing in the male between the ages of fifteen and eighteen years; and in the female from that of thirteen to sixteen; but in the hottest regions of the great continents, girls are said to arrive at puberty at ten, or even at nine years of age; and in the northernmost parts of Europe, not till that of from fifteen to eighteen. The arrival of this period is retarded by habits of active bodily exertion.

(813.) The characteristic changes induced by puberty in the male besides the developement of the genitals, and the secretion of the seminal fluid, are the enlargement of the larynx, which changes the quality of the voice; the growth of the beard on the chin, upper lip, and cheek, and of an increased quantity of hair on the rest of the body, and especially on the pubes; the enlargement of the chest and shoulders; an increase of physical activity and power; a greater capability of enduring fatigue; an exaltation of the active powers of the mind, and of the qualities of courage and resolution.

(814.) The act of sexual union is prompted by instinctive feelings, experienced by both sexes, and which generally depend on the condition of the body, and of the genital organs in particular, which are then in a state of high excitement. This mental feeling, and the local affection appear to be intimately associated together, and mutually produce one another. According to the doctrines of phrenology, the cerebellum is supposed to be that particular part of the encephalon which presides over the sexual function; and to be, in a word, the sensorium commune of the feelings relating to it; that is, the part to which impressions of a sexual kind proceed, and from which all sexual desire emanates; and to be the source of that power by which the generative organs execute their appropriate functions. Dr. Allen Thomson, after enumerating the proofs alleged in favour of this hypothesis,[4] observes, that he is not inclined to adopt it as established on sufficiently accurate and extensive data; and remarks, that the comparative anatomy of the brain, (in which, rather than in experiments on animals, he would be disposed to place much reliance, from the acknowledged difficulty of making correct deductions as to function, from the effects of morbid alteration or artificial injury of the encephalon,) affords very few arguments in favour of the phrenological doctrine, and furnishes several facts which militate strongly against it. (See the article PHRENOLOGY.)

SECT. IV.—*The Female System.*

Female generative organs.

(815.) The female generative system of organs, having to perform the offices of receiving, conducting, and applying to the ovulum the seminal fluid, of conveying the ovum into a situation where it can be evolved and properly nourished, and of bringing it forth at the appointed period into the world, is necessarily much more complicated and elaborate than the male system. The part performed by the male is quickly accomplished, while the female has to execute a long series of processes, which require a considerable time, and are connected with important changes in the economy.

(816.) The ovaria, of which we have already described the structure and offices, are connected with a hollow muscular organ, termed the *uterus*, *matrix*, or *womb*, by two ducts, called, from the name of the anatomist who first described them correctly, the *Fallopian tubes.* They commence by a trumpet-shaped mouth, opening from the abdominal cavity, and of which the edges are fringed or jagged with irregular filaments, or *fimbriæ*, as they are termed.[5] The mouth of the Fallopian tubes are endowed with the power, on certain occasions of venereal excitement, of attaching itself to the adjacent ovarium, and of firmly grasping it. The tubes, each of which is about five inches long, in their progress towards the uterus, soon contract in their diameter, and become exceedingly narrow at their termination in the upper and lateral corner of the triangular cavity of that organ. They are enclosed in the folds of the peritoneum which form the broad ligaments of the uterus.

[2] *Elementary System of Physiology*, p. 642, note.

[3] *Cyclopædia of Anatomy and Physiology*, art. Generation, p. 460.

[4] *Cyclopædia, &c.* p. 444.

[5] This part has also been termed the *morsus diaboli.*

(817.) The uterus itself is a compact, dense, membranous, and fleshy organ, provided with a copious supply of blood-vessels, lymphatics, and nerves. It has the shape of a flattened pear, and is situated in the pelvis, between the rectum and the urinary bladder. The outer surface of the uterus is covered with a reflected portion of the peritoneum, which, in passing from the sides of the uterus to the sides of the pelvis, forms the broad ligaments already mentioned, or the *Alæ Vespertilionis*, as they have been called. It is also provided with round ligaments, connecting it with the external parts of the pubes. The inner surface of the uterus is lined with a mucous membrane. The existence of muscular fibres in its substance has been called in question by many anatomists, and it is certainly difficult to demonstrate their presence; yet the extraordinary mechanical force which this organ exerts during parturition can scarcely be ascribed to any power but a muscular one.[1] The parts of the uterus are distinguished into the *fundus*, which is the broad end turned towards the abdomen, the body and the *cervix*, or narrow end. The channel of the cervix uteri, which proceeds from the lower angle of its triangular cavity, leads into the *vagina*, which is an elastic membranous canal, opening externally, and surrounding at its upper part the cervix uteri, which forms a protuberance in its cavity, called the *os uteri*, or *os tincæ*, from its supposed resemblance to the mouth of a tench.

The membrane which lines the vaginal cavity is continued from the mucous membrane of the uterus, but is thrown into numerous folds and wrinkles, admitting of occasional dilatation of the canal. This is surrounded by a tissue, of an erectile structure, termed *plexus restiformis*, or *corpus cavernosum vaginæ*.

(818.) The external parts are the *mons veneris*, which is formed by an accumulation of adipose substance on the upper part of the *symphysis pubis*. Below this are the *labia pudendi*, forming in their progress towards the anus, from which they are divided by the *perinæum*, what was called by the French anatomists *fourchette*. Between the labia is the *fossa magna*, in the upper part of which is lodged the *clitoris*, a small, round, and spongy organ, which is analogous to the penis in its erectile structure, being composed of two *corpora cavernosa*, arising from the tuberosities of the os ischii, and terminating in an impervious glans, furnished with a prepuce. The *meatus urinarius*, or orifice of the urethra, which in the female is very short, opens immediately below the clitoris. From this part, on each side of the fossa, extends the *nymphæ*, or *labia minora*, which are membranous and spongy folds. The *vulva*, or orifice of the os externum, is in part closed by a transverse membrane, of a crescentic form, called the *hymen*, the remains of which, after it has been lacerated, compose the folds called *carunculæ myrtiformes*.

Puberty and menstruation.

(819.) The changes which the female system undergoes at the period of puberty are on the whole as considerable as those of the male, although many of the external characteristics of the state of childhood are still retained, such as the delicate texture and inferior developement of the general frame, the large proportion of subcutaneous fat, smooth skin, and want of prominence in the muscles of the trunk and limbs. But the genital system undergoes a considerable and rapid developement at this period, the breasts enlarge, the pelvis becomes more capacious, and a peculiar periodical secretion, from the inner surface of the uterus, consisting of a certain quantity of sanguineous fluid, is established. This process, which is termed *menstruation*, recurs at periods nearly equal to a lunar month, and continues, with certain intermissions, determined by the occurrence of pregnancy, and the performance of the function of lactation, as long as the organs are capable of bearing progeny, which is, on an average, a term of thirty years. The fluid thus discharged is generally believed to contain less fibrin than blood, and to be less prone to putrefaction; it evidently contains a large proportion of the colouring particles of the blood, and is very seldom found to coagulate. The secretion amounts, on an average, to six or eight ounces, and usually continues for about four or five days, beginning and leaving off gradually, and being most abundant towards the middle of the period. The discharge in general takes place slowly, or drop by drop.

Conception.

(820.) The effectual fecundation of the *ovulum*, which is by this change converted into an *ovum*, and its removal to a situation where the *embryo*, then first brought into existence, can be perfectly developed, constitute the process of *conception;* but the exact nature of this process, as well as the precise circumstances which must concur for its successful accomplishment, have been but very imperfectly ascertained. The investigation of these phenomena in the lower animals, however, has rendered it extremely probable that Graafian vesicles are continually being produced in the ovarium, and come forwards at intervals, during the whole period of female fertility, and that they burst in succession, and shed the contained ovula, whether sexual intercourse take place or not, although there is reason to believe that their maturity is hastened by this act. The consequence of the bursting of one of these vesicles is the escape of the ovulum or ovum, as the case may be, and its passage down the Fallopian tube into the cavity of the uterus. The lacerated membrane of the vesicle closes, leaving a scar; the internal coat becomes thickened, and a yellow substance is deposited in its cavity, giving rise to the appearance which has been termed a *corpus luteum.* The presence of this substance is a certain indication of the previous bursting of a Graafian vesicle.

Corpus l teum.

(821.) Much discussion has arisen on the question as to the precise time when, and place where, the ovulum is impregnated. There seems now, however, little reason to doubt that the semen, immediately on its reception into the uterus, is conveyed by the Fallopian tubes to the ovarium itself, and then comes in contact with the exposed ovulum, which is ready for fecundation. On the bursting of the vesicle, the ovum is conveyed down the Fallopian tube, and arrives at the uterus, where the changes it next undergoes will be the subject of future inquiry.

SECT. V.—*Theories of Generation.*

Hypothe ses.

(822.) Having thus stated the provisions which have been made by nature for the fecundation of the ovulum, by the concurrent offices of the two sexes, we may here examine various speculations and opinions which, from time to time, have been entertained relative to the nature of this marvellous and mysterious process; speculations which, although for the most part exceedingly hypothetical, and often completely visionary, have been dignified with the appellation of *theories of generation.* This it is our intention to do very briefly, and to notice only the more important of these theories; for the total number of hypotheses which have been advanced on this subject is so great, that their mere enumeration might occupy many pages. Drelincourt, who lived in the latter part of the seventeenth century, collected from the writings of his predecessors as many as two hundred and sixty-two "groundless hypotheses" concerning generation; and "nothing is more certain," observes Blumenbach, "that Drelincourt's own theory formed the two hundred and sixty-third"

---

[1] Dr. Bostock has given in his *Physiology* an enumeration of the authors who have written on both sides in this controversy, p. 648, note.

(823.) These theories may be arranged according as they relate to the action of the parent organs, or to the changes in the egg occurring during the formation of the new animal; and Haller divided the first of these classes into three divisions, according as the offspring is supposed to proceed; first, exclusively from the organs of the male parent, which is the theory of the *Spermatists;* or, secondly, entirely from those of the female, which is that of the *Ovists;* or, thirdly, from the union of the male and female products, which is the theory of *Syngenesis.* The second class, again, may be arranged under two heads, according as the new animal is supposed, first, to have its parts rendered visible, by their being expanded, unfolded, or evolved from a previously existing though imperceptible condition of the germ, which is the theory of *evolution;* or secondly, to be newly formed from amorphous materials at the time when it makes its appearance in the ovum, which constitutes the theory of *Epigenesis.*

Of the erma- s.

(824.) The theory of the *Spermatists* regarded the male semen as furnishing all the vital parts of the new animal, the female organs merely affording the offspring a fit receptacle and suitable materials for its nourishment, until it could exist by the independent exercise of its own functions. One of the earliest supporters of this hypothesis was Galen; but its modern revival dates from the period of the discovery of the seminal animalcules, which were regarded by Leewenhoek as the proper rudiments of the fœtus. They were even considered by some to be miniature representations of men, and were styled *homunculi;* one author going so far as to delineate in each, the body, limbs, features, and all the parts of the grown human body. Even Leewenhoek describes minutely the manner in which they gain the interior of the ovum, and are retained after their entrance by a valvular apparatus.

Of the ists.

(825.) The Ovists, comprising some of the older philosophers, such as Pythagoras and Aristotle, maintained that the female parent affords all the materials necessary for the formation of the offspring, the office of the male being merely to awaken the dormant formative powers residing in the female products. Malpighi and Harvey asserted that the rudiments of the fœtus are derived principally from the female ovum; an opinion which was also elaborately defended by Vallisneri.[1]

Of Syn- esis.

(826.) The theory of *Syngenesis,* or of the simultaneous combination of products derived from both sexes, which after sexual intercourse, are supposed to unite together to form the germ, is also of very ancient date. In connexion with this theory may be mentioned that modification of it which may be termed the theory of *metamorphosis,* according to which a formative substance is held to exist, but is allowed to change its form, in order to be converted into the new being; as also the hypothesis of Buffon, which was eagerly adopted by Needham, who conceived that certain molecules which they termed *organic,* and which they believed universally to pervade plants and animals, were all endowed with productive powers, which enabled them, when placed in suitable situations, to attract one another, and to compose by their union living organized bodies. They imagined, that in the process of generation the superabundant portion of these organic molecules were accumulated in the generative organs, and there constituted the rudiments of the offspring.

Of evo- tion.

(827.) The hypothesis of *evolution,* or of pre-existing germs, coincides with that of the Ovists, in considering the fœtus as solely the production of the female; but it farther assumes that it already exists, with all its organs, in some part of the female system, previous to the sexual intercourse; and that it receives no proper addition from the male semen, the action of which is merely that of exciting the powers of the fœtus, and of endowing it with vitality. The observations of Haller with respect to the gradual enlargement or evolution of the chick during the process of incubation, were conceived to lend great support to the advocates of this theory, of whom the most strenuous and enthusiastic was Bonnet. This naturalist, so celebrated for the boldness of his speculations, contended, not only that the whole of the parts of the fœtus pre-exist in the ovum, before they actually make their appearance, but that the germs of all the animals which are in future to be born, also pre-exist in the female parent; so that the ovaries of the first parents of any species of animal, contained the germs of all their posterity, included the one within the other, like a nest of boxes; from which comparison he termed his theory that of "*emboitement.*" This extravagant notion was adopted by many physiologists, principally from its affording some kind of explanation of what no other theory seemed in the least adequate to solve. Spallanzani, in particular, was a zealous defender of the hypothesis of pre-existing germs. It appears, however, to be totally irreconcileable with the phenomena of hybrid productions, and of the resemblance which, in so many instances, the offspring bears to its male parent.

5. Of Epigenesis.

(828.) We have already mentioned that Harvey and Malpighi ascribed the formation of the fœtus principally to the powers of the female. This opinion gave origin to the modern theory of *Epigenesis,* first clearly promulgated by Caspar Frederick Wolff,[2] who not only described a successive production of organs, of the previous formation of which there existed no trace; but showed also, that after parts are first formed, they undergo many important changes in their shape and structure, before arriving at their finished state. The more recent researches, aided by delicate microscopical observation, of Meckel, Pander, Baer, Rathké, Oken, Purkinje, and Valentin; Serres, Rolando, Dutrochet, Prévost and Dumas, Coste, and others, have demonstrated that the theory of Epigenesis, or superformation of parts, is much more consistent with the observed phenomena than that of evolution. The facts which have thus been brought to light, are of peculiar interest with reference to the plans of nature, into which they give us a more extended insight, by exhibiting new and unexpected affinities between remote families and classes of animals; by showing that at one period the type of their formation is nearly the same, and by explaining the seeming caprice of nature in instances of monstrous and defective formation. But to attempt adducing the proofs and illustrations of these positions, would engage us into details requiring an extensive survey of the whole animal creation, to enter into which would occupy more space than is compatible with the limits of the present treatise. We must, therefore, content ourselves with referring, for more ample elucidation of this subject, to the Bridgewater Treatise *on Animal and Vegetable Physiology.*[3]

Sect. VI.—*Utero-Gestation.*

Utero-gestation.

(829.) On the arrival of the ovum in the cavity of the uterus, to which we have traced it in a preceding chapter, the first object of nature is to effect its attachment to a portion of the inner surface of that organ. A provision for this purpose has already been made, even while the ovum was contained in the ovarium. A vesicle, first noticed and described by Dr. Barry, is formed around the ovum; the granules of the *tunica granulosa* become less densely aggregated together, and gradually pass into the state of fluid albumen; oil globules appearing for the first time to take their place on the surface of the ovum. This fluid he supposes to correspond to the yolk of the eggs of birds; and the membranous vesicle above mentioned, in which it is enclosed, and which thus forms after impregnation, he considers as the rudimental chorion, by which the ovum is afterwards attached to the uterus.

---

[1] *Della Generazione,* part 2.

[2] In his inaugural dissertation, entitled *Theoria Generationis,* published at Berlin in 1759.

[3] Part iv. chap. ii. on *Organic Developement;* and chap. iv. on *Unity of Design.* Vol. ii. pp. 599, 625.

(830.) It results from these views, that mammalia differ from oviparous animals in the circumstance, that those parts of their ovum which are last formed, have a more internal origin; thus, the first portion of the albumen and the chorion of the ovum in mammalia, originate, not in the oviduct, but in the ovary; for which purpose, chiefly, there is provided the very large quantity of albuminous fluid in the Graafian vesicle; a provision which may be presumed to have especial reference to the development of the embryo within the body of the mother. The chorion, being formed in the ovary, it is an *ovum*, and not an *ovulum*, that is expelled from that organ in mammalia. On the other hand, in birds it is an *ovulum*, and not an *ovum*, that leaves their ovary; and it becomes an ovum, and receives an addition of the albumen, or yolk, and the shell membrane in their oviduct, and then becomes analagous in all its parts to the ovum of the mammal when the latter leaves the ovarium. The albumen, in the form of granules, lines the ovisac, constituting the *membrana granulosa;* and in the form of the *flake* it supports the ovulum in the centre of the fluid of the ovisac, and afterwards supports it at the periphery of the latter, sometimes in the form of the *petasiolus granulosus*, or *cumulus* of Baer. It closely invests the ovulum in the form of the *tunica granulosa;* it forms, in the rabbit at least, and probably in other mammalia, two bands or ligaments, termed the *chalazæ*, which are conspicuous in birds; and finally, it also provides the granulous bands by which, in some instances, too sudden a discharge of the ovum of the Graafian vesicle is prevented.

(831.) Dr. Barry finds that the ova of the rabbit of five or six days, when in the uterus, are in bulk about eight thousand times that of the ovulum in the ovary, and have three concentric membranes; namely, first, an outer vesicle, (the villous chorion,) originating in the ovary; secondly, the primitive membrane of the yolk, distended so as to fill the chorion; and, thirdly, an inner vesicle, or membrane, which has been called the *blastoderma*, or germinal membrane, presenting in its substance a central spot, which is the germinal spot, or *embryo*. Dr. Allen Thomson has seen this spot very evident in the ova of a rabbit, on the sixth day after impregnation. It corresponds exactly with the part called the *cicatricula* in the egg of a bird, which there lies immediately on the surface of the yolk, imbedded in a disc of granules. In the centre of the cicatricula, a dark round spot is seen, termed the *colliquamentum*, which contains a minute vesicle, discovered by Purkinje, and which bears his name. This vesicle, which is seen in the ovulum, afterwards bursts, and leaves in its place a thin and tender transparent membrane. In the centre of this transparent spot, may be perceived, seven or eight hours after the commencement of incubation, with the aid of a magnifying glass, a small dark line. This line, or *primitive trace*, as it has been termed, is swollen at one extremity, and is placed in the direction of the transverse axis of the egg. The rounded end is towards the left, when the small end of the egg is turned from us.

(832.) Having traced thus far the changes occurring in the ovum before it becomes attached to the uterus, we shall defer the consideration of the subsequent stages of its evolution to a future section, and here attend to the changes which have in the mean time taken place in the uterus, with a view to prepare it for the office it has now to perform.

Placenta.

(833.) A change has already taken place in the uterus, preparatory to the reception of the ovum, and before its arrival in that cavity. An increased flow of blood is directed towards that organ. A substance consisting of lymph, or organizable fibrin, exudes from its interior surface, furnishing it with a soft flaky lining, which, when the ovum is received, is reflected over that body, so as to give it a double covering. These two folds, the one being in contact with the uterus, and the other with the ovum, constitute the two layers of the *membrana decidua;* the former portion being termed the *decidua vera*, and the latter, the *decidua reflexa.* This membrane soon becomes organized, and highly vascular. The vessels in the progress of growth, are in some parts much dilated, so as to form sinuses, which are ultimately intermingled, though by no means continuous, with the blood-vessels of the fœtus. These latter blood-vessels, consisting of the umbilical arteries and veins, of which the trunks are collected in the umbilical cord, have passed to the chorion, which by the end of the first, and during the second month of pregnancy, has acquired a villous external surface. At the end of this period, the branches of these vessels penetrate and ramify in these villi, which become thoroughly vascular; and this thickening and vascularity is concentrated on one side of the chorion, generally on that which is adjacent to the fundus of the uterus, forming the body called the *placenta.* This body is of a flattened oval shape, from six to eight inches in breadth, and from an inch to an inch and a quarter in thickness at the middle part, becoming thinner towards the edges. It occupies about a fourth part of the chorion, and at birth is about a pound in weight. In ruminant quadrupeds, the substance corresponding to the human placenta, is confined to a number of circular and spongy elevations, varying in number from thirty to one hundred, which are termed *cotyledons.* The human placenta is evidently formed of a structure essentially the same, composed of many lobes consolidated by contact into one organ. It has been very generally supposed that the placenta is of a cellular structure, and that the arteries and veins of the uterus communicate with its cells; but the late researches of Dr. Robert Lee,[1] renders it very doubtful if these inter-placental cells really exist.

(834.) In proportion as the fœtus grows, the uterus enlarges, and about the fifth month it rises out of the pelvis, and rests against the front of the abdomen. As it enlarges, the distinction between the body and the cervix is lost; the os tincæ is flattened, and forms only a small rugous hole, not easily discernible; and it is closed by a tough glutinous matter, which is fixed in the irregularities of the surface.

SECT. VII.—*Parturition.*

Parturition.

(835.) The ordinary period of utero-gestation is forty weeks; on the expiration of which the uterus takes on itself a new kind of action; its contractility, which had lain dormant for so long a time, is now suddenly and powerfully excited. A mucous discharge takes place from the vagina, the external passage is relaxed, and slight pains are felt in the back and loins, which usher in the real pains of labour. These are occasioned by powerful contraction of the uterus, accompanied by a strong action of the diaphragm and abdominal muscles; and they are repeated at short intervals. Impelled by this pressure, the membranes of the fœtus project into the vagina, and dilate the os tincæ; on their bursting, the liquor amnii escapes, and at the next pain the pressure of the uterus falls directly on the fœtus. The head of the fœtus gradually descends, urged on by succeeding spasms, the occiput foremost, the long axis of the head being disposed obliquely across the lesser basin of the pelvis. The occiput, as the external parts yield, glides off the inclined surface of the ischium, presenting at the orifice of the vulva, and bringing at the same time the long diameter of the shoulders to correspond with the greatest breadth of the pelvis, and the head being thus disengaged, the trunk follows. After a short time, fresh pains return, and the placenta and membranes being detached from the uterus, comes away. In the majority of natural births, labour is completed in from four to six hours. The uterus then very slowly and insensibly contracts, so as to diminish the ample cavity which has been rendered vacant, and at the same time its volume is reduced by absorption. During the return of the uterus to its former state, a discharge, at first tinged with blood, and afterwards of a whitish colour, termed the *lochia*, ensues, which lasts for several days.[1]

---

[1] *Philosophical Transactions* for 1832.

SECT. VIII.—*Lactation.*

tation.

(836.) The function by which nourishment is prepared, of a nature suited to the early periods of infant life, belongs to the reproductive class of functions. The fluid provided for this purpose is the *Milk*, of which we have already examined the chemical properties, and noticed the qualities which peculiarly fit it for the purpose it is intended to serve. The organs which prepare it are the *mammæ*, which are glands consisting of the union of a great number of lobes, intermixed with adipose substance, and remarkable for the whiteness and fineness of their texture. The numerous excretory tubes from these lobules unite in forming ducts, which open separately in the folds of the integuments of the nipple. A remarkable sympathy is observed between this gland and the uterus; for it often enlarges and becomes tender for a few days before each monthly period. It enlarges during the latter months of pregnancy, and the brown circle surrounding the nipple, or *areola*, as it is called, assumes a darker colour. The secretion of milk would naturally continue until the middle of the second year, if the child were retained at the breast as long as it was supplied. During the period of suckling, the menstrual discharge is not renewed, but pregnancy may, however, again take place, before its recurrence.

SECT. IX.—*Fœtal Evolution.*

al evo-
n.

(837.) In judging of the changes which take place in the human embryo from the period when its evolution commences, we must be guided principally by those which, occurring in the developement of that of the chick, furnish the best means of following the whole succession of phenomena. Commencing the inquiry, then, from the appearance of the primitive trace in the blastoderma, or cicatricula, already described, (§ 831,) we find this part gradually dilating in bulk, and occupying a situation between the two layers, namely, the outer and the inner, into which, towards the twelfth or fourteenth hour of incubation, this cicatricula has divided itself. The outer of these layers is called by Pander the *serous layer;* and it subsequently gives rise to the nervous, the muscular, the osseous, cartilaginous, and tegumentary systems of the body. The innermost, which is situated in contact with the yolk, is the *mucous layer*, whence are derived the alimentary canal, and the glandular and pulmonary systems. A third layer, (the *vascular layer*,) is afterwards formed in the interval between the two former, and is the origin of the sanguiferous system of the fœtus, including the heart and all the blood-vessels. The respiratory system is the product of the combined changes which this, together with the last mentioned layer, undergoes.

(838.) The series of phenomena which present themselves in following the succession of changes occurring during the formation of the vital organs, are highly curious, and afford the most splendid instances of that refined intelligence and that provident adjustment of a long series of means for the effectual accomplishment of future and far distant ends, which strike us with profound astonishment when we penetrate into the remoter regions of physiology, removed from ordinary observation. It would far exceed the limits within which we must confine ourselves in the present treatise, to give the detailed history of these organic changes. We must content ourselves, therefore, with a brief outline of the principal phenomena, and with referring to works professedly treating on this subject, for more copious information on this highly curious department of physiology.[2]

(839.) On the outer surface of the serous layer, or that most distant from the yolk, there are raised two parallel ridges, which, joining along their upper margins, form a canal; in this canal, according to Baer and Serres, a semi-fluid matter is deposited; this matter, acquiring consistence, becomes the spinal chord, with a pyriform extremity, which last is the rudiment of the future head. Roland, Prévost, and Dumas, on the other hand, suppose that the primitive trace is itself the spinal cord and brain, in their rudimental state.

Rudimental intestine.

(840.) When the layers of the germinal membrane have so far expanded as to cover nearly one-third of the yolk, they no longer retain their flat and uniform appearance, but begin to exhibit various folds, which afterwards become the different cavities of the body. Those of the mucous layer turn downwards, and whilst its remote expansion includes within it the yolk, as in a sac, the inner folds close inwards, and by the union of their margins form two tubular cavities, one at each end of the embryo, communicating in the middle with each other, and also, by a common opening, with the cavity of the yolk. This tube is the nascent alimentary canal.

Vascular area, and heart.

(841.) The first rudiment of the heart is perceptible at the anterior part of the vascular layer, which, as we have already stated, is developed between the serous and mucous layers. In the mean time, the surrounding disc of the cicatricula, which continues to expand, exhibits, in the circumference of the transparent area, which now becomes thicker and more spongy, numerous irregular points and lines of a dark yellow colour. These lines gradually extend, unite together, first into small groups, and then into one net-work, which composes the *vascular area*. The space they occupy is terminated, on each side, by a circular vessel, of larger size than the rest, the *sinus* or *vena terminalis*, into which the smaller ramifications of the vessels open at the circumference, whilst towards the central part they unite into a vessel on each side, the two *omphalo-meseraic arteries*, which penetrate into the vascular layer of the embryo.

Of the spinal cord and brain.

(842.) Simultaneously with these changes, all the important organs of the body are formed in rapid succession. The spinal cord and brain, of which we have noticed the first traces, are quickly developed; the former, appearing first as a membranous tube, the latter, as three vesicular bodies; and both being gradually filled with opaque nervous substances of two kinds, the one being uniform, the other filamentous. The nerves next appear, but whether they are generally formed in their entire length at once, or are growths from the brain or spinal cord, or are first produced at their farthest extremity, and afterwards extended towards the central organ, are points not yet determined. Some, however, as the optic, auditory, and olfactory nerves, are certainly productions from the cerebrum. The muscles become visible in the human embryo at the third month; they are then soft and gelatinous, transparent, of a light yellow tint, and not distinguishable from their tendons. Each muscle is formed at once in its whole length, with its attachments perfect. The eyes are formed at a very early period, and their growth is rapid; they are situated at first at the sides of the head, as in quadrupeds, and subsequently move forwards. The iris has no central aperture, the place of the pupil being occupied by the *membrana pupillaris*, which disappears completely before birth. The organ of hearing is formed soon after the eye. The substance of the bones is at first an homogeneous jelly, enclosed in a membrane, and exhibiting no divisions into joints. This jelly gradually becomes cartilaginous, the conversion taking place from the surface inwards. It is gradually replaced by ossific matter, which grows from the interior, resembling a process of crystallization. Ossification begins in the human embryo in the seventh week.

---

[1] The above account of parturition is for the most part extracted from Mr. Mayo's *Outlines of Human Physiology*, as presenting a very clear and compendious account of the phenomena.

[2] The reader will meet with much instruction on these subjects, in Dr. Allen Thomson's papers on *Embryology* in the *Edinburgh New Philosophical Journal;* in the *Cyclopædia of Anatomy and Physiology*, by Dr. Todd; and also in Mr. Mayo's *Outlines of Human Physiology*, chap. xv. sect. ii. We would also beg to refer to the summary contained in the Bridgewater Treatise *on Animal and Vegetable Physiology*, vol. ii. p. 599. The greater part of the summary given in the present article is abridged from Mr. Mayo's work.

Of the skin and limbs. (843.) The integument is the outermost fœtal product of the serous layer, which gradually spreads like a mantle over all the other structures, and does not acquire proper strength till the middle of the fœtal period. At the end of the fifth month the body is covered with short, whitish, and silky down, which, however, disappears in the seventh month. The hair of the head and of the eye-brows, and the nails, are formed in the sixth month. About the fifth month there appears on the body a yellowish-white greasy substance, at first thinly, and afterwards more thickly spread, and termed the *vernix caseosa*. The limbs are formed originally below the skin, which they reach, pushing out like little globular shoots, in the sixth week. They originally grow straight out from the trunk. The upper arm is next laid against the breast, the fore-arm drawn upwards; the thigh is bent up to the belly, the leg drawn backwards towards the thigh, and the feet turned in, and crossed, with the soles turned inwards. When the fingers are first formed, they are contained in a common mitten of skin, which, gradually becoming thinner between them, forms a web, which is finally absorbed.

Amnios. (844.) Another product of the serous layer is one still more external than the integument of the fœtus, and consisting of a sac formed by a membrane reflected from the sides and from either extremity of the embryo, so as to enclose a space behind its body. This is the *amnios*, which forms a loose bag filled with a liquid *(the liquor amnii)* in which the fœtus floats, suspended by the umbilical cord. As the walls of the trunk close in front, the circular edge by which the amnios is attached to the body of the embryo becomes proportionably contracted; and it is finally limited to the umbilical opening, hereafter to be noticed.

The communication which we described as being left between the intestinal tube and the cavity of the yolk bag, or *vitelline sac*, and which in birds continues open, soon becomes closed in mammalia, the sac assuming the form of the *intestinal vesicle*, discovered as such by Bojanus in the ovum of the sheep; though it had been before seen and known by the name of *vesicula alba;* it disappears by the third month.

Glands. (845.) The glandular organs which communicate with the alimentary canal are formed by the extension of its mucous membrane in the form of tubular productions, shooting into small masses of matter lodged in its neighbourhood; the blind ends of the tubes being often dilated into spherical pouches. The gall bladder is, in like manner, formed by the extension of a tube, which not being received into a mass of elementary matter, enlarges into a simple sac.

Lungs. (846.) The lungs are regarded as another expansion of the mucous layer of the germinal membrane, growing from the back part of the œsophagus, and gradually advancing on either side of the aorta, so as at length to surround it.

Kidneys. (847.) The kidneys are preceded in the embryo by a substance first noticed by Wolff, and called after him the *Wolffian bodies*, or *false kidneys*, which originally extend the whole length of the spine, from the heart to the end of the intestines; but they become afterwards shorter, and, after a time, diminishing by absorption, wholly disappear. They appear to be subservient to the developement both of the true kidneys and of the testes and ovaria. The bladder and urethra, on the other hand, together with the external genitals, are formed partly out of a developement of the extremity of the intestine, and partly by fissure and folding of the integument, in the following manner.

Allantois. (848.) There is first the production of a bag of considerable length, called the *allantois*, from the intestine, or that part of it which may be considered as the *cloaca;* subsequent contractions of the sides of this sac, at different parts, next divides it into two cavities, the proper allantois and the urinary bladder; and the lower contraction is elongated into the canal of the urethra. The separation between the two former afterwards closes, and the coalesced membrane forms the ligament termed the *urachus*. The urethral tube never closes.

Genitals. (849.) The testes and ovaries appear in mammalia about the same time at the inner and fore part of the Wolffian bodies, attached to them by a fold of the peritoneum. From each testis or ovary there descends to the internal ring a membranous process, which in the male is called the *gubernaculum*, and in the female constitutes the *round ligament.* It passes, in either sex, along the spermatic passage to the filamentous tissue of the scrotum or labium. The ovaries descend to the brim of the pelvis; the testes pass through the ring into the scrotum.

Blood-vessels. (850.) Every organ begins to be formed without either blood, or blood-vessels; the circulation in them being established solely for the purpose of subsequent growth and perfection. Even the heart is formed and shaped, and its texture has acquired some degree of consistency, and it displays an undulatory motion, before the blood has reached it. We have already described the formation of vessels and of blood in the vascular area; but the blood is at first motionless. It afterwards finds its way from thence by the omphalo-mesenteric veins to the heart, whence it is expelled along the aorta, and thence again carried into the vascular area; thus establishing a simple circulation. In a few days arterial branches extend from the aorta, and venæ cavæ are formed, establishing the systematic circulation. Five pair of branchial vessels are formed from the aorta in the neck, the œsophagus being between the branches on each side, and there are also four openings in the neck of the embryo on each side. This single heart, branchial arches, and openings, are permanent parts of the structure in fishes. In the mammalia, these branchial clefts soon close; the heart becomes separated by the growth of partitions in each ventricle and auricle, into two separate cavities, and the artery is divided, in like manner, into an aorta and pulmonary artery. Some of the arches then disappear; others become permanent aortic, and others permanent pulmonary branches; and the fœtus is becoming prepared for pulmonary respiration.

Umbilical cord. (851.) The amnios, closing upon the shrunk urachus, forms with the umbilical artery and veins, and a connecting gelatinous tissue, the *umbilical cord*, or navel-string; connecting the fœtus with the placenta, which, as we have before seen, is formed by a thickened portion of the chorion. The umbilical vein distributes part of its blood to the liver, and then, under the name of the *ductus venosus*, joins the inferior cava, through which the mixed blood of the placenta and of the inferior part of the body is carried into the right auricle of the heart. Part of this blood passes directly from the right to the left auricle through the *foramen ovale*, which is an aperture in the yet imperfect septum of the auricles; the remainder, with the exception of the small quantity transmitted to the yet imperfectly developed lungs, passes from the pulmonary artery, through the *ductus arteriosus* directly into the aorta. The offices of the placenta are supposed to be those, first, of introducing nourishment, transmitted by imbibition from the maternal to the fœtal blood, through the membranes of the interjacent vessels of the mother and the fœtus; and, secondly, of oxygenating the blood of the fœtus by imparting to it oxygen from the same source. It has been supposed by many that the fœtus derives sustenance from the liquor amnii which surrounds it, and which might be introduced through the mouth into the stomach; but this opinion is now very generally abandoned. It is true, however, that the stomach of the fœtus usually contains a considerable quantity of ropy mucus, but without albumen. This last substance is found in the contents of the duodenum,[1] and the great intestines contain a green matter termed *meconium*, which has the appearance of being the refuse of a kind of digestion. It has been conjectured that the *thymus gland* has some relation to the function of fœtal assimilation.

CHAP. XIX.—PROGRESSIVE CHANGES IN THE ANIMAL ECONOMY.

anges in progress ife.

(852.) We have now traced the history of the changes which the human system undergoes, from the earliest rudimental state in which it exists in the embryo, through the period of its fœtal life, to the epoch of its birth; when it is ushered into the world, with organs fitted for maintaining a comparatively independent existence, yet still requiring the most tender offices and most fostering care of that parent, of whose system it had so long formed a part, and from which it has been so recently dissevered. To follow the narrative of the successive alterations which take place during the growth of the system, the proportional developement of its several organs, and the acquisition of its various powers, both corporeal and mental, during all the subsequent epochs, filling up the interval between the cradle and the grave, composes a long chapter in human physiology, and would occupy too large a space for the present treatise. All that we can pretend to attempt must be a faint sketch of the outlines of this "strange eventful history."

(853.) The greatest of all the changes which occur in the animal existence of every human being, is its emergence from the state in which it was dependent for its immediate supply of nourishment and of oxygen on the blood which is circulating in the vessels of its parent. On its birth, which cuts off the placental circulation, all these ties are at once dissevered. A new element surrounds it, from which it is in future to derive the principle that maintains its vital energies. The placental supply is superseded by respiration; and the first gasp of air received by an instinctive effort into its lungs alters at once the whole character of its organic constitution. It is now a breathing animal; and all the channels and passages, which had till then been adapted to a different mode of being, have now become useless, or rather worse than useless, and they must give way to a new order of processes, and a new mechanism of the hydraulic functions. The ductus venosus, the foramen ovale, and the ductus arteriosus are superseded in their functions, and must be speedily closed and obliterated, in order to give place to new courses of circulation and a new order of functions.

(854.) Besides these changes, which, being consequent on the sudden exercise of the new function of respiration, are immediate, the whole organization rapidly conforms itself to the great alteration of the circumstances in which it is now placed. As the growth of the fœtus had been progressively becoming more and more rapid in proportion as the term approached when it was to be ushered into the world; so, on the other hand, the growth of the body is greatest in the earliest periods of its extra-uterine life, and becomes more and more slow in proportion as it advances to the full dimensions it is destined to attain. The principal anatomical changes which follow birth, besides those already stated, are the gradual obliteration of the thymus gland, and of the renal capsules.

(855.) The natural term of lactation is succeeded by that of teething; the first set of teeth, or the *milk teeth*, being furnished by nature as temporary structures, until instruments of greater dimensions can be constructed in the enlarged jaws. The appearance of the teeth is an intimation that the organs of assimilation are prepared for the digestion of solid food; and that the proper period for weaning is arrived.

(856.) From this period an accurate observer may perceive that the intellectual education keeps pace with the physical; whilst the active exercise of the limbs consolidates the bones, and gives firmness to the muscles, that of the senses is continually adding to the store of ideas, and calling forth the latent powers of the understanding. The moral faculties are developed much earlier than is generally imagined; and the future character of the individual often receives a permanent impress from the events of infancy. No one can have watched its varying aspect at this tender age, without recognising how early its affections are called forth towards its protector and fosterer; how quick is the distinction it makes between kind and unkind treatment, and how keen is its sense of the least injustice which it may have either to bear or to witness.

(857.) To the periods of infancy and childhood succeeds that of puberty, which we have seen is attended in either sex with remarkable changes, both physical and moral. During the period of increase the powers of assimilation are in full activity in furnishing a sufficiency of materials for growth; the circulation is vigorously employed in applying them to that purpose; and the supply is even more abundant than the consumption. When, however, the fabric has attained its prescribed dimensions, the total quantity of nourishment furnished and expended being nearly balanced, the vital powers are chiefly exerted in consolidating and perfecting the organization of every part, and qualifying them for the continued exercise, during a long succession of years, of those functions of which we have given the history in the preceding part of this treatise.

(858.) But, in the mean time, the process of consolidation, begun from the earliest period of developement, is still advancing, and is producing in the fluids both greater thickness, and a diminution of their total quantity. By the gradual conversion of their gelatin into albumen, all the textures acquire increasing solidity; the cellular substance becomes firmer and more condensed, and the solid structures more rigid and inelastic. The contractile power of the muscles is also impaired; and the limbs no longer retain the elastic spring of youth. All these progressive modifications of structure tend slowly, but inevitably, to disqualify the organs for the due performance of their functions. Their vascularity gradually diminishes; for a large proportion of the arteries which had been actively employed in building the fabric, being now thrown out of employment, contract, and, becoming impervious, disappear. The parts of the body, having acquired greater rigidity, oppose a gradually increasing resistance to the propelling force of the heart, which is itself, in common with all the other vital powers, slowly diminishing. The absorbents are now active in removing the parts which have become useless or superfluous. Old age steals on by slow and imperceptible degrees, which, even when obvious to others, are unknown to ourselves. But nature kindly smooths the path along which we descend the vale of years, and conducts us by easy stages to our destined place of repose. When death is the simple consequence of old age, we may perceive that the extinction of the powers of life observe an order the reverse of that which was followed in their evolution. The sensorial functions, which were the last perfected, are the first which decay; and their decline is found to commence with those mental faculties more immediately dependent on the physical conditions of the sensorium, and more especially with the memory, which is often much impaired whilst the judgment remains in vigour. The heart, the pulsations of which gave the first indications of life in the embryo, generally retains its vitality longer than any other organ; but its powers being dependent on the constant oxidation of the blood in the lungs, cannot survive the interruption of this function, and on the heart ceasing to throb, the death of every part of the system may then be considered as complete.[1]

CHAP. XX.—TEMPERAMENTS.

Definition of temperament.

(859.) In the natural and healthy condition of the system, all its functions are nicely adjusted and proportioned to each other, so as to produce the most perfect harmony. Yet within the limits of health variations are admissible in this balance of functions, according as some predominate over others in regard to energy and activity; or rather, according as there prevails a tendency to such predominance, which, though it does not actually overset, may yet endanger the preservation of that balance which constitutes health, and may thus give at least a proneness to disease. This peculiar state of the system, depending on the relation between its different capacities and functions, by which it acquires a tendency to certain modes of action, is called its *Temperament.*

(860.) Much attention was paid by the ancients to the subject of temperaments; and the nomenclature they established to express the various combinations of peculiarities in the constitution, corresponding with the definition above given, has continued in general use even to the present day. They described four temperaments, corresponding to the four qualities of hot, cold, moist, and dry, ascribed to the human frame by Hippocrates, and which were supposed to confer the specific characters to the four ingredients of which the blood was thought to be composed; namely, the red part, the phlegm, the yellow, and the black bile respectively; and hence were derived the names of the sanguine, the phlegmatic, the choleric, and the melancholic temperaments, as indicating an excess of each of these principles.

(861.) In modern times the ancient doctrine of temperaments was adapted to the humoral pathology, by which all the deviations from the standard of health were attempted to be explained. Boerhaave, reasoning on these principles, and considering the several temperaments as being formed by different combinations of the four cardinal qualities, increased their number to the eight following: namely, the warm, cold, moist, dry, bilious, sanguine, phlegmatic, and atrabilious. Darwin, endeavouring to found his doctrine of temperaments on varieties in the vital actions of the system, which he had classified as referring to the four heads of irritation, sensation, volition, and association, formed four temperaments in conformity with this arrangement, in which these functions were conceived respectively to predominate.

(862.) Most of the modern physiologists, however, following the example of Cullen, have adopted the four temperaments of Hippocrates, which are characterized by the following peculiarities:

Sanguin

(863.) The *Sanguine* temperament is distinguished by a full habit and relaxed frame of body; by a greater vascularity, softness and delicacy of skin, in which the veins are of considerable size, and are particularly conspicuous by their blue colour, as seen through the thin layers of the skin. The surface of the body generally, and more especially the face, exhibits a florid and ruddy colour. The hair is generally of a light brown; but has often a yellow, and sometimes a reddish hue. Persons endowed with a sanguine temperament are acutely sensitive, and highly irritable: their pulse is frequent, indicating the general rapidity and energy of the circulation. Both the secretions and excretions are abundant, and little liable to obstruction. The disposition is free and open; the temper cheerful, and rather disposed to levity.

Melanc lic.

(864.) A remarkable contrast to the temperament just described is presented by the *melancholic* temperament, which is marked by a firm and robust frame, and a spare habit of body; by an integument of greater thickness, and of a brown and swarthy hue; and by an abundance of dark or black hair, which being particularly conspicuous in the eye-brows and beard, and being conjoined with a black colour of the iris, imparts to the countenance a stern and sombre aspect. In persons endowed with this temperament the pulse is habitually slower than the average condition; the blood is thicker and more sluggish; the secretions and the excretions are less copious, and more apt to be morbidly deficient than with the generality of men. The nervous system is, on the whole, less sensitive and excitable; but the mind, although not readily moved, when once set in motion, is remarkably retentive of its impressions, and tenacious of its purposes; persevering and indefatigable in action, ardent and constant in its affections; possessing great capacity of understanding, with a fondness for contemplation, and for speculative inquiries demanding profound thought. The temper is naturally grave, and often gloomy; the fancy imaginative, and of a poetic turn, but tinctured with melancholy, and betraying a proclivity to madness; when happily tempered, it exhibits that fortunate combination of genius and industry from which have resulted the noblest achievements of the human intellect.

Choleri

(865.) The *Choleric* temperament would seem to occupy a place intermediate between the two former, as partaking of some of the qualities of both. The frame is more relaxed, the senses more excitable, and the mind more irrascible than in the melancholic temperament. The complexion is less ruddy than in the sanguine temperament, and the pulse stronger and more frequent; the secretions are more copious, and the skin fairer and less hairy than in the melancholic temperament.

Phlegm

(866.) The *Phlegmatic* temperament is denoted by a relaxed and feeble frame, prone to obesity; a pallid complexion, a smooth integument, with but few hairs, that on the head being of a light colour. The circulation generally is languid, the pulse slow and weak, the blood-vessels less capacious, the fluids more bland and watery. The functions of digestion, secretion and excretion, are performed slowly, and are liable to frequent impediments. The mind is dull, sluggish, disposed to indulge in sleep; not easily moved, timid, inclined to fear, and prone to avarice.

---

[1] For more ample details on the subject of the changes which take place in the progress of age, see the article AGE in the *Cyclopædia of Practical Medicine,* and also the chapter on the Decline of the System in the Bridgewater Treatise *on Animal and Vegetable Physiology,* vol. ii. p. 619.

ervous
mpera-
ent.

(867.) Dr. Gregory has added to these four temperaments a fifth, which he denominates the *nervous* temperament, and which owes its peculiarities to the sensibility of the nervous system existing in an undue proportion to the contractility of the muscles; conjoining the qualities of excitability and of debility. Such an union of qualities, however, is compatible with the characteristics of other temperaments, but occurs more commonly in the sanguine, whether existing in its purest form, or blended with the phlegmatic; and it is found exemplified chiefly among those whose occupations are sedentary, and who lead a life of ease and luxury.

(868.) These several temperaments are found variously modified by occasional intermixture in different degrees with one another. Thus, the phlegmatic is often conjoined with the sanguine, and sometimes with the melancholic temperaments; and observation will readily suggest examples of other similar combinations. The predominance of each of these temperaments varies at different periods of life. At an early age the system inclines more to the sanguine; in middle life, to the choleric; and at a more advanced age, to the melancholic temperament. They admit also of being variously influenced and modified by climate, habits, and education; and accordingly each is found to prevail amongst particular tribes and nations, and in particular regions of the globe.

CHAP. XXI.—VARIETIES OF THE HUMAN SPECIES.

ingleness
f the hu-
an spe-
es.

(869.) It has been a question much agitated amongst naturalists, whether the differences observable in the complexion, features, and the intellectual and moral endowments of different tribes and nations which are found scattered over the surface of the globe, are sufficiently great to mark an original diversity of species, or whether they correspond merely to the character of varieties taking place in a single original race, analogous to those we behold in many domesticated animals, such as the dog, the horse, and the sheep, and therefore affording no objection to the hypothesis that every individual composing the human race belongs really to one and the same species. To Blumenbach belongs the merit of being the first who entered with a philosophical spirit into the investigation of this great problem. The generally prevailing opinion at present is, that all mankind are the descendants of the same original stock; and are therefore to be considered as members of the same family.

arieties.

(870.) It is a matter of considerable difficulty to establish an accurate classification of the different varieties into which the human race should be divided. Blumenbach, who, from having devoted to it much labour and attention, is justly considered as the highest authority on this subject, has fixed the number of these varieties at five; though, as Mr. Lawrence observes, these five races ought perhaps rather to be considered as principal divisions, each of them including several subordinate varieties. M. Bory de St. Vincent, in his *Treatise on Man*, extends the number of primitive varieties to fifteen. Cuvier, on the other hand, is inclined to refer all the varieties in the race to three principal heads, considering the others as merely modifications of these.

(871.) The five varieties which Blumenbach has pointed out, are designated by the terms *Caucasian*, *Mongolian*, *Ethiopian*, *American*, and *Malay*. He regards the Caucasian race as the primitive stock, or as the standard and type of the rest. It appears, indeed, to occupy an intermediate place between the Mongolian race, on the one side, and the Ethiopian on the other, which latter races are the most widely different from each other. The American variety has been considered as intermediate between the Caucasian and the Mongolian; and the Malay race as intermediate between the Caucasian and the Ethiopian. The various intermixtures which have taken place between these several races, in different parts of the world, render it very difficult, at the present day, to draw those precise lines of distinction which have probably, in remoter times, characterized the primitive races now enumerated. Thus, in Asia, we find considerable mixtures of the Caucasian with the Mongolian races; whilst in Africa, the Caucasian race has in various instances been blended with the Ethiopian.

1. Caucasian.

(872.) The following are the circumstances by which these several varieties are characterized:—1. The *Caucasian races* are distinguished by the general whiteness of the skin; the fairer complexions exhibiting a roseate tint, particularly conspicuous in the cheeks, and derived from the abundance of blood circulating in the vessels, and the darker races inclining to a brown, and by the abundance and softness of the hair, which is either black, or of a lighter chesnut colour, occasionally inclining to red. The cranium is large and oval, and developed especially about the forehead; the face comparatively small, and falling perpendicularly underneath the forehead. The features are distinct from each other; the nose narrow, and frequently aquiline; the mouth small; the front teeth in both jaws have a perpendicular direction; the lips, particularly the lower one, are gently turned outwards; the chin is full and rounded, and the general contour of the face has an oval form, and is broader in the upper than in the lower portion. This is the race in which the moral and intellectual energies of man have risen to a higher degree of excellence than in any other; and it is the race which has at all times been the most susceptible of cultivation and improvement. The hope may indeed be entertained that it is yet far from having arrived at the highest point in these respects which it is destined to attain.

2. Mongolian.

(873.) 2. The *Mongolian* races are characterized by a complexion approaching to an olive colour; the eyes being black; the hair also black, strong, and straight; the beard thin and scanty; and the head of a form somewhat square; the cheek bones large and prominent; the forehead low; the face broad; the features flattened, and running together; the nose small and flat; the aperture of the eyelids narrow, and the orbits situated obliquely; the lips thick; the chin slightly projecting; the ears large. The stature of most of the nations belonging to this race is, in general, inferior to that of Europeans.

3. Ethiopian.

(874.) 3. The *Ethiopian* or *negro race* is marked by the lateral compression of the skull, which is elongated forwards; by the prominence of the cheek bones, the narrowness and projection of the jaws, and the recession of the chin. The forehead is low, and very slanting; the eyes prominent; the nose broad, thick, and flat; the lips, the upper one especially, thick; the upper front teeth are oblique; the hair black and woolly; the legs are long and slender; the calf especially is small, and the knees are bent inwards; the arms are longer than in the other races.

4. American.

(875.) 4. The *Aboriginal American race* is remarkable for the red colour of the skin, the strong and straight black hair, the scanty beard, and low forehead, the deeply sunk eyes, and the round and prominent cheek bones. The mouth is large, the lips thick, and the face in general broad and square; characters which assimilate this race with the Mongolian, from which, however, it is sufficiently distinguished by the colour of the skin, and the projection of the features, especially of the nose.

5. Malay.

(876.) 5. The *Malay variety* of the human species varies considerably in the colour of the skin, from a light tawny brown, to one approaching to black. The head is narrow; the bones of the face are large and prominent; the mouth large; the nose full and broad at the point. The hair is black, and more or less curling.

Their distribution.

The following account of the filiation of the different races, and of their distribution over the globe, is given by Cuvier.

(877.) The Caucasian race has been so named from its presumed origin in the western part of Asia, in the neighbourhood of the Caucasian chain of mountains, which are situated between the Caspian and the Black Seas; whence it has spread as from a centre to the adjacent parts of the Asiatic, European, and African continents. The present inhabitants of these regions, namely, the Circassians and the Georgians, are reputed to be still the handsomest race on earth. The principal ramifications from the primitive stock, may be most satisfactorily traced by following the analogies of the languages of the nations which have proceeded from it. Thus, the Armenian, or Syrian branch, proceeded southwards, and gave rise to the Assyrian and Chaldean nations; and also to the Arabians, who, after the era of Mahomet, aspired to the empire of the world. The Phœnicians, Jews, and Abyssinians may be regarded as Arab colonies, to which class also the Egyptians may probably be referred.

(878.) The branch giving origin to the *Indian*, *Germanic*, and *Pelasgic* tribes was far more widely spread, and became subdivided at a much remoter period of antiquity. Among the four principal languages which prevailed among the nations composing these races, namely, the Sanscrit, the ancient Pelasgic, the Gothic or Teutonic, and the Sclavonic, we may trace the most multiplied affinities. The primitive Sanscrit is still preserved as the sacred language of the Hindoos, and is the model on which all the existing languages of Hindostan have been formed. The Pelasgic is the primitive source of the Greek, of the Latin, and of many other tongues now extinct, but from which most of the present languages of the south of Europe have been derived. The Teutonic has given rise to the languages of the northern and the western nations of Europe, such as the German, the Dutch, the English, the Danish, the Swedish, together with their various dialects. From the Sclavonic tongue are derived those of the north-east of Europe, namely, the Russ, Polish, the Bohemian, and the Vendean.

(879.) It is amongst this latter extensive race that philosophy, sciences, and the arts, have been most assiduously cherished, and have been carried to their highest states of perfection. This race had, in Europe, been preceded by the Celtic tribes, which originally came from the north, and were formerly widely spread, but which are now confined to very narrow spaces in the west of Europe and Africa, and are nearly effaced by continued intermixture with the numerous races which have supplanted them.

(880.) The ancient *Persians* have a similar origin with the Indians; and their descendants at the present time, bear the strongest marks of affinity to the modern European nations.

(881.) The *Scythian* or *Tartaric* branch, first directed itself towards the north and north-east, and composed the wandering tribes which traversed the immense plains of Tartary. In later times, become more numerous, they returned to spread devastation amongst the flourishing establishments of their more civilized brethren. The irruptions of the Scythians in Upper Asia, of the Parthians, who overthrew the domination of the Greeks and Romans in those regions; of the Turks, who destroyed that of the Arabs, and reduced to subjection the miserable remnant of the Greek nations in Europe; all proceeded from the overflowings of the northern swarms from this common race. The Finlanders and the Hungarians, which belong to this race, may be regarded as stragglers from these swarms, amidst Sclavonic and Teutonic tribes. On the northern and eastern coasts of the Caspian Sea, the original cradle of these races, there are still found tribes which have the same common origin with the former, and which speak a similar language; but they are variously intermixed with a great number of other smaller tribes, differing from them both in language and in origin.

(882.) The *Tartarian* tribes have remained more free from mixture, along the whole of that extensive tract whence they long defied the power of Russia, but to which they have at length been forced to submit; namely, from the mouths of the Danube, to the countries beyond those of the Irtish. But the conquests of the Mongols have led to considerable blending of the two races among the Tartarian nations.

(883.) The *Mongolian* race inhabits the remoter regions of Asia, extending from the eastern parts of the continent, where the Tartar branch of the Caucasian race terminates, to the Eastern Ocean. The different branches of this Mongolian race, such as the Calmuc Tartars, and the Kalkas, have no settled residence, but are wandering tribes over the extensive deserts of Eastern Asia. Thrice have their ancestors carried far and wide the terror of their arms; first, under Attila; next under Genghis Khan; and, lastly, under Tamerlane. The Chinese are an ancient branch of this family, which was very early trained to a high degree of civilization; at a period, indeed, apparently more remote than that to which our most ancient histories extend. The Manchew Tartars, who have recently achieved the conquest of China, are a third branch of the same Mongolian race. The Japanese, the Coreans, and almost all the hordes which extend to the north-east of Siberia, under the dominion of Russia, belong also to the same division of the human species.

The original seat of this widely-spread race appears to be the chain of the Altai mountains, the central ridge of Asia; in the same way that the race to which we belong was derived from the inhabitants of mount Caucasus; but it is quite impossible to unravel the complicated filiation of these various tribes. The history of these wandering people is as evanescent as their establishments; and even that of the Chinese, confined as it is to the limits of their empire, supplies only brief and unconnected notices of the surrounding nations. The affinities of their languages are too imperfectly known to afford any clue for our guidance in this mighty labyrinth.

(884.) The languages of the north of the Indian peninsula, beyond the Ganges, as well as that of Thibet, have some relations with the Chinese language; at least they resemble it in their monosyllabic structure. There is also a general resemblance of features among all these Mongolian tribes. But the southern division of the same peninsula is inhabited by a different race, namely, *Malays*, distinguished from the former by their greater symmetry of form, and by a peculiar language. This race is spread over the coasts and islands of the Indian Archipelago, as well as those of the Southern Pacific. In the largest of the Indian Islands, however, we meet with a much more barbarous race of men, with dark woolly hair, with black skins, and with the negro features, and savage and ferocious in their dispositions. They are known by the name of *Papuans*, and are principally met with in the Islands of New Guinea, and the New Hebrides. It has been conjectured that this singular tribe was descended from negroes accidentally cast on the shores of these remote islands.

(885.) The inhabitants of the northernmost regions both of the old and new continent, comprising the Samoides, the Laplanders, and the Esquimaux, possess many peculiar features, and have been classed by some naturalists under the Mongolian races, but are considered by others as degenerated scions from the Scythian and Tartaric branches of the Caucasian race.

(886.) The aboriginal American Indians have never been satisfactorily assimilated to any one of the races of the ancient continent; yet they scarcely possess any precise or well marked distinctive characters, which may entitle them to be regarded as one of the primitive races of mankind. The copper hue of their skin is certainly not of itself sufficient to establish such a distinction. Their dark hair and scanty beard would incline us to refer them to the Mongolian race, were it not that their well defined features, and prominent nose, are opposed to such a classification. Their languages are as diversified as their tribes are numerous; and no analogy has yet been traced either amongst one another, or with any of those of the old world.

(887.) The analogy of what we observe in the inferior animals, affords the strongest grounds for believing that natural causes are perfectly adequate to explain the diversities which occur in the several varieties of the human race, on the supposition of their having originated from a common stock. The variations in size, colour, and even forms, which take place amongst different kinds of dogs, characters which are transmitted from the parent to the offspring with as much constancy as those of the human race, are no less considerable than the differences observable between the European and the negro, and yet are admitted by naturalists to be perfectly compatible with the unity of the species, and with a community of source. Of the causes which originally produced the peculiarities in the several varieties of the race, and which have become permanent, we can have no certain knowledge; nor can we even supply the want of precise information by any rational conjecture. The common hypothesis which ascribes the black colour of the negro to the more powerful influence of the solar rays in tropical climates, will not bear the test of close examination; no permanent effect of that kind having ever been produced by the same cause operating for any length of time on the complexion of Europeans. Different opinions have been entertained with regard to the natural and original complexion of the human race. Dr. Prichard contends that it was black, and that the Ethiopian form was the primitive type of the race; the successive changes produced being that from the imperfect to the more perfect form, and from barbarism to refinement; terminating at length in the Caucasian race, in which it has attained the greatest state of improvement compatible with its nature, accompanied by the highest degree of capability of civilization, and of intellectual and moral excellence.[1]

(888.) In opposition to the doctrine of the unity of species in all human races, it has been contended by Rudolphi, Virey, Desmoulins, Bory St. Vincent, and others, in the most positive manner, that these races were originally different. The arguments on each side of the question are fully discussed in the work of Dr. Prichard referred to.

CHAP. XXII.—COMPARATIVE PHYSIOLOGY.

(889.) We purpose, in giving an account of the most important facts relating to the physiology of the animal creation, to take as the standard of comparison the mode in which the functions of the human body are conducted. The history we have given of the animal economy in man will easily enable us to refer all the facts relating to comparative physiology to this standard type; and this view of the subject, besides the interest which naturally attaches to it, will have the further advantage of reflecting light on various subjects of human physiology, which, as we formerly remarked, must ever receive important elucidation from a comparison with that of the lower animals.

(890.) Conformably with this design we shall take a review of the different divisions of the animal kingdom; first pointing out the general characters of organization and of function which are common to each class and order; and noticing, in the next place, the peculiarities that are most worthy of remark in the several species included in those divisions. By thus following the logical order of descending from generals to particulars, we shall avoid the numerous repititions that would otherwise be requisite, and comprise in the smallest space the greater number of particular facts relating to the science.

Sect. I.—*Comparative Physiology of Mammalia.*

1. *Peculiarities in the Human Conformation.*

Peculiarities of the human structure,

(891.) Since man, in his zoological relations, must be comprehended in the class of mammalia, it is evident that the general characters of this class must consist of those possessed by the human species in common with quadrupeds, and even with the other families of mammalia still farther removed from man in their external conformation. While the points of resemblance are so numerous, the easiest mode of instituting a comparison between them will evidently be by pointing out, not the features which they possess in common, but those in which they differ. We shall begin then with an account of the peculiarities which distinguish the human structure from that of the lower animals, and more especially from that of the quadrumanous tribes, which approach the nearest to him in their conformation.

referable to mental endowments.

(892.) The great distinctive features which characterize the human conformation, as compared with that of all other mammalia, have reference to the superiority of his intellectual powers, and to his maintenance of the erect position. In the number and excellence of his mental faculties, and in his capabilities of improvement, he leaves all other animals behind by an immeasurable distance. The faculty of speech is a consequence of this developement of intellectual power, which is favoured, indeed, by the conformation of the larynx; but the organization requisite for the uttering of articulate sounds would have been in vain conferred unless it had been placed under the guidance of the mental faculties; thus to the parrot the gift of the organs of articulation, without the mind which is to use them as expressions of thought, becomes a comparatively unprofitable boon.

(893.) The superiority of the human intellect is accompanied by a much greater developement of the cerebral hemispheres than is found in any other animal. Hence also the great magnitude of the cavity in which it is contained, together with that part of the skull which protects it, when compared with the face, which is composed of the organs of the principal senses, and of the apparatus for mastication. The mass of the brain bears also a large proportion to the size of the cerebral nerves. The cerebellum is entirely covered by the hemispheres of the brain. The forehead in man is particularly distinguished by its elevation, and the beauty of its convex arch. The shortness of the lower jaw, and the prominence of its mental portion, are particularly remarkable. The elephant is the only quadruped in which the lower jaw is equally short in proportion to the size of the head; but this animal is still deficient in the projection of its lowest point, so that the possession of a chin seems to be peculiar to the human race.

Adaptation to the erect position.

(894.) In every particular connected with the mechanism of the fabric, man enjoys the most decided advantage over those mammalia which are most nearly allied to him in their physical conformation. Man is the only species amongst the mammalia whose body can maintain itself for any length of time in an erect position, and in whom the office of supporting the trunk is entrusted solely to the lower extremities. We find that every part of the osseous fabric, as well as the disposition of the principal organs of sense, are in obvious conformity with this design. The lower limbs, being the great instruments of support and progression, are larger, and of greater strength, compared with the body, than in most quadrupeds, the only exceptions being met with among those which are formed expressly for leaping, as the hare, the jerboa, and the kangaroo. In the monkey tribes the lower limbs are comparatively much weaker than in man;

---

[1] See his *Researches on the Physical History of Mankind.* Third edition. London, 1806.

and in other quadrupeds the disproportion is still greater, the thigh bone being short, and almost concealed by the muscles which connect it with the trunk of the body, while the rest of the limb is very slender, and not covered by any considerable mass of muscle. In man the articular surfaces of the knee-joint are very broad, and admit of greater extent of motion than in quadrupeds, and the two portions of the limb can be brought into the same straight line, thus constituting firm perpendicular columns of support for the body. The long neck of the thigh bone allows of more complete rotation of the limb at the hip-joint; and this, together with the greater breadth of the pelvis, which affords an ample basis for sustaining the trunk, are circumstances peculiar to the human frame. The heel in man forms a greater projection than in other animals; and by its being extended so as to touch the ground, it forms, as we have seen, one of the points of support, by which, in conjunction with the toes, a much larger base is comprehended. The muscles which raise the heel, and which compose the calf of the leg, are of greater size and strength than in monkeys, besides acting with the mechanical advantage arising from the long lever which the heel affords for the insertion of their united tendons; and by the direction of the foot, which forms a right angle with the leg.

(895.) The form of the chest exhibits similar differences. In quadrupeds the thorax is compressed laterally, and is deepest from the spine to the sternum; a structure which allows the front legs to come nearer together, and to support with more effect the front part of the trunk. But in man the thorax is flattened anteriorly and extends more in width, that is, from side to side, thus throwing out the shoulders, and giving a more extensive range to the motions of the arms.

(896.) That the erect posture is natural to man is strongly indicated by the position of the head with respect to its articulation with the spine, which takes place at the middle of its basis; and thus, by the great extension of the occiput, its weight is more nearly balanced than it is in the monkey. The cervical vertebræ of the monkey have very long and prominent spinous processes, evidently adapted to give greater purchase to the muscles sustaining the head, of which the front part considerably preponderates, in consequence of the elongation of the jaws, and the backward position of the centre of motion.

(897.) The same design may be traced in the position of the eyes, the mouth, and the face in general; and is so obvious as to have been noticed by Ovid, while describing the formation of man, in the following celebrated lines:

> "Pronaque cum spectant animalia cætera terram,
> Os homini sublime dedit: cœlumque tueri
> Jussit, et erectos ad sidera tollere vultus."

(898.) All the internal organs have been regulated by the same intention. The human heart is placed obliquely in the chest, and rests by a flat surface on the diaphragm, to which its investing membrane, the pericardium, is firmly attached. In quadrupeds, no such attachment exists; but the heart is situated more perpendicularly with the apex directly downwards, and cannot be felt, as in man, striking on the left side of the ribs at each contraction of the ventricles.

Arm and hand.

(899.) The fore legs of quadrupeds are in general appropriated solely to the support and progressive motion of the body. In some instances, indeed, they are employed, besides, in other actions; such as seizing and securing their prey, raking and digging up the earth, or climbing and laying hold of the branches of trees; but it is only in a few species, and chiefly among the monkey tribes, which resemble man in their form, that they are instrumental in carrying food to the mouth, or even in grasping weapons of offence. But in man the superior extremity being entirely released from the office of maintaining any portion of the weight of the trunk, is at liberty to be employed for a great variety of purposes; and the exquisite structure of the human hand, which has already been noticed, renders this exemption of still greater value, and constitutes unquestionably one of the great perfections which mark the human structure, as compared with that of the brute creation. The arm and head are thus rendered an organ at once of prehension and of touch, for both of which purposes it is admirably adapted by the great latitude and variety of movements it is capable of executing. One of the chief sources of perfection in the hands is the structure of the thumb, which is furnished with muscles of so great a power, compared with those of the fingers, as to enable it to oppose and balance their united strength. Hence it is enabled to grasp a spherical body, and to retain firm hold of many objects, which otherwise could not have been held without the united efforts of both hands. This conformation is peculiar to man; for the paw of a monkey cannot exercise the same force and readiness of prehension, in consequence of the thumb being inferior in strength to the other fingers.

Vocal organs.

(900.) The great perfection of the organs which modulate the voice and produce so great a variety of articulate sounds, is another striking instance of the high destination to which the human structure has been adapted. In those tribes of monkeys which come nearest to the human conformation, the power of uttering articulate sounds is prevented by the interposition of two sacs connected with the larynx, which receive part of the air when the animal uses any effort to expel it from the lungs.

Man omn vorous.

(901.) The structure of the digestive organs in the human species is similar to that of many quadrupeds, and has generally been regarded as intermediate between that of the carnivorous tribes, and of those that live altogether on vegetable food. Man may very justly, and almost exclusively be entitled to the appellation of an omnivorous animal; being equally capable of subsisting on different kinds of aliment; and also of using at the same time a great mixture of different sorts of food. No other animal is capable of so great a versatility of powers in this respect. It has also been remarked, amongst the characteristic circumstances of the human race, that whilst other animals are contented with food in the state in which nature offers it, man alone employs artificial processes for improving its flavour, and rendering it more fit for digestion. Man is the only animal that is known to practise the art of cookery; an art which indeed appears necessary to enable the stomach to extract from his usual food all the nutriment it is capable of yielding.

(902.) The teeth of man are distinguished from those of all the other mammalia by their being arranged in either jaw, in a uniform unbroken series; and also by the circumstance of their being all of the same length. The cuspidati, or eye-teeth, as they are called, which correspond to the canine teeth in quadrupeds, are, perhaps, at first a little longer than the others, but their sharp points are soon worn down to a level with the rest. In all the monkey tribes, these teeth are long and prominent, and are separated by an interval from the neighbouring teeth. The cutting teeth in the lower jaws slant backwards in the monkey, and the jaw itself has the same direction; but in man these teeth are perpendicular, and in a line with the front of the jaw, which descends to form the prominence of the chin, a part of the face which does not exist even in the orang utan. The tubercles on the surface of the grinders are different in their shape, both from the ridges of enamel on the crowns of the teeth of herbivorous animals, and from the sharp-pointed eminences on the grinders of carnivorous animals.

Encephalon.

(903.) The human brain is not only larger in its relative proportion to the body than in any other of the mammalia, but its absolute size is greater, if we except only that of the elephant, and of the whale. With these few exceptions, all the larger animals with which we are more commonly acquainted, have brains absolutely, and even considerably smaller than that of man. Besides the prodigious expansion of the hemispheres, we may remark in the human brain a more elaborate structure, and a more complete developement of all its minuter parts. There is no part of the brain found in any animal, which does not exist also in man; whilst several of those which are found in man are either extremely small, or altogether absent in the brains of the lower animals. Soemmerring has enumerated no less than fifteen visible and material anatomical differences between the human brain and that of the ape. The proportion of medullary to cortical substance is greater in the human brain than in that of other animals.

icial gle.

(904.) Although the negro race is a branch of the great family of man, and although the peculiarities which distinguish the conformation of that race rank only as varieties in the species, it yet cannot be denied, that in almost every one of the circumstances in which it differs from the type of the Caucasian race, it exhibits an approach to the structure of the monkey or quadrumanous tribe of animals. In nothing is this approximation more remarkable, than in the proportion between the size of the face as compared with that of the brain. One of the most convenient methods of roughly estimating this proportion is that invented by Professor Camper. Drawing a line from the most prominent part of the frontal bone, to the anterior point of the upper jaw bone, just at the roots of the incisor teeth, which is called the facial line, it is to be intersected by another line, drawn from the external orifice of the ear to the inferior edge of the aperture of the nostrils. The angle formed by these two lines is the *facial angle* of Camper, which determines by its magnitude the degree of preponderance of the bones of the cranium, in which the brain is contained, over those of the face, which contain the organs of sense.

(905.) In man the facial angle is greater than in other animals; it differs, however, in different varieties of the human race, and appears to indicate with tolerable exactness the comparative degree of intellectual excellence appertaining to each variety. In the Caucasian variety the facial angle is between 80° and 90°; in the Mongolian, 75°; in the American Indian, 73½°; in the Negro it is only 70°. Pursuing the application of this test to the lower mammalia, we find it in the orang utan reduced to 65°; in the baboon, 45°; in the mandrill, one of the most ferocious of that tribe, only 30°. The mastiff has a facial angle of 41°, the bulldog of 35°. In the feline tribe it is still farther diminished; being only 28° in the leopard. In the sheep and hare it is 30, in the horse it is only 23°.

(906.) The varieties in the magnitude of the facial angle have thus been traced through a number of gradations amongst different tribes of mammalia and also of birds, till we arrive at its almost total obliteration in the snipe and the woodcock, animals which are reputed to be extremely deficient in intelligence.

(907.) The projection of the bones of the face, which tends to diminish the facial angle, is universally considered as expressive of stupidity or ferocity. An ample and projecting forehead, on the contrary, is associated in our minds with the idea of superior intelligence. It was probably for that reason that the owl was selected by the Athenians as the emblem of wisdom. In the statues of their divinities, the Greek sculptors have exaggerated the facial angle, making it as much as 100°, which is considerably greater than it is ever found in the human form. The Italian painters, also, in their representation of saints, have often given them a facial angle of 95°.

(908.) But in applying this method to some of the most sagacious species of animals, such as the horse, which, as we have seen, has a very small facial angle, we meet with great and striking exceptions. We arrive at more correct determination of the proportional developement of the face and brain, by comparing, as proposed by Cuvier, the areas respectively occupied by each in a longitudinal vertical section of the head. But in the elephant all these criteria, but especially the admeasurement by the facial angle, fail, in consequence of the great projection of the frontal bones, which are raised to a considerable distance from the brain by the interposition of large cells, or frontal sinuses, and which give an undue proportion to the size of the forehead.

Occipital angle.

(909.) Daubenton proposed, for the comparison of different skulls with one another, what he called his *occipital lines;* the one passing from the posterior margin of the great occipital foramen through the lower edge of the orbit; the other, taking the direction of the opening itself, beginning at its posterior edge, and touching the articular surface of the condyles. The angle formed by the intersection of these lines is his *occipital angle.* But the variations of this angle are too inconsiderable to furnish sufficient criteria of the character of the head.

2. *Peculiarities in the Conformation of other Mammalia.*

Mammalia in general.

(910.) The bones of quadrupeds appear, as Blumenbach observes, to possess a less fine and delicate texture than those of man. Their fibres are more easily loosened by maceration, and are of a coarser grain; this is more particularly observable in the jaw-bones and the ribs.

Spine.

(911.) The spine is formed of the same classes of vertebræ as in man, namely the cervical, dorsal, lumbar, and sacral. In all quadrupeds belonging to the class of mammalia, the number of cervical vertebræ is constantly seven, as in man. The length or shortness of the neck has no influence on their number, though it has a material one, of course, on the comparative length of each individual vertebræ. The cameleopard, whose neck is extended to so great a length, and the mole, in which it is so short, have each of them seven cervical vertebræ. An apparent exception to this general rule occurs in the three-toed sloth, in which Cuvier found nine vertebræ of the neck instead of seven; but it has since been found that the two last of the cervical vertebræ, which appeared to be supernumerary, ought properly to be classed amongst the dorsal vertebræ, of which they possess the distinctive characters.[1]

(912.) The number of dorsal vertebræ depends principally upon that of the ribs, which differ in different quadrupeds, and are usually more numerous than in man. Their transverse and spinous processes are generally longer than in man, for the purpose of affording a broader surface of attachment to the powerful muscles which support the head and neck.

The number of the lumbar vertebræ is various in different quadrupeds. There are only three in the elephant; five in the ass; six in the horse; and seven in the camel. Still greater differences are met with in the number of component parts of the sacrum.

Caudal vertebræ.

(913.) Most quadrupeds have a prolongation of that part of the skeleton which corresponds to the os coccygis of man, and which in them composes the tail, and consists of a great number of imperfectly formed vertebræ.

Skeleton.

(914.) The thorax of quadrupeds is, as we have already noticed, more compressed laterally, but deeper from the spine to the sternum, than it is in the human skeleton. The scapula is constantly found; but in most tribes there is no clavicle whatever, and in others only a short rudiment of that bone, connected merely with the muscles. In other respects the number and connexions of the bones of the extremities are generally very similar to the human conformation; we may observe, however, that the os femoris is usually much shorter than the tibia, and being covered by the large muscles which attach it to the trunk, appears to belong to that division of the body. The bones of the carpus and tarsus, together with those of the fingers, are in many cases exceedingly compressed, and some of them are so consolidated together, as not to be distinguishable as separate bones.

---

[1] See a paper by Mr. Thomas Bell, *Philosophical Magazine*, third series, iii. 376.

Intermaxillary bone.

(915.) In all the mammalia we find a peculiar bone, called the *intermaxillary bone*, interposed between the two upper jaw-bones, and locked in between them; its office appears to be to contain the upper incisor teeth, when these teeth exist; but it is also met with when there are no incisor teeth.

Teeth.

(916.) The number, form, and internal structure of the teeth is exceedingly diversified in the different tribes; and afford excellent characters for the distinction of orders and genera of the class mammalia. As these characters have a strict relation to zoological classification, we shall abstain from entering here into the details of this subject.

(917.) In proceeding to notice the peculiarities of structure in the mammalia, we shall next examine the organs of the functions of assimilation, to which that part of the skeleton we have just adverted to, namely, the jaws and teeth, are subservient.

Digestive organs.

(918.) The tongue of quadrupeds is, for the most part, more narrow, long, and slender than that of man. Except in the genus simia, we do not meet with any structure corresponding to the uvula. The œsophagus has two layers of muscular fibres, which have a spiral course, and cross one another. This structure gives it greater power of propelling its contents into the stomach; a power which is the more required, inasmuch as the food has often to ascend considerably in passing along this canal.

(919.) The conformation of the stomach presents very considerable diversities, apparently determined by the habit of the animal and the nature of its food. From the simple structure it exhibits in the purely carnivorous tribes, we may observe a gradually increasing complication as we pass to those that feed on fish, and on vegetable aliment. In the latter orders of mammalia, and especially in the ruminants, we meet with a very complicated apparatus for digestion. But these diversities will come more properly to be noticed in the examination of the orders and families to which they relate. It will be sufficient here to remark, that the stomach is often divided into several distinct portions, such as the cardiac and pyloric; and often presents several intermediate subdivisions, and expansions into separate pouches, so as to exhibit the appearance of a multiplicity of cavities or stomachs. They differ also considerably as to the degree in which the glandular structures attached to their coats are developed in different parts.

(920.) Similar varieties are met with in the structure of the intestines of different mammalia. As a general rule, to which, however, there are several exceptions, it may be remarked, that the intestinal canal is much shorter, and more contracted in its diameter, in carnivorous animals than in those which feed on vegetables. This probably depends on the more rapid assimilation of animal than of vegetable materials; the latter requiring a more complicated apparatus, more capacious cavities, and a more extensive surface both for secretion and absorption. It has been observed that the canal of the intestines is longer in the domesticated breed than in the wild animal of the same species. Thus, in the wild boar, the length of the intestines is to that of the body in the proportion of nine to one; but in the tame animal the proportion is as thirteen to one. In the domestic cat it is as five to one; in the wild cat as three to one. It may also be remarked that in the class mammalia, the comparative length of the intestinal canal is greater than in any of the other vertebrated classes; and diminishes successively as we compare it in birds, reptiles, and fishes.

(921.) The liver in the mammalia generally, is divided into a greater number of lobes, and the divisions penetrate deeper into its substance, than in man. In a great many instances, as in the horse and the goat, there is no gall-bladder, the bile being carried at once by the hepatic ducts into the intestine. Occasionally when the gall-bladder is present, there exist also hepato-cystic ducts which convey the bile directly from the liver into the gall-bladder, and not by a retrograde course, as in man.

The mammalia is the only class of animals provided with omentum, which, in some, as in the racoon, is particularly large and stored with fat.

Kidney.

The kidney generally presents a lobulated appearance; sometimes to such a remarkable degree, as to bear a resemblance to a bunch of grapes, being composed of numerous small and distinct portions, connected together by their blood-vessels and excretory ducts. The urinary bladder is more capacious in herbivorous than in carnivorous quadrupeds.

Heart.

The heart of the mammalia corresponds in every essential particular of its structure with the human conformation; but it differs in its position with regard to the other organs, being situated more longitudinally, and resting on the sternum, which is below it, and not on the diaphragm, as in man. Hence, also, the direction of its axis is not so oblique, and it is placed more in the centre of the chest; and the pericardium is scarcely at all connected with the diaphragm.

(922.) In many quadrupeds the thoracic duct is double, and forms more distinctly than in man the enlargement which has been termed the *receptaculum chyli*. The mesenteric glands are frequently collected into a considerable mass, called the *pancreas of Asellius*.

Sensorial functions.

(923.) From the consideration of the organs of nutrition we pass on to those of the sensorial functions, and shall for this purpose revert to the osteology, in as far as relates to the bones which protect the brain and principal organs of the senses.

(924.) The divisions of the cranium of quadrupeds into separate bones, differs but little from that of the human skull. The os frontis is frequently found divided into two lateral portions by the prolongation of the sagittal suture forwards to the root of the nose. Sometimes, again, the sagittal suture is obliterated by the consolidation of the two parietals into a single bone; in other cases, these bones are united with the occipital. We often find, also, a bone, distinct from the temporal, termed the *tympanic bone*, provided for containing the tympanum of the ear. But it may be observed, in general, that the sutures present fewer indentations, and less irregularity in their course in the skulls of quadrupeds than in man, a circumstance which is naturally explicable by the smaller developement of the brain, and consequent diminution of the general size of the cranium. From the position of the head in the quadruped the occipital foramen is situated less anteriorly in the basis of the skull than in man, and is for the most part nearly vertical in its position. The tentorium sometimes contains within the laminæ of the dura mater which compose it, several strong plates of bone, and the same thing has also been observed in the falx.

(925.) The brain of quadrupeds is considerably smaller, when compared with the size either of the spinal cord or the cranial nerves, than in man. The cerebral hemispheres are also much smaller compared with the cerebellum. This arises in a great measure from the absence of the posterior lobes of the brain, which, in man, when viewed from above, conceals the cerebellum; whereas in quadrupeds the cerebellum is brought immediately into view in removing the upper bones of the skull. In the proper quadrupeds the anterior lobes of the brain extend forwards into two large processes, called the processus mamillares, which give origin to the olfactory nerves, and which contains a cavity on each side, communicating with the lateral ventricle, being in fact its anterior prolongation. On the other hand, this ventricle has no posterior prolongation, there being no posterior lobe.

rgans of ell.

(926.) Every part of the organ of smell is developed in quadrupeds in a degree corresponding to the greater extent and acuteness in which they enjoy this sense, compared with man. The æthmoid bone is much more complicated in its structure, as well as larger in its dimensions; the turbinated bones are considerably larger, more intricate in their formation, and present a much more extensive surface, being composed either of a great multitude of arborescent laminæ, or of numerous spiral convolutions. The internal nasal cavities are also generally enlarged, and particularly the frontal sinuses.

earing.

(927.) The organ of hearing also frequently presents a greater complication of structure than in man. A cavity, called by Soemmerring, the *bulla ossea*, communicates with that of the tympanum, and corresponds with the mastoid cells in the human subject. In the aquatic mammalia the external meatus is furnished with a valve for the purpose of excluding water from the passage. In these animals, also, as well as in those that live under ground, the external ear is altogether wanting. The structure of the internal parts of the organ agree in all essential points with those of the human ear. The cochlea sometimes makes an additional turn in its spiral convolution.

ision.

(928.) The eyes of mammalia exhibit considerable variety as to the position of their axes with respect to the general direction of the head. They are generally separated to a greater distance, and directed laterally. The figure of the globe is nearly spherical, as in man; but in several quadrupeds the sclerotic coat is much thicker and firmer at its posterior than at its anterior part. The choroid coat is distinctly divisible into two layers, of which the internal bears the name of the *tunica Ruyschiana*, and which often exhibits at the back of the eye the most brilliant colours. This coloured portion of the choroid is known by the name of the *tapetum*.

(929.) Several quadrupeds have an additional lacrymal gland, besides that which corresponds to the one in man; and also another gland, situated near the nose, and termed the *glandula Harderi*. The globe of the eye in quadrupeds is also provided with an additional muscle, the *suspensorius oculi*, for the purpose of supporting its weight. Many quadrupeds also possess a third, or internal eye-lid, called the *nictitating membrane*, which is very large and moveable in the cat, and all the animals belonging to the same genus.

egu- nts.

(930.) The panniculus carnosus is a muscular expansion, situated immediately under the skin, and subservient to the movements of the integuments, which it suddenly corrugates and throws into wrinkles, thereby driving off insects, or shaking away any other offensive matter, is peculiar to quadrupeds, not being found in man; unless the platysma myoides of the neck be considered as a muscle having an analogous function with relation to the skin of the neck.

(931.) In many quadrupeds some of the sebaceous glands of the integuments are very much developed. In some predacious animals, a gland exists in the orbit, described by Nuck, and of which the excretory duct opens near the last tooth of the upper jaw. It appears referable to the class of salivary glands. Another gland, particularly noticed by Professor Jacobson, and of which the use is wholly unknown, is generally met with in the anterior and lower part of the cavity of the nostrils: this he has called *the nasal gland of Steno*.

3. *Quadrumana.*

adru- na.

(932.) We have already had occasion, when describing the distinctive marks by which the human structure is characterized, when compared with that of the monkey, to point out several circumstances which are deserving of notice in the anatomy of this tribe of mammalia. Of all the animals of the family of the quadrumana, the orang-utan (*simia satyrus*, Geoff.) is that species which makes the nearest approach to the human conformation. This approximation is observable in the position of the great occipital foramen of the skull, which is placed farther forwards than in other kinds of apes; in the distinctness and serrated form of the sutures of the cranial bones; in the absence of the intermaxillary bone; in the eyes being directed forwards; in the smallness of the os coccygis, composed, as in man, of five imperforated bones; in the possession both of a cœcum and an appendix vermiformis; and in the oblique position of the heart with respect to the cavity of the thorax.

(933.) A still more remarkable peculiarity of structure in the orang-utan is that discovered and described by Camper; namely, two membranous sacs, which communicate with the glottis, and deprives the animal of the power of giving utterance to sounds.

(934.) In other species of this order we trace still further deviations from the human structure. The laryngeal sacs are found in many species of baboons; these are either single or double, and communicate with the larynx by openings between the os hyoides and the thyroid cartilage. The simia seniculus, and the simia beelzebub, have a large dilatation of the middle of the body of the os hyoides, which is expanded into a spherical bony cavity. This cavity, instead of interfering with the sonorous vibrations, adds to their strength, and gives the power of producing those loud intonations which are peculiar to this tribe, and from which they have obtained the name of *howling apes*.

(935.) The mandrill baboon has seven instead of five lumbar vertebræ. The appendix vermiformis of the cœcum is not met with in many species of apes. The crest of the occipital bone, though very large in the baboon of Borneo, is scarcely perceptible in most monkeys. The central foramen of the retina discovered in the human eye by Soemmerring, has been seen in the eyes of many animals of this order.

(936.) In the lemur tardigradus, and in the sloth, a singular structure has been observed by Sir Anthony Carlisle, with regard to the distribution of the arteries of the limbs. The trunks of these arteries suddenly subdivide as they enter the limb into a great number of parallel branches, which are again re-united when they arrive at the remote end of the first division of the limb; that is, about the joints corresponding to the elbow and the knee in man. After their re-union into single trunks, these arteries proceed to ramify in the usual manner.

4. *Chiroptera.*

Chiroptera.

(937.) In the bat tribe we have to notice the strictly hinge-like nature of the articulation of the lower jaw with the skull, which limits its motion to mere opening and shutting, and excludes all lateral movements. The zygomatic arches are expanded and raised, so as to allow room for the large and powerful muscles which close the jaw. The parietal bones are united into a single bone. The sacrum is composed of four bones consolidated together. Four clavicles are met with, and they are of extraordinary length. The ulna is deficient in the fore-arm, or exists only in a rudimental state, as a slender sharp-pointed process of the radius. The phalanges of the anterior extremities are enormously lengthened for the purpose of supporting the thin membrane which is stretched between them, and which serves the office of wings. The tongue of the bat is covered with sharp-pointed horny papillæ.

Vampire bat.

(938.) The vespertilio noctula is remarkable for the shortness of the intestinal canal, which is only twice the length of the animal's body. In the vampire bat, on the contrary, and in the vespertilio caninus it is seven times as long. In all bats, not only is the appendix cœci vermiformis wanting, but also the cœcum itself. The epiglottis is also wanting in most of the animals of this tribe. In many the tongue is slender, and prolonged into an organ of suction. The pectoral muscles are of enormous size; and the sternum has a prominent crest for the purpose of affording an extensive surface for their attachment. The eye is remarkably small; but the imperfections which probably exist in the sense of sight are amply compensated by the singular acuteness of that of hearing, the organ of which is exceedingly developed; and also by the extreme sensibility of the expanded membranes of the wings, which is such as to enable the bat to direct its flight through the most intricate passages without the aid of the sight, and without striking against obstacles purposely placed in its way.

5. *Insectivora.*

Insectivora. Mole.

(939.) Among the animals arranged by Cuvier in this family, the mole presents the most remarkable peculiarities of conformation, both as regards the skeleton and the internal organs. The sternum has the same crested process as in the bat, and apparently with the same design of enlarging the surface of attachment to the powerful muscles employed in digging. But the anterior extremity of this crest is still farther prolonged into a sharp process, having the figure of a plough-share, which is situated under the cervical vertebræ, and resembles the keel-like projection we shall have occasion to notice in the sternum in birds. The cervical vertebræ are remarkable for having no spinous processes. The ligamentum nuchæ is particularly strong, and is almost wholly ossified. The clavicle is of a singular shape, being nearly cubical. The humerus is very slender in the middle, and remarkably expanded at both its extremities. The fore-paw is provided with a bone of a peculiar shape, called the falciform bone, placed at the end of the radius. The phalanges have numerous processes, and are furnished with sesamoid bones; structures which, by giving considerable mechanical advantage to the muscles that move them, contribute greatly to increase their power. The great muscles of the trunk, the pectoralis major, the latissimus dorsi, and the teres major, are of great size, and give the animal great facility in digging the ground, and throwing up the earth as it proceeds.

(940.) The æthmoid bone is of very complicated formation in the mole, especially in the numerous convolutions of its turbinated processes, by which a very large surface is given to the Schneiderian membrane which lines every portion. This structure indicates the possession of a very acute sense of smell. The remarkable developement of the internal parts of the ears, is also conclusive evidence of the delicacy of the sense of hearing in this animal, although it has no external ear whatever. The eye is so minute, that even the existence of that organ has been denied by some naturalists; it is, in fact, not larger than the head of a pin. The cavities in which they are placed are so very superficial, as scarcely to deserve the name of orbits. The zygoma is not arched, but straight, and as slender as a thread.

6. *Plantigrada.*

Plantigrada.

(941.) Animals of the plantigrade family have a long but narrow intestinal canal, unprovided with any cœcum or appendix, and consequently not presenting any marked distinction between the small and the large intestines.

Bear.

(942.) To this family belongs the bear, remarkable for possessing supernumerary canine teeth, which are small, and situated behind the principal ones. The stomach is divided into two portions by a slight contraction in the middle; the intestines are furnished with remarkably long and numerous villi; the kidneys are conglomerated; the tentorium is bony; the nasal cartilages are extremely mobile.

Racoon.

(943.) In the racoon, another animal of this tribe, the valve of the colon is wanting, and the omentum is very large, consisting of innumerable lines of fat, disposed in a reticular form, and connected by an extremely delicate membrane having the appearance of a spider's web. The skin of the neck is very loosely connected by cellular substance with the subjacent muscles.

7. *Digitigrada.*

Digitigrada.

(944.) The cœcum is wanting in the greater number of the animals of this tribe. It is met with, however, in the ichneumon. Many have anal glands and follicles, which prepare a strongly odoriferous secretion. This is the case with the skunk, pole-cat, and several others. When these animals are pursued, they pour out this fetid matter, the odour of which is so offensive as to deter their pursuers from approaching them. The civet has also similar glands that secrete the peculiar perfume which derives its name from that animal.

Weasel.

(945.) The stomach, in the weasel tribe, is a simple cylindrical canal, having no expanded extremity to the left of the cardia; but the œsophagus enters at one end, and the intestine proceeds from the other, so that the food may pass quickly through it. In the stomach of the sea otter, Sir Edward Home describes a remarkable glandular structure near the pylorus. The receptaculum chyli, in this animal, sends two trunks to form the thoracic duct, which have frequent communications, so that there are sometimes three, frequently four, and never fewer than two branches of this duct, running parallel to one another. In two instances the foramen ovale of the heart was found open, but the ductus arteriosus was closed.

Dog.

(946.) In the dog a row of mucous glands, corresponding to the labiales and buccales in man, is found opposite to the molar teeth, having several small openings into the mouth. A large salivary gland also exists under the arch of the zygoma, covered by the masseter muscle. Its duct is nearly equal in size to that of the parotid, and opens at the posterior extremity of the alveolar margin of the upper jaw. What is called the *worm* in the dog's tongue, is merely a packet of tendinous fibres, passing longitudinally the whole length of its tongue, and lying loose in a membranous sheath, unconnected with any of the muscles. It has been supposed to assist in lapping up fluids in the peculiar way in which dogs are observed to drink. There is a popular, but wholly unfounded idea, that the extirpation of this pretended worm, is a preservation against hydrophobia. The anal glands are of considerable size.

(947.) The thoracic duct is double in the dog, and forms a large receptaculum chyli. The crista occipitalis varies considerably in its degree of prominence in the different breeds of dogs. In all, the tympanic bone is distinct from the temporal bone, being separated from it by a suture. The urethra passes along a groove in a cylindrical bone. In the hyæna, however, which in other respects is very similar to the dog, this bone is not found. The extremities of the rings of the trachea, in the hyæna, overlap one another, and admit of being much compressed; a circumstance which has been considered as connected with the shrill and peircing cry which this animal is capable of uttering.

Lion.

(948.) The genus felis, of which the lion affords the most remarkable example, resembles the dog in many circumstances of conformation. We find the same set of mucous glands about the mouth, and at the extremity of the rectum. The tongue is beset with sharp prickles, the points of which are directed backwards; they are of such strength as to tear off the skin from any part which the lion may lick. The stomach is divided by a slight middle contraction, into a cardiac and a pyloric portion. The ductus choledochus forms a pouch between the coats of the intestine for receiving the pancreatic duct. In all animals of this genus the tentorium is bony. The zygoma is arched, and very large and prominent. The long bristly hairs which constitute the whiskers, receive very considerable nervous filaments, and appear subservient to the sense of touch in a very remarkable degree. Two delicate membranes are met with lying under the ligaments of the glottis, and are probably the cause of the piercing sound peculiar to animals of this tribe. The retraction of the claws into a sheath is matter of familiar observation in the cat. The pupil of the lion is circular, but that of the cat has the form of a vertical slit when closed; and the motions of the iris appear to be partly voluntary.

8. *Amphibia.*

mphibia. eal.

(949.) Whiskers having the same properties are likewise found in the seal, an animal of aquatic habits, and whose conformation is modified with reference to the element it is intended to inhabit. The feet act as fins, adapted for swimming; the radius and ulna are flattened; the spine is very flexible; the pelvis very narrow. The bones have no medullary cavities. Neither the parotid nor the sublingual glands are met with in this or any other animal of the order of amphibia, belonging to the class mammalia; and the teeth are adapted chiefly to the seizing and detention of objects, and are scarcely capable of serving the purpose of mastication. The stomach is a straight cylinder, having no cardiac expansion. The intestinal canal is of great length, thus forming an exception to the general rule of its being comparatively short in carnivorous animals. The renal veins form a kind of net-work, the reticulations of which intersect the furrows between the mammary processes on the outer surface of the kidneys. The proportional size of the brain of the seal is greater than in most mammalia.

(950.) The eye of the Greenland seal is peculiarly formed, having, according to Blumenbach, the anterior segment of the sclerotica, or that immediately behind its junction with the cornea, thick and firm; its middle circle thin and flexible; and its posterior part very thick and almost cartilaginous, while the cornea itself is thin and yielding. The whole eye-ball is surrounded by very strong muscles capable of shortening the axis of the eye, and of adapting it, according to circumstances, to distinct vision in air; while in their ordinary state of relaxation, the axis of the eye being lengthened, the animal when under water is still enabled to see objects distinctly.

alrus.

(951.) The walrus, another animal of this order, is remarkable for the form of its teeth and tusks, part being external; but these fall more within the province of the naturalist. The zootomist may notice in this animal the smallness of the intermaxillary bone, and the total absence of the gall bladder.

9. *Marsupialia.*

arsu- alia.

(952.) The marsupial family of mammalia compose an interesting group of animals, which present many remarkable singularities in their internal conformation and economy. The principal of these is the apparently premature birth of their young, which come into the world at a period of their developement corresponding to that to which the fœtuses of mammalia have arrived only a few days after conception. Nearly the whole extent of the integument of the fore part of the abdomen forms a kind of sac or pouch for the reception of the fœtuses in their early state, and whilst they present only a shapeless mass, destitute of external members, and totally incapable of locomotion. They become attached to the nipples of the mammary glands, situated under the integument of the pouch next to the abdomen of the mother; and they remain in this situation for a long time, imbibing nourishment from these glands, until they acquire a growth equal to that which the young of other animals attain in the uterus before birth. Two bones, peculiar to these animals, and therefore called the marsupial bones, are expressly provided for the protection of the abdominal viscera, lying in the horizontal position of the trunk above this extraordinary pouch, which performs the function of a supplementary uterus. It is farther remarkable, that the same bones occur in the skeleton of the males, where, of course, there are no pouches; and also in those species where the fold forming the pouch is scarcely perceptible. The uterus communicates with the vagina, not by a single opening, but by two curved lateral tubes. This has been called the *uterus anfractuosus*, to distinguish it from the ordinary form, which is the *uterus simplex;* the *uterus bicornis*, which has two horns, either straight or convoluted; and the double uterus, or *uterus duplex*, which has the appearance of two horns opening laterally into the vagina, as in the mole, the hare, and the rabbit. The Fallopian tubes, in marsupial animals, are much enlarged at their extremities.

Opossum.

(953.) In the oppossum, the cardiac and the pyloric openings of the stomach are placed very near one another. The anal glands are large. The tongue is covered with pointed processes.

Kangaroo.

(954.) The kangaroo has a stomach composed of three pouches, but in consequence of the power which different portions of it possess of contracting separately, it is occasionally divided into a much greater number of portions.

Phascolome.

(955.) The phascolome, a species of rat from Australia, which possesses an abdominal pouch, is remarkable for possessing, in common only with man, and the orang-utan, both a cœcum and an appendix vermiformis.

10. *Rodentia.*

Rodentia.

(956.) In this order of mammalia, we find the incisor teeth furnished with enamel only in front; the frontal sinuses are absent; the os frontis is divided into two bones by a middle longitudinal suture, and the tympanic bone is distinct from the temporal. The brain presents no appearance of convolutions on its surface; the eyes are placed on the side of the head, so that the direction of their axes is completely lateral; and the orbits are not separated from the temporal fossæ; the cœcum, in particular, is exceedingly voluminous, so as often to exceed the stomach in size. The dormouse, indeed, presents an exception to this rule, being destitute of any cœcum.

Beaver.

(957.) The beaver has a remarkably strong and prominent zygoma. A peculiar glandular body is found near the upper orifice of the stomach, full of cavities, apparently for the purpose of secreting mucus. The urethra terminates in the rectum, thus constituting a kind of *cloaca;* a structure which, as we shall find, prevails universally in birds. The direction of the axes of the orbits is upwards.

Rat.

(958.) The common rat has no cœcum; its zygoma has its convexity turned downwards; the testes are capable of being retracted within the abdomen. A similar circumstance occurs in the hamster, the squirrel, and the guinea-pig.

Mus typhlus.

(959.) The mus typhlus is remarkable for having its eye covered over with the common integument of the face, which, together with the hair growing on it, completely intercept light, and must destroy the use of the eye as an organ of vision.

Hamster Marmot.

(960.) Cheek pouches are met with in many species of this genus; as in the case of the hamster and marmot. In the ear of the latter of these animals, a portion of bone is described by Cuvier as passing between the crura of the stapes, from one side of the fenestra ovalis to the other, the use of which conformation is entirely unknown.

Hare.

(961.) In the hare, the following peculiarities are met with. The coronoid process of the lower jaw is almost entirely wanting. The transverse processes of the lumbar vertebræ are remarkably large. The stomach may be distinguished into two portions, differing in the structure of their coats; the cardiac portion being lined with cuticle, and the pyloric division having the usual villous and secreting surface. The former may be regarded as a reservoir for the food, while the latter is the part which performs the function of digestion. The undigested state in which the contents of the stomach is found in the former, and its altered appearance in the latter, corroborate this view of the different offices of these two portions of the stomach. The rabbit agrees with the hare in this conformation. The cœcum is of enormous size; it extends to a length which is greater than that of the whole animal; it is curiously convoluted, and is lined internally with a peculiar spiral fold or valve. The urinary bladder is peculiarly large in the hare

(962.) The retina exhibits very distinct and beautiful medullary striæ, which pass, for the most part, in a transverse direction. The glandula Harderi is found in these animals, and unites itself with the proper lacrymal gland, but is distinguishable by its whiter colour. Both the hare and the rabbit have a slit, opening into the lacrymal canal, which serves as a substitute for the puncta lacrymalia. Sebaceous sinuses exist on the outer side of the upper jaw, near the nasal bones; whence a large quantity of a viscid adipose substance is secreted. Cavities are also formed in the groins, called by Pallas, *antra inguinalia*, which contain a strongly odorous substance prepared by the neighbouring subcutaneous glands.

11. *Tardigrada.*

Tardigrada.

(963.) The tardigrade mammalia are distinguished by having the same peculiar distribution of the arteries of the limbs which we have already noticed in the lemur tardigradus. They possess neither cœcum nor gall-bladder. The stomach of the sloth is complicated in its structure, being divided into several pouches; the intestinal canal is very short; there is also at its extremity an approach to the structure of the cloaca of birds, inasmuch as the rectum and urethra have a common termination. The zygoma is furnished with a large descending process, which comes from the os malæ.

Sloth.

(964.) The two-toed sloth *(bradypus didactylus)* has twenty-three ribs on each side. We have already noticed the apparent anomaly presented by the three-toed sloth, (the *bradypus tridactylus*) in its seeming to possess nine instead of seven cervical vertebræ; this appearance being given to the two last of these vertebræ, which are, in fact, dorsal, by the ribs which are attached to them being very short, and rudimental in their conformation, (see § 911.) In the anteater and manis, which belong to Cuvier's family of the edentata, the six last vertebræ of the neck are anchylosed or united so as to form only one bone.

12. *Monotremata.*

Monotremata.

(965.) The singular animals which compose this family of mammalia, instituted by M. Geoffroy, are all inhabitants of the continent of Australia, so fertile in extraordinary productions in every department of natural history. They are included in the genus ornithorhyncus, and are distinguished into the three species of paradoxus, histrix, and setosus.

Ornithorhyncus.

(966.) Although they are not furnished with abdominal pouches like the kangaroo and other marsupial animals, yet they are provided with two bones corresponding in their position to the marsupial bones, already described (§ 952), as attached to the bones of the pubis, and supporting the abdominal viscera. The number of ribs in the ornithorhyncus is seventeen. Pouches exist in the cheek of the animal. The bill, shaped like that of the duck, is abundantly furnished with nerves, chiefly from the second branch of the fifth pair. Its teeth have no fangs which sink into the jaw, as in most quadrupeds, but are merely imbedded in the gum, and are very peculiar in their shape. In the ornithorhyncus paradoxus, there is one on each side of either jaw; it consists of a horny substance of an oblong shape, flattened at the surface, and adhering to the gum. There are likewise two horny processes at the back of the tongue, which are directed forwards, and prevent the food from passing into the throat before it has been sufficiently masticated. The tongue is very short, not an inch long, and the moveable portion not half an inch; its surface is beset with long conical papillæ. The ornithorhyncus hystrix has six transverse rows of pointed horny processes at the back of the palate, and about twenty similar teeth on the corresponding part of the tongue. The intermaxillary bones are of a very singular shape, consisting of two hooked pieces joined together at their bases.

The stomach of the ornithorhyncus hystrix is lined with cuticle, furnished at the pyloric extremity with sharp horny papillæ. There is no valve of the colon, nor is there any cœcum, although we find an appendix vermiformis. They possess a cloaca at the termination of the rectum, as in birds.

(967.) Sir Everard Home denied the existence of mammæ in the female ornithorhyncus; but these glands have been distinctly delineated by Meckel, and described by him as being largely developed. In a paper since read to the Royal Society, Sir Everard Home again asserted that further inquiry had convinced him of the non-existence of these glands; but in a paper subsequently read to that learned body,[1] Mr. Griffin describes the mammæ of the ornithorhyncus paradoxus as considerable glands, which occupy the greater part of the under surface of the animal, and have numerous excretory ducts perforating the skin in two circumscribed places, but not forming any elevations analogous to nipples. This subject has, since that period, been investigated with great care by Mr. Owen,[2] who found the structure to correspond very exactly with the account given by Meckel, and he is accordingly led to regard them as real mammæ. The falx, as well as the tentorium, contains a plate of bone. The external auditory passage is very long and tortuous, and there are only two ossicula in the internal ear. A singular kind of clavicle is found in the skeleton of these animals, common to both the fore extremities, and situated in front of the ordinary clavicles, bearing some analogy to the furcular bone of birds. The conformation of the ribs also exhibits an approach to that of birds. Each rib consists of two pieces of bone; a longer one joined to the spine, and a shorter connected with the sternum; the two being united by an intermediate cartilage.

13. *Pachydermata.*

Pachydermata. Elephant.

(968.) In this natural family of animals, which was established by Storr, in his *Prodromus Methodi Animalium*, the elephant first claims our notice. In addition to the thick integument common to all the animals of this tribe, we find that remarkable organ, the *proboscis*, which is a prolongation of the nose, formed of a double cylindrical tube, extremely flexible in all directions, endowed with exquisite sensibility, and terminating in an appendix very much resembling a finger, all the functions of which it is capable of performing. The motions of this admirable organ are executed by an infinite number of muscular fibres, collected into small bundles, which pass in a great variety of directions, and are continually interlaced with one another, so as to be adapted to the performance of every kind of movement. The enormous tusks which are given to the animal as formidable weapons of offence, are merely developements of incisor teeth, proceeding from the inter-maxillary bones in the upper jaw, and which on issuing from the mouth are incurvated upwards.

(969.) That part of the cranium which corresponds to the frontal sinuses is enormously enlarged; the two tables of the skull being separated to a considerable distance from one another, the intermediate space being occupied by a vast number of cells, which are full of air, and communicating with the throat by means of the Eustachian tube. Camper has very ably pointed out the advantages resulting from this structure, by the increase of surface it affords for the attachment of the great muscles of the lower jaw, neck, and proboscis, and for the augmentation of their mechanical power. The frontal and parietal bones become united at a very early period with all the other parts of the cranium, so as to form a bony cavity in which no trace of sutures can be discerned. The tympanic bone, however, is distinct from the temporal. The optic foramina commence from a single canal, which receives the two optic nerves. A rudiment only of the nasal bones is observable; and the same remark is also applicable to the ossa unguis, or lacrymal bones; neither can we trace the existence of any lacrymal gland, or lacrymal sac, or any passage for the tears into the nose. The foramen ovale in the base of the cranium is very large. Between the arched sides of the upper part of the cranium, a broad and deep depression is met with, having a small longitudinal crest in the bottom.

---

[1] *December* 15, 1831.

[2] *Philosophical Transactions* for 1832, p. 517. See also his paper in the *Transactions* for 1834, p. 333.

(970.) Between the eye and the orifice of the external ear, a gland of large size is situated, occasionally secreting a brown fluid, which oozes out through an opening in the skin. There are twenty ribs on each side; and there appear to be only three lumbar vertebræ. The ligamentum nuchæ is of great size and strength, for it has to support the enormous weight of the head with its ponderous tusks and proboscis. The articulation of the thigh bone with the pelvis, is destitute of the ligamentum teres, which is found in almost all other quadrupeds. The toes are five in number, but they are almost concealed by the thickness of the skin of the foot in which they are encased. The condyles of the lower jaw are simply rounded eminences. The form and structure of the teeth are very peculiar, and afford distinctive characters of the different species of elephants, which belong more properly to natural history. In addition to the usual component parts of bones and of enamel, a third is superadded, called the *crusta petrosa,* which fills up the interstices left by the duplications of the enamel. The ivory which composes the tusks is exceedingly dense, and differs considerably in its structure from the ordinary bone of other teeth. It is distinguished by the curved lines which pass in different directions from the centre of the tusk, forming by their decussation, a regular arrangement of curvilinear lozenges. The tusk is constructed by the successive deposition of osseous matter from within, being secreted from the outer surface of the vascular pulp, which occupies the central part of the growing tusk. Hence, iron balls, fired at the animal, have been known to penetrate the latter soft portion, and to remain fixed in the interior of the tusk, till they were completely covered over, and imbedded in the successive depositions of ivory.

(971.) The stomach is simple in its structure; the intestines are voluminous, the cœcum of great size, and the colon large, long, and divided into cellular compartments. There is no gall-bladder. The ductus choledochus forms a pouch between the coats of the intestine, as it does in the cat, for the reception of the pancreatic duct.

Tapir. (972.) The snout of the tapir bears a slight resemblance to the proboscis of the elephant; being, although much shorter, extremely mobile, and provided with a very complex arrangement of muscles.

Rhinoceros. (973.) The rhinoceros is furnished with a rough and slightly elevated surface of the large nasal bones, consolidated into one bone, for the attachment of the horn which is supported upon it. Such, at least, is the structure in the one-horned rhinoceros; in the two-horned species it is the front horn to which this description applies; for the posterior horn rests on a similar process of the os frontis. Like the elephant, the rhinoceros has no gall-bladder.

Hog. (974.) In the hog we also meet with a considerable developement of the frontal sinuses. The molar glands are large, and their openings very conspicuous. There are two considerable membranous bags in the throat, situated above and in front of the ligaments of the glottis. Two small flat bones are found at the base of the heart, at the origin of the aorta from the left ventricle. Their use has been supposed to be that of giving support to the valves of the aorta.

Peccari. (975.) The peccari, or Mexican musk-hog, has a remarkable gland situated in the back, near the sacrum; it is composed of several lobules, the ducts of which unite into one canal, which passes through the skin, and pours out a secretion having a scent similar to musk. A singular dilatation is often met with in the aorta of this animal, as if it were affected with aneurism.

14. *Solipeda.*

Solipeda. (976.) This family comprehends the horse, ass, zebra, and quagga. The great interest attached to all that relates to the horse, from its utility to man, has occasioned its anatomy, the study of which is the foundation of the veterinary art, to be cultivated with peculiar zeal. The principal circumstances worthy of notice in the osteology of this animal are the following. As is the case with most quadrupeds whose necks are very long, the cervical vertebræ have very short spinous processes. The dorsal vertebræ, the number of which of course corresponds with that of the ribs, being eighteen, and sometimes nineteen, have, on the contrary, very large and broad spinous processes. The space from the first to the eighth vertebra, is called the *withers,* against which the upper part of the shoulder rests. There are six lumbar vertebræ, having strong spinous, and also broad and long transverse processes. Large lateral processes also extend from the sacrum, which is composed of five consolidated portions; and the united spinous processes of these are likewise exceedingly prominent. The tail is formed of eighteen cylindrical pieces, which, towards the extremity, have nearly the softness of cartilage.

(977.) The true ribs are, on each side, eight in number, the remaining ten or eleven being joined to the sternum by cartilage. The sternum is composed originally of seven pieces of bone united into one. Its anterior extremity is sharp-pointed, like the prow or keel of a ship. In the pelvis of the horse, denominated the *haunch,* we find the ilium, or hip-bone, extended in three directions, above, below, and behind, forming three large processes, for the attachment of the strong muscles which surround the hip joint. The ischium is much extended, forming a strong process posteriorly for a similar purpose. This elongation of the ischium has been termed, from its figure, the *processus triquetrus ischii.* By removing the point of attachment of the muscles to a greater distance from the axis of motion, it gives them the mechanical advantage of acting by a long lever. The symphysis of the pubis (or the junction of the bones of that name) is remarkable for its depth, thus affording an extensive surface for the attachment of muscles.

(978.) The bones of the extremities of the horse are constructed on the same general model as the human, though varying much in the details of their form and relative proportions; and some parts only appearing in an imperfect or rudimental state. The scapula is of an oblong triangular shape, considerably narrower and longer than the same bone in the human skeleton, and exhibiting only faint traces of the acromion and coracoid processes. Its axis is nearly in the same line with the os humeri, which latter bone is very short, and scarcely descends below the line of the chest, and possesses scarcely any rotatory motion on the scapula. The radius and ulna are consolidated together; the olecranon is much elongated. The carpus, or as it is vulgarly called, the knee, of the horse, is composed of seven, or sometimes eight, small bones, disposed as in the human carpus, in two rows; though with respect to their individual form, they have but little resemblance to the latter.

(979.) That part of the skeleton which corresponds to the metacarpus is, in the horse, consolidated into a single bone termed the *shank*, or *canon bone*, to which are united behind, and on the side, two much shorter and very slender bones, called the *styloid*, or *splint bones*, frequently found consolidated with the canon bone by ossific union. It is only the latter, or principal bone, that is articulated with the next, or *pastern bone*, which corresponds with the first phalanges of the fingers, and may be regarded as the consolidation of these five bones into one. In like manner, the second phalanges are consolidated in the horse into the next bone of the foot, which is termed the *coronet bone*, and which is articulated by a divided condyle with the *coffin bone*, of which we shall presently speak. Before proceeding, however, we must notice two or three small rounded bones placed at the back of the pastern joint, (between that and the shank bone) which correspond in their office to sesamoid bones, and which have accordingly received that appellation.

(980.) The coffin bone corresponds in situation to the third phalanx of the fingers. It supports the single hoof; from which this family of mammalia derive their characteristic name. Connected with this is a small bone, called the *shuttle bone*.

(981.) In the posterior extremity we find a very similar arrangement of bones. The thigh bone is unusually short, scarcely extending beyond the trunk of the body, when surrounded by its muscles. The glutæi muscles, and especially the glutæus medius, are particularly powerful in their action for extending the thigh backwards, and performing the motion necessary for kicking. There is a process in this bone of the horse which is not observed at all in the human os femoris; it is a strong curved spine, situated on the outside, opposite to the lesser trochanter. It has been termed the *processus recurvatus femoris*.

(982.) The *patella* of the horse is large, thick, and very prominent. From the *tibia* there arises a small spinous process, which may be considered as the rudiment of a fibula. The tarsus, or *hock*, is composed of six or seven bones, and forms a very obtuse angle with the tibia, when the horse has his foot to the ground. The astragalus differs from the human bone of that name, by having two very large and prominent condyles. The metatarsal bones correspond in every respect with those of the carpus already described.

(983.) In the skull of the horse we may observe that the temporal bone is divided by a suture into the squamous and tympanic portions. The occipital bone has a deep depression in the middle, where the cervical ligament is attached. The antrum maxillare and turbinated bones are of great size. The lower jaw-bone is also very large, and presents a very extended surface for the attachment of muscles.

The horse is provided with a large salivary apparatus of glands. Its stomach is divided into two portions; the first of which, next to the œsophagus, is lined with a cuticular membrane which terminates in a loose expansion, supposed to have the office of a valve, and to prevent the possibility of the animal's vomiting. There are generally found adhering to its coats a great number of the larvæ of the œstrus equi, and the œstrus hæmorrhoidalis, called in common language, *botts*. The intestinal canal is of great length, the large intestine alone being twenty-four feet in length. The colon is very capacious, and divided into cellular compartments. The liver is large, divided by deep indentations into lobes, and unprovided with a gall-bladder.

(984.) The peculiar sound produced in neighing is ascribed to the presence in the trachea of a delicate membrane, attached by its middle to the thyroid cartilage, and of which the two extremities pass along the external margins of the rima glottidis. The Eustachian tube opens, not immediately over the larynx, but into a sac peculiar to this tribe of animals, situated on the lateral parts of the lower jaw; and these cavities then open by a long fissure, furnished with a cartilaginous valve, into the pharynx.

(985.) The eye of the horse presents a remarkably beautiful and delicate structure in the folds of the internal membrane of the corpus ciliare. The pupil is oblong, the superior margin of the iris having a fringed appearance.

15. *Ruminantia.*

Ruminantia.

(986.) The anatomy of the ruminant family of quadrupeds, which comprises so many of those animals that man has domesticated and rendered subservient to his most urgent wants, has also very strong claims on our attention.

(987.) In their skeleton they correspond very closely with the horse, of which we have already given so detailed a description. The principal differences are observable in the terminal bones of the extremities, each limb presenting us with two hoofs, instead of one, and a corresponding division of the metatarsal bones and phalanges into two. On the other hand, the slender traces of a fibula met with in the horse, disappear in the ox and other animals of this tribe.

Digestive organs.

(988.) The whole track of the alimentary canal in these animals presents us with objects of interest. The tongue is covered with a thick cuticle, provided with pointed papillæ, which, being directed backwards, are fitted for laying firm hold of the grass, and tearing it up from the roots. The salivary glands are extremely large; the coats of the œsophagus particularly strong and muscular, in subservience to the function of rumination peculiar to this tribe. The organs provided for digestion are more complicated than in any of the animals we have yet considered. There are no less than four cavities which have been regarded as performing the office of stomachs. The first is the *paunch*, which is a capacious reservoir, abundantly supplied with secretion from its coats, which are beset with numerous flattened papillæ. The second is the *honey-comb* stomach, so named from the reticulated appearance of its inner membrane, the folds of which are disposed in polygonal lines, somewhat resembling the hexagonal margins of the cells of the honey-comb. The third stomach, which is the smallest, is termed the *manyplies*, and contains a great number of broad folds, or duplicatures of its inner membrane, which have been compared to the leaves of a book. The fourth, or the *reed*, has a pyriform shape, an internal villous coat, and a structure altogether analogous to that of the simple stomachs of carnivorous animals. It terminates in the beginning of the intestinal canal. A groove extends from the termination of the œsophagus along the edge of the three first stomachs, at the part where they communicate together; the edges of this groove are thick, so as to admit, when brought into close contact, of forming a canal for the direct communication of the œsophagus with any one of these four stomachs.

Process of rumination.

(989.) The grass which the animal takes into the mouth undergoes but a small degree of mastication, and passes, on being swallowed, into the paunch, where it undergoes maceration, and is transferred, by small portions at a time, into the honey-comb, or second stomach, which serves to perform an auxiliary office to the first. Thence it is sent up again directly through the œsophagus into the mouth, for the purpose of undergoing a second and more deliberate mastication, which the animal performs when reposing, and from which it appears to enjoy considerable pleasure. After being thus ruminated it is again swallowed, and the sides of the groove being brought into contact, so as to constitute a canal, and exclude all passage into the first or second stomachs, it passes directly into the third stomach; whence, after having been subjected to the further action of the secretions of that organ, it is transferred to the fourth or last stomach, where the process of digestion is completed. Liquids drunk by the animal pass at once into the second stomach, and assist in the maceration of its contents. But the milk taken by the calf, requiring to be neither macerated nor ruminated, is conveyed directly from the œsophagus into the fourth stomach.

(990.) The biliary organs present us, in horned cattle, with numerous hepato-cystic ducts, conveying the bile immediately from the liver to the gall-bladder, which cyst is found in all the animals of this order, though it is absent in the horse. The urinary bladder is particularly large. In like manner, as we found in the pig, two small bones are met with also in ruminants, at the origin of the aorta; and the same purpose has been assigned to them as in the former instance. In the stag, these have been called the *bones of the heart.*

(991.) The internal carotid artery, at its entrance into the cranium, is suddenly subdivided into numerous branches, which are variously contorted, and afterwards re-united at the basis of the brain. The intention of this curious structure, which has been termed the *rete mirabile,* appears to be to diminish the impetus with which the blood would otherwise be forced into the arteries distributed to the brain; a force which would be increased by the effect of gravity when the animal stooped in grazing. The frontal sinus, and other parts connected with the sense of smell, are much developed. The lacrymal bones and ossa nasi are of considerable size. The tapetum is particularly conspicuous in the eyes of ruminants. One or two additional small bones are found among the ossicula auditus. The mastoid cells are numerous, and in the arrangement of their compartments somewhat resemble a ripe poppy head. In the ox and the sheep, the superior ligament of the glottis, as well as the ventricles of the larynx, are absent.

Camel.

(992.) Ruminant animals are distinguished into two tribes, the first consisting of those which are without horns; the second, of those provided with horns. Of the former, the camel is remarkable for the great expansion of the hoof, which adapts it for treading upon sand. It has seven lumbar vertebræ. A peculiar moveable bag, glandular in its structure, exists behind the palate, probably designed for the lubrication of the throat: it has received the name of *bursa faucium.* Connected with the paunch is a large receptacle divided into numerous cells, for the purpose of holding water, as in a natural reservoir. Hence, when a camel dies in the desert, the Arabs open the stomach, and quench their thirst with the water it contains, which is found to be pure and wholesome. Like the horse, it has no gall-bladder. It has no fibula; but this latter bone is met with in the musk, which is also a hornless ruminant.

Horns.

(993.) The horned ruminants have an eminence on the os frontis for supporting the horn. This process is in the stag a real bone, remarkable for the rapidity of its growth, which is annual, and for its death and separation from the skull at certain periodic intervals. The osseous bases of the horns of the ox, the sheep, the goat, and the antelope, on the contrary, are permanent, and are invested with a horny covering, which has a structure very different from bone. The cameleopard, or giraffe, on the other hand, has two osseous prominences, which remain permanently covered with the integuments, and are even surmounted by a tuft of hair. But the details relating to organs so external as the horns fall more properly within the province of natural history.

Cameleo-
ard.

Rein deer.

(994.) The rein deer has, like several of the baboon tribe, large laryngeal sacs on the front of the neck, communicating with the larynx.

Ox and
heep.

(995.) In the ox and sheep the spleen is remarkable for being of a distinctly cellular structure. In these animals we find a great developement of the salivary glands, and more particularly of the submaxillary gland, which extends along the side of the larynx quite to the back of the pharynx.

16. *Cetacea.*

etacea.

(996.) From the consideration of the quadrupeds of the class mammalia, we pass now to that of a tribe of animals which, although warm-blooded and mammiferous, are formed on a model adapting them for inhabiting the water; nature having bereft them even of the rudiments of hinder extremities. The bones of the spine are continued, without being interrupted by an interposed pelvis, into the vertebræ of the tail, which terminates in a horizontal fin. The head and trunk are united by a neck, so short as to exhibit scarcely any diminution of diameter, and containing cervical vertebræ, which are extremely compressed, and the greater number of which are consolidated together by a bony union. The superior extremities are supported by bones, which have no medullary cavities, and which, compared with the analogous bones of quadrupeds, are much shortened and compressed. They do not admit of motion amongst themselves, and being enveloped by a tendinous membrane, are reduced to the office of fins. The internal organs correspond, however, with that of other mammalia. Cetacea breathe by means of lungs, their circulation is double, and they are warm-blooded. The females are viviparous, and are provided with mammæ for the nourishment of their young.

(997.) The necessity of occasionally receiving air into the lungs, whilst the animal is generally immersed in water, renders it requisite that a provision should be made for their readily rising to the surface in order to breathe. Hence the movements of the tail are from above downwards; hence in the cachalot and other kinds of whale, a large quantity of oil is accumulated round the head, which gives greater buoyancy to this part of the body. Hence, also, when the animal, in seizing its prey, takes into the mouth a large quantity of water, there is a necessity of getting rid of it, which is effected by its transmission into a sac placed at the external orifice of the nasal cavity, whence it is expelled with great force, by the contraction of powerful muscles, through a passage which conducts it to the top of the head. In this way are produced the enormous spouts of water that mark the track of the whale on the surface of the sea.

(998.) The olfactory organs are not adapted to the possession of any accurate sense of smell, being furnished neither with turbinated bones nor with any considerable nerves. The larynx rises in a pyramidal form into the posterior part of the nostrils, in order to receive the air from those passages, and convey it to the lungs, without its being necessary for the animal to extend more than the end of the snout above the surface of the water. The glottis is simple, and is not interrupted by any projecting membranes.

(999.) The stomach is composed of as many as five, or sometimes even of seven distinct pouches. There is no cœcum or appendix vermiformis; and the gall-bladder is absent in the greater number. The spleen is divided into a number of small globular lobes. The kidneys are conglomerate. The brain is large, and its hemispheres much developed. The tympanic bone is separated from the rest of the cranium, adhering to it only by ligamentous connexions. There is no external ear; the stapes is nearly solid; in the walrus it exhibits no perforation. The ossicula, semicircular canals, and other parts of the labyrinth of the internal ear are remarkably small. The external meatus is cartilaginous, and so small, that its external orifice in the dolphin will only just admit a pin. It pursues a winding course through the fat, which is of great thickness, until it reaches the tympanum. The Eustachian tube opens at the blowing hole, and is furnished with a valve preventing the admission of the water which the animal expels through that passage. The lacrymal organs are entirely wanting; the sclerotic coat of the eye is very thick at its posterior part, so that although the eye-ball has exteriorly a spherical form, the figure of the vitreous humor is very different; its structure at the back of the eye has the hardness of cartilage.

(1000.) In many parts of the arterial system of the cetacea, we find reticular plexuses, or convolutions of the vessels, the purpose of which is probably to serve as reservoirs of arterial blood, for the use of the system, when the animal is long under water.

(1001.) In the trichecus manatus borealis, or manati, a gland of the size of the human head is found between the coats of the stomach, near the œsophagus, discharging, on pressure, a fluid resembling the pancreatic juice.

Whale.

(1002.) The whale is remarkable for having, in place of teeth, an apparatus apparently intended for filtration, and consisting of plates of the substance called *whalebone*, descending vertically into the mouth from the lower surface of the upper jaw, into which they are fixed by a ligamentous substance. On each side their number amounts to three or four hundred. The inner edge of each plate has its fibres detached so as to form a kind of fringe, which retains the small fishes and mollusca on which the animal feeds. The lower jaw is unprovided with any similar appendages. Although there are no teeth in the upper jaw, yet an intermaxillary bone is still present. Rudiments of teeth exist in the interior of the lower jaw before birth, lodged in deep sockets, and forming a row on each side. The developement of these imperfect teeth, however, proceeds no farther, and they disappear at an early period. The tongue, which is supported by an os hyoides of singular shape, is very thick and fleshy. The œsophagus is exceedingly narrow. The stomach is complicated in its structure. The intestinal canal is of considerable length, and contains a great number of longitudinal folds. There is a short cœcum. The mesenteric glands contain large spherical cavities, into which the trunks of the lacteals open, and where the chyle is probably blended with secretions proper to those cavities. The eye is extremely small in comparison with the size of the animal; and it occupies but a small portion of the orbit.

SECT. II.—*Comparative Physiology of Birds.*

1. *General Description.*

Birds.

(1003.) The whole of this class of animals exhibits great uniformity in its comparative anatomy; insomuch that the whole may easily be comprised in one general description. The structure of every part of the frame of birds is adapted to facilitate rapid progression through the air; for which purpose the anterior extremities are converted into wings, and are not employed in any other action. The support of the body when the animal is not flying, is entrusted solely to the posterior extremities; so that birds are, strictly speaking, *bipeds*. Hence we may trace some degree of approximation to the human structure in the conformation of the skeleton.

Skeleton.

(1004.) The bones are dense in their texture, but are at the same time rendered light by having large cavities, occupied, not with marrow, as in the mammalia, but with air. There is a smaller proportion of cartilaginous to osseous structure in the skeleton of birds than in that of quadrupeds.

(1005.) The neck of birds being required to be very flexible, we find the cervical vertebræ very numerous, and freely moveable upon one another. The swan has twenty-three cervical vertebræ. Those of the back, on the other hand, are perfectly fixed and immoveable, their spinous processes being large and often united by osseous substance, so as to preclude the possibility of any relative motion. As the ribs occupy the whole of the sides of the trunk, there are properly no lumbar vertebræ. The os coccygis is short and compressed; and can scarcely be regarded as a proper tail, although it affords support to the long feathers which constitute what is usually called the tail of birds. The pelvis consists almost entirely of a broad os innominatum, the lateral portions of which are widely separated, in order to admit of space for the developement of the eggs; and for the same reason the two ossa pubis do not join to form a symphysis, but are at a considerable distance from one another. The exceptions to this general rule will be noticed afterwards.

(1005.) The number of true ribs never exceeds ten pair; the false ribs are numerous, and directed forwards. Those which occupy the middle of the body are distinguished by a flat process, directed upwards and backwards. The sternum is composed of five pieces, and is of great size and strength. From the middle of its lower surface there rises a sharp process, or spine, resembling the keel of a ship, and evidently adapted to accommodate the large and powerful pectoral muscles, which take their rise from this part of the chest, and which act in depressing the wings. The bones which connect the wings to the trunk are apparently three in number; the coracoid process of each scapula being distinct and largely developed bones, having the semblance of ordinary clavicles, whilst the real clavicles are consolidated into a single bone, denominated the *furcular bone*, from its resemblance to a fork, and which in the fowl is better known by the name of the *merry-thought*. Its extremities rest on two strong processes of the scapula. Many anatomists, considering the coracoid as the true clavicles, have regarded the furcular bone as an additional, or supplementary clavicle, corresponding to the coracoid apophysis.

(1006.) The bones of the wing are analogous in their divisions and distribution to those of the upper extremity in man: there being a humerus, radius, and ulna; two carpal bones; and two metacarpal bones, generally consolidated into one; one bone corresponding to that of the thumb and two fingers; that next to the thumb consisting of two phalanges, and the outer one, of a single bone.

(1007.) In the legs we find a femur and a tibia, to which there adheres a very slender fibula, (which is, indeed, often wanting;) one metatarsal bone, and the phalanges of the toes. The patella is often supplied by a process from the tibia.

Provision for roosting.

(1008.) The muscles possess a high degree of irritability, and contract with great quickness and force. Many of the tendons become ossified in the progress of age. A remarkable arrangement exists in the tendons of the flexor muscles of the toes, by which the flexion of the knee and heel puts them on the stretch, and thus mechanically bending the toes, enables the bird to lay firm hold of the branch of a tree or perch whilst roosting. This is effected by the flexor tendons passing round over the outer side of the angle formed by each of these joints. Thus a bird, while roosting, supports itself on one leg only, by the mere effect of the weight of the body producing the necessary flexion of the toes, to enable it to preserve its hold. This remarkable provision of nature was long ago observed, and well explained by Borelli; and though the fact has been controverted by Vicq. D'Azyr, it appears to be well established. In order to give great latitude of motion to the head, the articulation of the os occipitis with the atlas is performed by a single condyle only, which procures it the advantages of a ball and socket joint. This condyle is situated at the anterior margin of the great occipital foramen. The proper bones of the cranium are not joined by sutures, but are consolidated into a single piece. The orbits for the eyes are very large, and are frequently found to communicate laterally in the skeleton, being separated, in the living animal, only by a thin membranous partition. The ossa unguis are generally very large. The upper jaw is almost always moveable upon the other bones of the head. To this bone is joined the bill, the structure of which is horny, and thus supplies the place of teeth, occupying the situation of the palate. The functions of the teeth, indeed, are not wanted, for the animal swallows its food without any mastication. The lower jaw is connected with the skull by the intermedium of a peculiar bone of irregular form, called the *os quadratum*. Another small bone resting against the palate is connected with it.

Digestive rgans.

(1009.) The energy of the digestive functions in birds corresponds with that of respiration, and muscular irritability. The stomach may be considered as consisting of three cavities; the first of which, termed the *crop*, is rather a dilatation of the œsophagus, furnished with numerous glands disposed in a regular arrangement of rows; the second is the *ventriculus succenturiatus*, or *pro-ventriculus*, situated lower down, and just at the entrance of the proper stomach. It is furnished with a still more complex glandular apparatus; and hence has been termed the *bulbus glandulosus*. Its form and structure vary much in different genera of birds. The third is the proper stomach, which resembles in the structure of its coats the simple stomachs of the mammalia, being thin and membranous in those birds which feed on insects and flesh. But in all granivorous birds the coats of this stomach are farther armed with a thick cuticular lining, of nearly the density of horn, which is surrounded by four immensely thick and powerful muscles, capable of exerting a strong compression on the contents of the stomach, and a slight degree of lateral motion, and thus performing the office of trituration. Such is the structure of what is called a *gizzard*. Between these opposite structures there exists, in different species of birds, a great number of intermediate gradations, corresponding to the peculiar nature of the food to which nature has adapted their organization. The trituration of the grain is assisted by small stones voluntarily swallowed by the animal, and in the selection of which the animal is directed by a principle of instinct.

(1010.) The intestinal canal of birds is much shorter than in most of the mammalia; but a similar disparity is also noticed in the former, with regard to the greater length of the canal in birds consuming vegetable food, when compared with that of the carnivorous tribes. There is scarcely any distinction in point of size between the small and large intestines; though the division between them is generally marked by the presence of two cœca. The rectum terminates in an expansion, termed the *cloaca*, in which the ureter terminates, and which therefore performs the function of the urinary bladder. Connected with the cloaca, there is an oval glandular bag termed the *bursa fabricii*, and opening into it by a narrow longitudinal aperture. The oviduct in the female also opens into the same cavity. Two blind pouches. opening into the rectum, are found near to its termination.

(1011.) The liver of birds is usually divided into two lobes; but in some birds there is in addition a third smaller lobe. Two ducts proceed from the liver; the one is the hepato-cystic duct, the other the hepatic duct. The former conveys the bile into the gall bladder, the latter into the duodenum. Thus the bile is conducted into the duodenum by one hepatic duct distinct from the cystic duct, and these two alternately with two or three ducts from the pancreas, which is large, and generally consists of two distinct glands; the spleen, on the other hand, is usually round, and of small size. The gall-bladder is situated under the right lobe of the liver; but some birds have no gall-bladder. There is no omentum. The chyle is transparent; there are no glands in the mesentery; the thoracic duct is double. Magendie has denied the existence of lymphatic vessels in birds; but they have been distinctly seen by others. ' The kidneys form a double row of conglobate glands, connected together, and situated on the sides of the lumbar vertebræ, in the hollows of the ossa innominata. There is no cavity corresponding to the pelvis of the kidneys of the mammalia; but renal capsules, similar to those of mammalia, are found also in birds.

art

(1012.) The heart of birds is furnished, as in the mammalia, with a double set of cavities; the one subservient to the general or systemic, and the other to the pulmonary circulation. The valves of the right ventricle are supplied by a strong triangular muscle, which gives additional impetus to the blood propelled into the pulmonary artery. Jacobson has discovered a singular distribution in the abdominal veins; those returning the blood from the hinder extremities being ramified through the kidneys and liver, previously to their termination in the vena cava.

Lungs.

(1013.) The lungs are not divided into lobes, and are fixed in their situation, being tightly braced in the cavity formed by the ribs, on each side, by a membrane, which is perforated by a number of holes. These apertures are the terminations of collateral branches of the bronchiæ, through which the air received into the chest passes out, and circulates through a multitude of cells interspersed through various parts of the body, and communicating ultimately with the central cavities of the bones. An immense surface is thus exposed to the influence of the air, which, having access to every part of the body, acts very extensively on the blood circulating in the vessels lining these air-cells and cavities. Hence the energy of the function of respiration is greater, and the temperature higher, than in any of the mammalia. There is properly no diaphragm in birds; a few muscular fibres only surround the larger air-cells, and assist in expelling the air from them back again into the lungs. The trachea is supported by a series of cartilages, which form entire rings, and overlap each other at their upper and lower margins, so as to preserve the tube open amidst the violent bendings and twistings of the neck. It is provided, at its bifurcation, with a peculiar set of muscles, which, aided by a second rima glottidis, enable this part to perform the functions of a second larynx, and to give rise to sounds; and, indeed, to be apparently the principal organ of the voice. In many aquatic birds, as in the male swan, the trachea makes a large circumvolution, which is contained in the hollow of the sternum. In other birds it is not enclosed in this bone; but there is a bony structure surrounding the inferior larynx, which tends to strengthen the voice. These convolutions and bony cells of the trachea, have been compared in their office to the turns of the French-horn, or the divisions of a basoon. This great developement of the vocal organs is peculiar to the male bird.

Brain.

(1014.) The brain of birds is characterized by the smallness of the hemispheres, which are not united by any corpus callosum. There is no appearance of convolutions on its surface. The optic thalami are voluminous, and are situated behind and below the hemispheres; a cavity is found in each. The crura of the cerebellum do not form any eminence at their junction with the medulla oblongata, corresponding to the pons varolii. The cerebellum is comparatively large, but has no lateral lobes, being almost wholly constituted by the processus vermiformis. The total bulk of the brain, compared with the size or weight of the body, is generally greater than in the mammalia.

Eyes.

(1015.) The eyes of birds are very large, in proportion to the size of the head, and appear to be adapted to a great range of vision. The adjustment of the position of the lens appears to be effected by means of a vascular and plicated membrane, called the *marsupium*, extending obliquely from the bottom of the retina, through the vitreous humor, to the edge of the crystalline. Its figure is trapezoidal; its surface is covered with the pigmentum nigrum, which of course absorbs all the rays of light that fall upon it. The anterior part of the eye-ball is, in many carnivorous birds, strengthened by a circle of bony plates, lying close upon the sclerotica, and overlapping each other. Besides the two external eye-lids, birds are always provided with a strong nictitating membrane, proceeding from the internal corner of the eye, and drawn over the cornea by a special muscular apparatus. In some birds the lower eye-lid is the most moveable, and in others it is the upper.

Ear.

(1016.) There is no cartilaginous external ear; what has this appearance in the owl is formed only by the feathers;

the cavity of the tympanum contains only one ossiculum auditus, and communicates with the air-cells of the skull. The Eustachian tubes have a common opening over the arch of the palate. The part corresponding to the cochlea has the figure of a cone, with scarcely any curvature, but with two scalæ. The semicircular canals are large, and project from the bone.

Nostrils. (1017.) The nasal organs are unprovided with an æthmoid bone; the olfactory nerves passing to them through the orbits, and being distributed upon the *bullæ turbinatæ*, which are oftener cartilaginous than osseous in their structure.

Tongue. (1018.) The tongue is thick and fleshy, covered with a thick cuticle, and therefore not adapted to be an organ of taste. It is supported by an os hyoides of a singular shape, having besides the anterior and posterior processes, and the cornua, with their appendices, another bone jointed to it anteriorly, and moveable on it. This last bone, which supports the tongue, is called *the lingual bone*.

Incubation. (1019.) The evolution of the chick from the egg being a subject of great interest, has long engaged the attention of physiologists. The following is an outline of the history of these changes in the common fowl. The ovulum, or first rudiment of the egg, is formed in the ovary, and consists simply of a bag containing the yolk; this afterwards becomes covered in its progress along the oviduct, by successive layers of albuminous substance, which composes the white of the egg, so called from the colour it assumes when coagulated. The white of the egg is invested with a firm membrane, which is easily divisible into two layers; and there are also other membranes dividing the mass of albumen into concentric layers. The membrane of the yolk, the *membrana vitelli*, or *yolk-bag*, is connected with that of the white, or the *membrana albuminis*, by a kind of ligament, which extends from the two ends or sides of the yolk, to those of the white; these, when partially stretched and torn by the motion of the yolk, have a flocculent appearance, and form what are called the *chalazæ*. They appear to act as ligaments to the yolk, keeping that surface uppermost in which the chick is situated, so that it may receive warmth from the hen during incubation. In the lower part of the oviduct the egg acquires a calcareous covering or shell, which is secreted by the inner membrane of that canal, and which is composed of nine-tenths carbonate of lime, the remaining portion being phosphate of lime and animal matter. Between the two membranes which line the shell, a small quantity of air is contained at the larger end of the egg.

(1020.) A small, round, milk-white spot, called the *cicatricula*, is formed on the surface of the yolk-bag during incubation. It is surrounded by two or three concentric circles, called the *halones*. Previously to the appearance of the embryo, a small shining spot of an elongated form, with rounded ends, but contracted in the middle, is seen within the cicatricula. This is called the *areola pellucida*. In the centre of this may be discerned, on the second day, a gelatinous filament, bent into a curve. This is the *primitive trace*, or earliest perceptible rudiment of the chick, in which the first organs that can be discovered are the two lobes of the brain, and the primitive filaments of the spinal cord, with the caudal dilatation. Vessels begin to appear on the surface of the yolk-bag, being spread on a separate membrane, and presenting what has been called the *figura venosa*, or *area vasculosa*, the marginal vessel at the remotest part being termed the *vena terminalis*. These veins correspond to the mesenteric veins; they are collected together, and form the vena portæ, whilst the arteries are derived from the mesenteric artery of the chick. The heart may next be perceived, as three red pulsating points, constituting the *punctum saliens*. These points are the rudiments of the auricle, ventricle, and aorta. Next, the separate vertebræ may be distinguished, then the eyes, and afterwards the stomach, liver, and intestines. Then a vascular membrane, the *allantois*, is rapidly formed, having the form of a bladder communicating with the cloaca. It soon extends over nearly the whole of the internal membrane of the shell, and is covered with numerous ramifications of arterial and venous vessels, derived from the internal iliacs of the chick; the former contain carbonized blood, and are therefore dark coloured; the latter, which conduct back the same blood after it has received the influence of the air at the surface, have a bright scarlet hue, and unite in forming the umbilical vein of the chick. Hence it is evident that this membrane performs a function analogous to that of the placenta in mammalia, and to that of the future air-cells of the lungs, or, in other words, that it is the organ of embryonic respiration. The chick is nourished by the matter of the yolk, which is partly absorbed by yellow vessels (*vasa vitelli lutea)* having a fringed appearance, and flocculent extremities, floating in the yolk, and partly by the direct passage of this matter into the intestine by means of a canal of communication, called the *ductus vitello-intestinalis*. The white of the egg also gradually disappears, being absorbed into, and mixed with the yolk. Towards the latter periods of incubation, the whole of the yolk-bag is taken into the abdomen, and soon disappears. On the twenty-first day of incubation, the chick, being fully formed, breaks the shell which confines it, and enters into the world; for which temporary purpose it is provided with a hard beak, which is afterwards lost.

2. *Peculiarities in particular Families and Genera of Birds.*

(1021.) The shades of difference in the anatomy of each organ in individual genera and species of birds, are exceedingly numerous, and to enter into their detail would far exceed the limits within which we are obliged to confine ourselves in this treatise. We must not, however, pass over some of the most remarkable differences which offer themselves to our notice in a few families of birds. Amongst these none are more singular than those presented by the tribe of the brevipennes of Cuvier, comprehending the ostrich and the cassowary. These birds not being intended for flight, have very imperfectly formed wings; the sternum exhibits no carinated figure, but presents a plane and uniform surface, being destitute of an inferior spine; the pectoral muscles of the hinder extremity, on the contrary, are very large and powerful. The furcular bone exists only in a rudimental state. The pelvis of the ostrich differs from that of all other birds in being closed below by the complete junction of the ossa pubis. The cœca in this bird are furnished with a remarkable spiral valve. The feathers are also exceedingly peculiar; but as this subject belongs rather to the external characters, we cannot dwell upon it here.

Brevipennes.

Levirostres. (1022.) The same consideration prevents us from dilating on the varieties in the structure of the bill, and of the toes, which offer to the naturalist abundant topics of interesting inquiry. We shall only remark that the cellular bills, which are of such enormous size in the levirostres, have free communications with the air cells subservient to respiration, and may therefore be auxiliary to that function.

Woodpecker. (1023.) The tongue of the woodpecker is provided with a singular apparatus for darting it forwards with great rapidity; this is effected by a long cartilaginous band, which passes completely over the top of the cranium, and is fixed to a groove on the right side of the upper jaw.

Sect. III.—*Comparative Physiology of Reptiles.*

1. *Reptiles in General.*

Reptiles. (1024.) The class of reptiles comprehends all those vertebrated animals which breathe atmospheric air by means of lungs, but which are cold-blooded. This latter quality is a consequence of the partial extent of their respiration, the heart being so constructed as to transmit to the lungs only a portion of the circulating blood, and the remaining part being again sent into the arterial system of the body without having been exposed to the action of the air. Reptiles are distinguished by the negative characters of being destitute of either hair or feathers, and having no mammæ, organs for which there appears to be no occasion, in consequence of these animals being oviparous. The limited degree in which their blood is oxygenated appears to have a considerable influence on the whole condition of their vital functions. Not only is the temperature of the blood scarcely different from that of the surrounding medium,[1] the actions of life seem to be more sluggish and torpid, and the muscular powers less energetic; their sensations are more obtuse, and in cold climates they pass the winter in a state of torpor. The comparative smallness of the pulmonary system of vessels, and the less extent of the surfaces of the air-cells of the lungs, render them less dependent on respiration than warm-blooded animals; hence they bear submersion under water for a considerable time with impunity, although, if the interruption to respiration be too long continued, they ultimately perish, with as much certainty as any of the mammalia would do under similar circumstances.

There is ground for believing, according to Geoffroi St. Hilaire, that crocodiles and turtles possess, in addition to the ordinary pulmonary respiration, a partial aquatic abdominal respiration, effected by means of two channels of communication which have been found to exist between the cavity of the abdomen and the external surface of the body, and also that some analogy may be traced between this aquatic respiration in reptiles, by these *peritoneal canals*, and the supposed function of the swimming bladder of fishes, hereafter to be described, in subserviency to a species of aerial respiration.

(1025.) As their vital functions do not require for their performance any elevated temperature, so we find reptiles destitute of those appendages to the integuments, such as hair, wool, or feathers, which in the other classes retain the warmth of the body. Their brain is very small compared with the rest of the nervous system, being less necessary for the exercise of the vital actions. The parts immediately instrumental in sensation are less concentrated in a particular spot, but would appear to be more diffused over the spinal cord and ganglia. Thus they not only continue to live, but even exhibit motions which have the semblance of being voluntary, though probably not so in reality, long after the loss of the brain, or even of the entire head. In like manner the irritability of their muscles is retained for a much longer time, after they have been separated from the body, than in the case of warm-blooded animals. The heart, when removed from the body, still continues to beat for several hours; and the body, thus deprived of its heart, may still possess the power of voluntary motion, in consequence of the continuance of a species of obscure circulation, which is carried on in the capillary system of vessels.

rders of
ptiles.

(1026.) Reptiles present a much greater variety of forms and of structures than is met with in any other class of vertebrata. The characters of the orders are derived principally from the form of their organs of progressive motion. These orders are four in number, namely, *chelonia*, *sauria*, *ophidia*, and *batrachia*.

2. *Chelonia.*

ielonia.

(1027.) This order comprehends turtles and tortoises, animals whose skeleton presents a trunk composed of two large plates of bone, the one derived from an expansion of the dorsal vertebræ and ribs, the other from a corresponding expansion of the sternum; these are united at the edges, and form a complete case for the thoracic and abdominal viscera, leaving apertures in front for the head and neck, together with the fore legs, and behind for the hind legs and tail. This arrangement produces a singular reversal of the positions of the scapula, the pelvis, and the muscles attached to these bones, all of which, instead of being placed externally, are situated in the interior of the ribs. The humerus is remarkably curved, especially in the tortoise, where it has nearly the form of a semicircle. The radius and ulna are distinct from each other; the carpus and phalanges are short and stunted, forming a compressed sort of hand. The vertebræ of the neck and tail are the only parts of the spinal column which are moveable upon one another.

(1028.) The cavity in which the brain is contained is very small compared with the size of the skull, the greater part of which consists of the bones surrounding the orbit, and giving attachment to the large muscles that move the jaw. There are no teeth, and the horny coverings of the jaws has some resemblance to a horse's hoof in the mode of its connexion with the bones. The tongue is short, and covered with villi, which extend also down the œsophagus; their points are all directed towards the stomach, so as to prevent the return of the food when it is once swallowed. The stomach is simple in its structure; the intestinal canal of moderate length; its inner membrane presenting only longitudinal folds, together with innumerable villi, which are more thickly set in the upper part of the canal than in the lower; there is no cœcum, but occasionally small processes, or appendices epiploicæ, are attached to the outer membrane. The urinary bladder is exceedingly capacious. The lungs are voluminous, and are contained in the same cavity as the abdominal viscera. The air-cells are very large, and the general texture of the lungs is loose. Respiration is performed entirely by the muscles of deglutition; the animal in fact closes its mouth, and swallows the air received from the nostrils, which is thus poured down into the trachea, the os hyoides being alternately raised and depressed. The liver is divided into two round irregularly-shaped masses.

(1029.) The heart has two auricles, separated by a complete septum, the one receiving the blood from the venæ cavæ, the other from the pulmonary veins. The ventricle into which these veins pour their contents is single, but has two chambers of unequal size, which communicate together, so that the blood received from the lungs is more or less mixed with that returning from the body in the systemic circulation; and it is this mixed blood which is sent through the aorta. The pulmonary artery is merely a branch of the aortic system.

(1030.) In the internal ear, we find a tympanum, Eustachian tube, and semicircular canals, together with ossicula, and also stony concretions in the vestibule. The eye has a bony ring at the anterior part of the sclerotica, as in birds. There are large lacrymal glands, and a very moveable membrana nictitans.

3. *Sauria.*

Sauria.

(1031.) The various animals included in this order, or the tribe of lizards, have a heart with two auricles, with generally four feet, and a scaly integument. They are always provided with teeth, and with nails; there is invariably a tail. The ribs are very moveable, and their motions are subservient to respiration. The lungs are long and vesicular, extending far into the abdominal cavity.

Crocodile.

(1032.) The crocodile may be taken as an example of this order. Its jaws are of immense size. The upper jaw consists of a large intermaxillary bone, which is immoveably joined with the skull, although the animal, in opening the mouth, appears to raise it independently, a circumstance which misled the older naturalists into the belief, that it was really moveable. There is an os quadratum as in birds. The sternum extends to the abdomen, and consists of seven pair of cartilaginous arches, to which ten ribs, not however reaching to the spine, are attached. There are no clavicles. The tongue is thick and flat, and attached very near its edges to the jaws, so as not to be easily perceived.

---

[1] The temperature of animals of this class has been shewn by the experiments of Dr. Davy, Tiedemann, Czermack, and Wilford, to be in general two or three degrees higher than that of the surrounding medium. It partakes, however, of the vicissitudes in the temperature of that medium.

The teeth are of the simple conical kind chiefly adapted to the prehension and retention of the food; and each tooth when worn, is replaced by a fresh one, which grows underneath it; a succession which takes place several times during the life of the animal.

The œsophagus has the shape of a funnel, and leads to a stomach which resembles that of granivorous birds, in the thickness of its coats, and the approximation of its two apertures. The liver has two distinct lobes. There is no urinary bladder. The single ventricle of the heart is divided into three compartments, which communicate together; there is one cavity belonging to each auricle, and an intermediate cavity, into which the blood from the two others is poured, and where the intermixture of the carbonized and oxygenated portions is made. There is an external meatus of the ear, which may be voluntarily closed by a species of lips. Ossicula auditus are found, as well as stony concretions in the vestibule. In the other kinds of lizards, the tympanum is on a level with the integuments, and there is no external meatus. A membrana nictitans is found in the eye. The area of the section of the cavity containing the brain does not occupy the one-twentieth part of that of the whole head.

Chameleon. (1033.) The chameleon has comparatively a large head; but its brain is only of the size of a pea. Its lungs have numerous projecting processes. The tongue is constructed in a manner which bears some analogy to that of the woodpecker in the mechanism by which it is darted forwards to a considerable distance from the head, and suddenly retracted. It terminates in a sort of club, which is moistened with a glutinous secretion, for seizing flies and other insects, and its upper surface is hollowed. The eyes project considerably from the head, and admit of being turned very freely in their orbits. The most singular circumstance in the constitution of this animal, is the change of colour of its skin under various circumstances of temperature or excitement. These changes appear to be connected with the variable activity of respiration, which quickly influences the colour of the blood circulating under the very transparent skin; and which is visible to a greater depth, in consequence of the ample extension of the lungs along the sides of the abdomen: when the lungs are inflated, indeed, the whole body appears as if it were semi-transparent.

Draco volans. (1034.) The draco volans is a remarkable instance, in this tribe, of the subserviency of the ribs, which are expanded on each side so as to support a thin membrane resembling a wing, to the purposes of progressive motion.

4. *Ophidia.*

Ophidia. (1035.) Serpents, being wholly without feet, are constrained to crawl upon the surface of the earth, and are, therefore, more especially entitled to the appellation of *reptiles.*

(1036.) Their skeleton presents us with the simplest possible condition of the vertebral type; for it consists merely of a simple spinal column descending from the head, and furnished only with ribs. There appears, at first sight, to be no vestige either of sternum, of scapula, or of pelvis; the body of each vertebra is articulated by a convex surface, which is received into a concave surface of the next. The number of vertebræ is often exceedingly great; being sometimes as many as three hundred. The number of the ribs corresponds with that of the vertebræ, and when acted upon by their muscles, they assist in the progressive motion of the animal, by pressing on the ground, in succession, like imperfect feet. In the rattle-snake, the last vertebræ of the tail are broad and covered with the hollow pieces which compose the rattle. Obscure rudiments of pelvic bones were found by Mayer to exist in the anguis fragilis, the anguis ventralis, and the typhlops crocotatus; and it is probable that they may be discovered in most reptiles of this order. Some serpents have external claws, which may be considered as rudiments of feet. In others they exist concealed under the skin; and in others, again, there are cartilaginous filaments which Mayer regards as rudimental claws, connected with a series of small bones, which appear to be the rudiments of the bones of the lower extremities.

(1037.) The upper jaw-bone is detached from the rest of the skull, and admits of great latitude of motion. In most species of serpents, the jaws are so constructed as to render the mouth capable of great dilatation, and to enable it to receive objects even larger than the animal itself, and a corresponding power of dilatation exists also in the œsophagus.

(1038.) Serpents that are not venomous have usually four maxillary bones in the upper jaw, beset with small teeth, placed in two rows, widely separated from one another. The external row is not found in venomous serpents, but in their place large tubular fangs are met with, which are the terminations of the ducts from the poison bags, and which convey the venom into the wound inflicted by the tooth. This poison is secreted by glands, situated below the eyes, and surrounded by very strong muscles. Teeth.

(1039.) The stomach of serpents can scarcely be distinguished from the lower extremity of the œsophagus, and is very short, compared with the great length of that canal. There is no urinary bladder, the ureters opening at once into the cloaca.

(1040.) The heart has generally two auricles, though in some genera only one is met with; the ventricle is always single. The lungs consist of a membranous cavity, on the sides of which there are cells; their form is exceedingly elongated. The lung on one side is often much smaller than the other. The tongue is long and slender, and forked at the extremity; its root is contained in a kind of sheath, whence it can be protruded and retracted at pleasure. There is properly no tympanum belonging to the ear; but the long process of an ossiculum is found under the skin, and is connected with a tympanic bone.

5. *Batrachia.*

(1041.) The batrachia, (so termed from the Greek name of the frog, which may be assumed as a type of this order,) have a heart consisting of only a single auricle and ventricle; when arrived at maturity, they are possessed of two lungs; but in the earlier stages of their growth, they are wholly aquatic animals, and breathe like fishes by means of gills, which are affixed to the sides of the neck, by cartilaginous arches connected with the os hyoides. Such is the condition of the tadpole, which is the young of the frog. The aorta, on its exit from the heart, sends branches to each of the gills; whence the blood is collected by corresponding veins, that unite near the back to form a single arterial trunk, which again ramifies and distributes the blood to every part of the body, including the rudimental lungs, which are not yet developed In the process of the transformation of the tadpole into the frog, though these branchial arteries become obliterated, yet the vessels which supply the lungs remain, and are afterwards the channels of pulmonary respiration. Batrachia.

(1042.) In the skeleton of the frog, in place of ribs, small slender cartilages affixed to the extremities of the transverse processes of some of the vertebræ, which in the dorsal vertebræ are very broad. The spine is short, and terminates behind in a straight sacrum, which is impacted into the fork-shaped or innominatum. The scapula is thin and flat; and, together with the clavicles, are united to the sternum; but as there are no ribs, these, with the bones of the anterior extremities, are detached from the rest of the skeleton. There are properly no teeth; but the margin of the jaws is serrated. The urinary bladder exists, and is even sometimes double.

(1042.) The lungs do not collapse on opening the chest; this arises from the power which the frog possesses of distending them by the muscles of the mouth; the respiration being conducted on a plan similar to the one which has been already described in the tortoise, (§ 1027). Many species, as the pipa, have the vocal organs much developed. The tongue is of great length, and doubled back in the mouth; it is thrust forwards to a considerable distance in seizing its prey, and retracted with great rapidity. There is no external meatus to the ear; but the membrana tympani is external, and appears as part of the integument. The Eustachian tube opens at the fauces by an expanded mouth. There are two ossicula auditus; and the vestibulum contains rudiments of the calcareous bodies met with in other reptiles, and still more remarkably in fishes. The eye has two fleshy eye-lids, and also an internal nictitating membrane, which is transparent and horizontal in its direction.

alaman-
er.

(1043.) The salamander is constructed on the same model as the frog, with regard to all its internal organs; but it is provided with a tail. Its ear has no tympanum; but there is merely a cartilaginous plate laid over the fenestra ovale; there is no third eye-lid. The skeleton presents small rudimental ribs, but no sternum. This animal is remarkable for the power it possesses of reproducing the parts which have been mutilated, such as entire limbs; and even the eyes. In the newt, or aquatic salamander, the lungs have numerous processes, as in the chameleon, which terminate behind in an elongated bladder.

Müller has lately discovered that the frog, and several other animals of the same family, are provided with large receptacles for the lymph, situated immediately under the skin, and exhibiting distinct and regular pulsations, like the heart. The use of these *lymphatic hearts* is evidently to propel the lymph in its proper course along the lymphatic vessels. Their pulsations do not correspond in time with those of the sanguiferous heart; nor do those of the right and left sides take place at the same moment; but they often alternate in an irregular manner.

roteus

(1044.) The proteus anguinus, the siren, and the amphiuma, are remarkable for possessing both gills, like the tadpole, and lungs like the frog. They are, accordingly, adapted for living both in water and in air; and are the only animals that can strictly be said to be amphibious. The eye of the proteus is completely covered by the integuments, as it is in the mus typhlus.

Sect. IV.—*Comparative Physiology of Fishes.*

shes.

(1045.) Fishes are vertebrated animals with red blood, breathing by means of water applied to the gills, or *branchiæ*, which in them supply the office of respiratory organs. Their powers of motion are adapted to progression through the medium they inhabit. This design is conspicuous in the form of their bodies, the great muscularity of the tail, the shortness of their members, which are expanded into fins, and the coverings of the body, which are smooth and scaly. The oxygenation of the blood, being effected solely by means of the atmospheric air contained in the water they respire, takes place only to a small extent; hence the temperature of the body in fishes is not sensibly raised above that of the surrounding medium, and these animals display little energy either in their vital or their sensitive powers. The brain, accordingly, is of small size, and the organs of the external senses but little developed; they scarcely possess any organs calculated to convey accurate impressions of touch. Nature has denied them any vocal organs. The circumstances in which they are placed would appear to give little exercise to the sense of hearing; and the deep recesses of the ocean, where darkness eternally reigns, afford as little to that of sight. No lacrymal organs are wanted by animals immersed in a liquid medium. The voracity with which fishes devour their prey, leaves them scarcely any opportunity of discriminating its taste; and their tongue is not adapted by its structure for receiving the impressions of this sense. Neither can the sense of smell be exercised in the same degree as in animals respiring atmospheric air, through which odorous emanations are so extensively and so rapidly diffused. Exclusively occupied in the two great objects of animal desire, that of food and of progeny, all their movements appear exclusively directed to these ends; they appear insusceptible of attachment, and incapable of any but the lowest degree of intellectual developement.

Skeleton.

(1046.) The osteology of fishes presents a very complicated subject of study, not only from the great number of peices of which their skeleton is composed; but also from the great variety of forms exhibited in the different genera and species of this class. Fishes, with regard to their skeleton, admit of a great primary division into the cartilaginous and osseous. The former, or the *chondropterygii*, possess no real bones, but merely cartilages, having the form of bones, of a homogeneous and semitransparent substance, sometimes, however, as in the rays and sharks, presenting on its surface small calcareous granules, very closely compacted together. In a few fishes arranged under this division, as the sturgeon, and the chimera, we meet with several true bones in the head and shoulder, while the rest of the skeleton is cartilaginous. Even among the strictly osseous fishes, the density of the bones of some species is inferior to that of others, the calcareous substance, or phosphate of lime, being deposited in fibres, or layers, in the cartilage which serves as the basis of the bone. The truly osseous fishes have bones as hard and as dense as other vertebrated animals; they are even more homogeneous in their texture, and present no appearance of pores or of fibres, as are seen in the bones of the mammalia. We never find in them any medullary cavities.

(1047.) The spinal column consists of dorsal and caudal vertebræ only, those of the neck and sacrum being absent. The bodies of vertebræ have always a conical depression on both their surfaces; the double cone thus left by the junction of their margins being filled with a gelatinous fluid. These cavities generally, indeed, communicate together throughout the whole spinal column by apertures in the centre of each vertebra, at the apices of the cones. In the lamprey this opening is so wide, as to reduce the vertebral column to a mere series of rings, traversed from one end to the other by a ligament. The spinous processes are usually very long, and their roots form a canal for the passage of the spinal cord. Spinous processes are also frequently found on the opposite or abdominal side of the vertebræ; and these also form a canal for the protection of the aorta, which is admitted through it. The ribs are attached each to a single vertebra, and are frequently furnished with appendices adhering to them at one end, whilst the other end is imbedded in the muscles.

(1048.) The fins of fishes do not present much analogy with the bones of the extremities of quadrupeds, although such analogies have been sought with much eagerness. The fins are composed of parallel bones called rays, which are connected with others, called by Cuvier, *interspinal bones*, and by Meckel, *accessory spinal apophyses*. The sternum, where it exists, is composed of a series of bones, of various figures in different fishes; but which unite the lower extremities of the ribs. In the pectoral fin, or anterior extremity, are found bones somewhat analogous to the two bones which compose the scapula of reptiles; a styloid bone composed of two pieces, analogous perhaps to the clavicle and coracoid bone. The two bones corresponding to the radius and ulna are connected with a row of ossicula representing the carpus, and which support the rays of the fin itself.

(1049.) The posterior extremity, or base of the ventral fin, is composed of four bones, which may be considered as a pelvis; but these support the rays, without the interposition of any bones comparable to the femur, tibia, or tarsus.

(1050.) The bones of the head are exceedingly complex, and the mere enumeration of them would require a more lengthened discussion than can here be afforded. The bones composing the jaws, namely, the maxillary and intermaxillary, are not only moveable on the skull, but also on each other. The palatine, the pterygoid, and the tympanic bones, have also independent motions. A row of suborbitar bones also exists, different from what is met with in any other class. To the bones of the skull are joined also the opercular system of bones, which protect the gills, and are subservient to the motions which open and close them during respiration. The proper bones of the skull are placed in the midst of these four systems, and are very similar to those of reptiles, containing a receptacle for the brain, another for the labyrinth of the ear, and others for the eyes, and for the nasal cavities. The os frontis is composed of six pieces; the parietal of three; the occipital of five; each temporal of two; and the sphenoidal of five. Much ingenuity has been lavished in the attempt to discover analogies between these bones and the parts which compose the skeleton in the other classes of animals. Thus the opercular bones have been supposed to correspond to the ossicula auditus of mammalia; a notion which, although ably supported by Geoffroy St. Hilaire, may perhaps at first sight appear extremely fanciful and hypothetical, and which Cuvier represents as utterly unfounded.

Teeth.

(1051.) The teeth of fishes exhibit almost every possible variety in form, number, and situation. They may be distinguished, according to their position, into intermaxillary, maxillary, mandibular, vomerian, palatine, pterygoid, lingual, branchial, and superior and inferior pharyngean. Some fish have almost all these denominations of teeth; others a smaller number, and a few genera of fishes are entirely destitute of teeth. The teeth are generally of a conical and incurvated form, like so many hooks; sometimes the points are so small and united as to resemble a brush or file; others are round, or club-shaped; others present more flat surfaces, like a mosaic pavement. Their structure is always simple, being formed by a single pulpy membrane, which afterwards ossifies; and is, in process of time, replaced by a new tooth. This successive renewal of the teeth of fishes is continued during the whole period of their lives. The degree of mastication given to the food depends, of course, on the form and situation of the teeth.

(1052.) Deglutition is assisted by means of a membranous velum placed behind the anterior teeth. There is no appearance of salivary organs; unless we regard as such a soft and highly vascular organ found in the palate of the carp. This organ is highly irritable, and swells in a remarkable manner on the application of any stimulus; it perhaps performs the function of an organ of taste.

Digestive organs.

(1053.) The œsophagus is generally very short and capacious; it is continued into the stomach without any marked line of separation; and part of the food is often retained in the œsophagus undigested, until room can be made for it in the stomach. In a few fishes, the parietes of the stomach are muscular, so as to entitle it to be considered as a gizzard. The intestinal canal is generally very short; its internal coat is more or less villous; there is never any cœcum; the only distinction between the different portions of the canal is formed by a valve near its extremity; but this is not succeded by any dilatation.

(1054.) A remarkable structure is met with in the intestines of rays, sharks, and sturgeons; which present a spiral valve, or duplicature of the inner coat, running nearly the whole length of the canal. A great number of blind pouches, or *appendices pyloricæ*, as they are called, from their being more numerous in the beginning of the intestine, are generally found; their office appears to be to secrete a quantity of mucous fluid, probably analogous to saliva, or to the pancreatic secretion. In the sturgeon, these are short and united by vessels and cellular substance into one mass, which union becomes more close and compact in the rays and the sharks, constituting a real conglomerate gland, having a single excretory duct.

(1055.) In many fishes, namely, in the ray, shark, sturgeon, lamprey, and salmon, there are two passages opening outwards from the general cavity of the abdomen, at the sides of the termination of the intestine. The use of these passages is unknown.

(1056.) The liver is of considerable size, and placed more on the left side; great variety exists with regard to its shape and the number of its lobes in different fishes; its texture is softer than in quadrupeds and birds, and it contains a large quantity of oil. There is almost always a gall-bladder of greater or smaller size. The hepatic ducts are sometimes very numerous, and are successively joined to the cystic ducts. The mesentery is incomplete; and is often prolonged into folds containing fat, which folds may perhaps be considered as corresponding to an omentum. Although the lacteals are numerous, there are no lymphatic glands in the mesentery.

(1057.) The lymphatic vessels are very distinct in other parts of the body. Fohman has succeeded in injecting them in the gills. Several fishes have a urinary bladder, which is situated behind the rectum; in other instances there is merely a common cloaca, into which the ureters terminate. The kidneys are more voluminous than in any of the preceding classes, and are often joined together posteriorly; there are no suprarenal glands. The spleen is constantly present, and occupies various situations in the abdomen.

Circulation.

(1058.) The circulation in fishes is conducted upon a very different plan from what it is in reptiles. There is, as in warm-blooded animals, one complete circulation for the body in general, or a systemic circulation; and another for the organs of respiration; and besides this, a partial circulation for the hepatic system of organs; but what more particularly characterizes this mode of accomplishing that function is, that branchial circulation is the only one which is effected by a muscular apparatus, that is, by a heart. The systemic circulation has no such organ for communicating to it a mechanical impulse.

(1059.) The muscular apparatus for carrying on the circulation in fishes consists of four cavities, namely, the sinus venosus, the auricle, the ventricle, and the bulbus arteriosus; the three latter are inclosed in the pericardium, and may be said to constitute the heart, which is situated underneath the pharyngeal bones, and between the bronchial arches. The blood returning from the veins of the body and head, is collected in the sinus venosus, which transmits it by a single opening into the auricle, valves being interposed at the entrance. The auricle discharges its contents into the ventricle, which again propels it into the bulbus arteriosus, whence it proceeds along the bronchial arteries to be distributed on the gills. Thence it is returned by the bronchial veins, which unite near the spine to form a single arterial trunk corresponding in its office to the aorta, and distributing the blood, by a succession of ramifications, to every part of the body The veins from the digestive organs are collected into the vena portæ, which as usual ramifies through the liver; and there appears also, from the observations of Mr. Jacobson, to be in addition a lesser venal circulation, independent of either of the former, and analogous to what has already been observed in birds.

espira- ion.

(1060.) The vivifying influence of the air contained in the water which is applied to the gills of fishes, is quite as necessary for the continuance of their vital functions, as that of atmospheric air is to animals of the preceding classes; and fishes perish with equal rapidity as mammalia, when their natural element is withdrawn. This happens whether the water has been deprived of its air by boiling, or whether the absorption of air from the atmosphere is prevented by a body capable of intercepting it, placed on the surface of the water. It appears from the researches of Mr. Ehrmann, that some fishes, as the cobitis, swallow air, which passes along the intestinal tube, where it loses oxygen and acquires carbonic acid. Fishes taken out of the water are killed not so much from the want of oxygen, as in consequence of the drying of the branchiæ, which impedes the circulation of the blood through them. The water is taken in at the mouth, and after acting on the gills, which are filamentous organs, affixed in rows to the branchial arches, and protected by the operculum, is discharged through the branchial openings below. In the cartilaginous fishes there are several openings provided for the outlet of the water, at the side of the head.

ir blad- er.

(1061.) Most fishes possess a large bladder full of air, called the *swimming bladder*, placed immediately underneath the spinal column; it communicates with the œsophagus, and sometimes with the stomach, by a canal, called the *ductus pneumaticus*. In the carp, there are valves in this canal which only allow of the passage of air out of the bladder. In many fishes, especially in flat fish, no such air-bladder exists. Its figure is very various; its cavity is generally simple; but it is sometimes divided by a number of partitions. A glandular body is met with in the coats of this bladder, which probably secretes the air. The obvious intention of this instrument is to give greater buoyancy to the fish when this air is present, and to allow of a sudden increase of specific gravity by its escape. In by far the greater number of fishes, however, the air-bladder has no outlet whatever. In many fishes it is called the *sound*, and furnishes the best kind of jelly. Isinglass is the product of the air-bladder of the sturgeon. The air it contains is usually nitrogen gas, with a small proportion of oxygen and carbonic acid gases. The swimming bladder of fishes is regarded by many of the German physiologists as having some relations with the function of respiration; and as being the rudiment of the pulmonary cavity of land animals; the passage of communication with the œsophagus being conceived to represent the trachea. (Sec § 1022.)

ervous stem.

(1062.) The brain of fishes is remarkable for the smallness of its size, not only as compared with the total bulk of the animal, or with that of the nerves connected with it, but also with the cavity of the cranium, which it does not by any means fill, the space left being occupied by an oily secretion, and by loose cellular texture. The disparity is less observable in young fish; for it would appear that the growth of the brain does not keep pace with that of the rest of the body.

(1063.) The several parts which compose the brain of fishes are more detached from one another than in the higher classes, and are placed in a consecutive series. The foremost lobules give rise to the olfactory nerves, or rather appear as the bulbous enlargements of the origin of these nerves. The next in succession are solid lobes, which give origin to the optic nerves; behind these we find larger lobes containing a ventricle, with a striated eminence, at the back part of which are four smaller tubercles corresponding to the corposa quadrigemina. Behind these is the single lobule of the cerebellum, and below are two inferior lobes. The optic nerves pass before these lobes, and always decussate in their course to the orbits. Between these nerves, and in front of the inferior lobes, is the pineal gland. Behind the cerebellum are also two lobes, which may be termed the posterior lobes. There is, however, much difference of opinion as to the parts in the human brain to which these several portions of the brain of fishes are analogous.

Eyes.

(1064.) Great variety is met with in the size, position, and direction of the eyes of fishes. In general, however, they are large. There are neither eye-lids nor lacrymal organs, and the globe of the eye has but little mobility. In the ray and shark tribes, it is supported on the end of a moveable cartilaginous pedicle, articulated with the bottom of the orbit. The anabliss has the cornea divided into two by an opaque line, and two perforations exist in the iris, but there is only one crystalline lens, vetreous humor, and retina. The crystalline lens is completely spherical, and of great size, so as to leave but little space for the vitreous humor. It is composed of concentric laminæ, which are of greater density as they approach the centre. A falciform ligament, commencing at the entrance of the optic nerve, following its curvature downwards, and containing vessels and nervous filaments, is observable; its extremity is attached to the capsule of the crystalline lens. In some fish this ligament has a black colour, like the marsupium of birds. The sclerotica is often supported by osseous or cartilaginous plates, as in birds. The pupil is incapable of altering its dimensions; in the rays and flat fish, its border is fringed with palmated processes. The cornea is nearly flat, and there is but little aqueous humor.

(1065.) There is found in the eyes of fishes a peculiar body, the *membrana vasculosa Halleri*, having the shape of a horse-shoe, situated between the internal layer of the choroid coat, or *tunica Ruyschiana*, and the middle layer; it gives origin to a vascular membrane, called the *campanula*, which proceeds towards the lens, and has some analogy with the marsupium.

(1066.) The gastrobranchus appears to be wholly destitute of any organ of vision. In the blind murena, no trace of an eye can be perceived externally, but a rudimental organ exists beneath the skin.

Ear.

(1067.) The ear of fishes consists only of the parts belonging to the labyrinth; and these organs are generally suspended in a cavity of the cranium, which is a part of that in which the encephalon is contained. The two vertical semi-circular canals are suspended to the top of the skull by a vertical ligament. The oily or macilaginous fluid which surrounds the brain has free access to the cavities which surround the membranous labyrinth. The three semicircular canals are dilated into ampullæ, which receive the filaments of the auditory nerve. There is an appendix to the *sinus medianus*, or principal vestibular sac, termed the *utricle*, and a smaller one termed the *cysticule*. The hard calcareous bodies consist of one in each of these cavities, being three in number. There is no part corresponding to the cochlea.

(1068.) In the ray there is a spiral tube, wholly within the skin, which terminates in a kind of finestra ovale, and appears to be the rudiment of an external meatus.

Electrical organs.

(1069.) Many fishes present the extraordinary phenomena of the developement and accumulation of electricity in large quantities, which they have the power of discharging at pleasure, so as to give strong shocks to animals coming in electric contact with them, or forming part of the circuit of the discharge. This effect is often so powerful as to benumb and paralyse their assailants. The electric fishes which are known to possess this power in a high degree are the electric ray *(raia torpedo)*, the electric eel, *(gymnotus* *electricus*), and the *silurus electricus*, or *malapterurus electricus.* The first of these are met with principally in the Mediterranean Sea; the second in several rivers in South America; and the last in the Nile and Senegal rivers. Other fishes, however, are known to be electrical, although they have been less studied than those already mentioned, such as the *rhinobatus electricus*, *trichinus electricus*, and *tetrodon electricus.*

(1070.) The electrical organs of the torpedo consist of a great number of five or six-sided prisms, placed on each side of the head perpendicularly to the surface, and occupying the whole thickness of the animal. Each prism consists of a tube, with membranous sides, surrounded with nerves and blood-vessels, and containing a vast number of extremely thin plates, parallel to one another, but in a transverse position; the intervals are filled with a gelatinous fluid. Three large branches of the par vagum, and one branch of the fifth pair of nerves, are distributed to these organs on each side. The electrical apparatus of the gymnotus and silurus are disposed somewhat differently; they are two in number on each side, and extend the whole length of the fish from the head to the tail. One of these is situated deeply, and the other superficially; the two being separated by a membranous partition, and each being formed of horizontal plates, distant one-third of a line from one another, with septa passing perpendicularly between them, and directed from within outwards, and a fluid occupies the intervening spaces. Their nerves are derived from the intercostals, and are 224 in number.

(1071.) The identity of the agent called into play by these organs with electricity is beyond all doubt. The same bodies which conduct or intercept the transmission of the latter, have the same property with regard to the former; and shocks are propagated through a chain of several persons, when those at the extremities of the chain touch the fish. Electric sparks have been obtained by Walsh from the discharge of the gymnotus when passed through a strip of tin foil gummed to a piece of glass and cut through in the middle. Dr. John Davy[1] has obtained electro-magnetic effects from the torpedo, by the test of the galvanometer; and has also rendered needles magnetic by the electrical discharge from the fish.

(1072.) It appears that the power of producing these electrical discharges is quite voluntary, and dependent on the nervous influence; for it does not take place every time that the fish is touched, and it wholly ceases on the destruction of the brain, or the division of the nerves. The animal appears to have the power also of determining the direction of the discharges; and often, when irritated, it refrains from giving shocks. The destruction of the electric organ on one side does not interrupt the action of the opposite organ. Dr. Davy states, that the dorsal surface is charged with positive, and the ventral surface with negative electricity, and that unless both surfaces be simultaneously touched, no shock is felt; and Matteuci and Colladon[2] arrived at the same conclusion by experiments made with the galvanometer, as to the direction of the electric currents. Electric fishes, when vigorous, exert this power as strongly in the air as in the water. We are quite in the dark with regard to the theory of these phenomena. Matteuci imagines that the source of electric power in these fishes is in the brain; and that the purpose served by the complex arrangement of parallel plates, with intervening fluid, which composes the structure of the electric organs, is that of mere accumulation, analogous to the property of the Leyden phial.

Nasal cavities.

(1073.) What may be called the nasal cavities or nostrils of fishes, are placed generally in front of the head, and their openings are a valvular membrane or partition; behind this is found an elegantly plaited membrane, disposed in semicircular folds, on which the ramifications of the olfactory nerves terminate.

SECT. V.—*Comparative Physiology of Mollusca.*

Mollusca.

(1074.) The class mollusca comprehends all the variety of what are commonly called shell-fish, together with the animals, such as the slug, which resemble them in their anatomical character, but which are not furnished with shells. Their comparative anatomy has been studied with great care and diligence by Cuvier, whom chiefly we shall follow in our general description of this class.

(1075.) The mollusca have neither articulated skeleton nor vertebral canal. Their nervous system does not present a central spinal cord, but merely a certain number of medullary masses, dispersed in different situations in the body, and of which the largest, which may be designated the brain, is placed near the œsophagus, where it is connected with a collar of nerves that embraces that tube. The circulation is always double, like that of fishes, that is to say, the pulmonary circulation is always complete in itself, as well as the systemic. But the muscular ventricle, or heart, is not, as in fishes, placed at the commencement of the former, but of the latter; it impels the blood not into the branchial arteries, but into the aorta. The blood is either white or of a bluish colour; and it contains less fibrin than that of vertebrated animals. The veins probably perform the office of absorbents.

(1076.) The muscles are endowed with great irritability, and retain this property long after they are divided. They are attached to different points of the skin, which is smooth and moistened with a viscid liquor. The muscular actions produce contractions and inflexions of the different parts, and elongations of others, by means of which the animal is enabled to accomplish different kinds of progressive motion, whether in water or on land, without the aid of articulated members, or the advantage of solid unyielding structures, like the bones of the vertebrated classes. These movements, however, are necessarily less rapid and energetic, and less perfectly executed.

(1077.) A leading characteristic of the structure of the mollusca, consists in a muscular expansion, connected with the integument, which envelopes all the viscera, and is hence denominated the *cloak* or *mantle.* It assumes various forms in the different genera, being sometimes contracted into a flat disc, at other times being folded into a tube, or doubled into a sac, or expanded into the form of fins or oars. Most frequently we find a calcareous secretion formed on different parts of one or both of the surfaces of the mantle, which hardens and forms a layer of shell. Successive depositions take place, occasioning the enlargement of the shell in different directions; when the shell is wholly external to the animal, it serves for its habitation and protection; this is the case with the testaceous mollusca; in others, which have no such covering, (or the naked mollusca,) there frequently takes place an internal deposition of the same material, forming an internal shell. The calcareous matter is always intermixed, when deposited, with animal matter, which is sometimes in the form of a distinct membrane, and which has frequently a shining or irridescent appearance, constituting the substance known by the name of mother-of-pearl.

(1078.) Great variety exists in the organs of the digestive functions, as will be seen by the examples we shall give in speaking of the different orders established in this class by Cuvier.

1. *Cephalopoda.*

Cephalopoda.

(1079.) The various genera of sepiæ or cuttle-fish, are comprehended in this order.

---

[1] *Phil. Trans.* for 1832 and 1834.

[2] *Séances de l'Acad. des Sciences,* Oct. 1836.

epia.

In these animals, the mantle is folded so as to form a sac enveloping all the viscera; its sides being more or less extended into fins. The head alone protrudes from the sac; its form is round, furnished with large eyes, and with long processes or tentacula, flexible in every direction, endowed with great muscular power, and having on the surface a great number of suckers, by which they are capable of adhering with great force to the objects to which they may apply them. These tentacula, or feet, are employed by the animal in walking, which it does with the head downwards; in swimming, which it executes with the head turned backwards; and also in seizing hold of bodies, for which action they are well adapted. Between the basis of the feet is placed the mouth, containing strong horny mandibles, resembling in their form the beak of a parrot. The excretions pass out by a funnel-shaped aperture, situated at the mouth of the sac, and near the head.

(1080.) The pulmonary organs consist of two branchiæ situated within the sac, one on each side, and having the figure of a fern leaf. The great vena cava, on arriving near them, divides into two trunks, terminating in two muscular ventricles placed at the base of the branchiæ, for the evident purpose of propelling the blood with more force into the branchial arteries. The branchial veins corresponding to these arteries, unite in a third ventricle situated near the bottom of the sac, and which sends the blood forwards through the aortic system as usual. Thus there may be said to be three separate hearts in the cuttle-fish, one aortic and two branchial. The water respired enters at the open margin of the mouth and passes out by the funnel-shaped aperture already described.

(1081.) There is found a tongue, of which the surface is bristled with sharp horny points; the œsophagus is dilated into a *crop*, and terminates afterwards in a gizzard, equally muscular with that of a granivorous bird. To this succeeds a third stomach, which is membranous, coiled into a spiral form, and receives the bile by two ducts from the liver.

k.

(1082.) A singular secretion is prepared by a gland in this animal, of a deep black colour, resembling ink, which, when effused, darkens the surrounding water to a considerable distance, and gives the animal an opportunity of escaping from its pursuers. The brain is large; a nervous ganglion surrounds the œsophagus. The optic ganglions are very large; and the nerves form plexuses in the abdomen and in other parts. The eye is similar in its conformation to that of the higher classes of animals; but the ear is constructed in a still simpler manner than that of fishes, having neither semicircular canals nor external meatus, but consisting merely of a membranous sac lodged in a cavity near the brain, in which a small cretaceous body is contained.

2. *Gasteropoda.*

astero-
da.

(1083.) The mollusca which have a shell consisting of a single valve, compose a numerous order, a familiar example of which occurs in the snail. The slug, on the other hand, belongs likewise to this order, although it has no external shell. Mollusca of this description are termed *gasteropodous*, because they crawl on a flat disc placed under the belly; the back is covered with the mantle, which is of greater or less extent, and secretes the shell. The head comes out more or less from the mantle, under which it is occasionally retracted, so as to be both concealed from view, and protected from injury. A small number of tentacula, from two to six, appear above the mouth, but do not surround it. The eyes are exceedingly small, and sometimes adhere to the head, sometimes to the base, or the side, or the extremity of the tentacula; but occasionally none are found. The position and structure of their respiratory organs varies in the different families of this order; and they are always situated under the last turn of the shell when this latter has, as is generally the case, a spiral form; and they receive the water either by a broad opening under the mantle, or by a narrower aperture, and often through a tube formed by the prolongation of the mantle, which is frequently protected by an indentation or tubular process of the shell. A further protection is often afforded by a flat, horny, or calcareous plate, which closes the shell when the animal has retired within it, and which is termed an *operculum.*

(1084.) Instead of branchiæ, the pulmonary gasteropoda are provided with cavities for the admission of atmospheric air, which they respire in its gaseous form. These cavities are opened and closed at the pleasure of the animal, the mechanism of their respiration consisting in these movements.

The stomach and intestinal canal are of very various structure in the different genera. In some, as the scyllæa, we find cutting teeth implanted in the coats of the stomach itself; in the pleurobranchus there are four stomachs, like those of ruminant quadrupeds. The aplysia is provided with a very capacious crop, which leads to a muscular gizzard, armed, moreover, with a number of cartilages of a pyramidal shape; a third stomach succeeds to this, having its inner coat lined with sharp hooks; and a fourth, shaped like a cœcum; and the intestines are, besides, exceedingly voluminous.

Many of the gasteropodous mollusca present the curious phenomena of the double hermaphrodite generation formerly adverted to, (§ 781.) Impregnation of the ova requires the union of two individuals, the female organs of each receiving the male organs of the other, and the fecundation being mutual. This is the case with the helix and the lymneus.

3. *Acephala.*

Acephala.

(1085.) The acephalous mollusca, so named from their having no head, have all the vital organs enclosed in the two folds of the mantle, which shuts like a portfolio, leaving apparent only the orifice of the mouth; but in some cases the mouth is here prolonged in the form of a tube. In almost every case each of the two sides of the mantle is covered by a valve of shell, so as to constitute a *bivalve* molluscous animal; in another tribe the shell is *multivalve.* The brain is situated immediately over the mouth, and consists of a certain number of small ganglions. The branchiæ have almost always a laminated form, the plates, generally four in number, being covered with a net-work of blood-vessels. The mollusca of this order are unprovided with teeth, the food brought by the water being received into the mouth, and swallowed in its original state, whence it passes into the stomach; sometimes there are two successive cavities performing the functions of the stomach; the intestine is of various length. The liver surrounds the stomach, and pours its secretion directly into the cavity by several apertures.

Foot

(1086.) A large fleshy process, resembling in appearance a tongue, and which has been compared to a foot, projects from the body, and by the varied movements of which it is capable, enables the animal to perform a slow progressive motion. Muscles are also provided for closing the shell, and they generally pass directly from one valve to the other; sometimes there are two muscles, but commonly only one. The valves are separated by the force of an elastic ligament placed at the extremity of the hinge, which is called into action when the muscles that close the shell are relaxed.

Byssus.

(1087.) The threads, or byssus, spun by many acephalous mollusca in order to attach themselves to rocks, as a ship is moored by her cables, is another peculiarity in these animals, and particularly of the genera mytilus and pinna.

(1088.) In many mollusca of this order the rectum passes through the cavity of the heart, and this latter organ receives the blood from the veins by means of two auricles.

Some acephala are hermaphrodite; but the union of the sexual organs necessary for fecundation takes place in a single individual. This occurs in the holothuria.

Ascidia.

(1089.) One of the most singularly constructed of the animals referred to this division of mollusca is the ascidia. The mantle and its envelope, which is a thick and cartilaginous tunic, form together a sac, everywhere closed, excepting at two orifices, the one corresponding to the termination of the intestine, the other leading into a cavity, of which the sides are the branchiæ, and at the bottom of which is placed the mouth, the principal viscera subservient to nutrition occupying a second cavity, and the heart being lodged in a third. The principal nervous ganglion is situated between the two external orifices of the sac.

SECT. VI.—*Comparative Physiology of Articulata.*

Articulata.

(1090.) This great division of the animal kingdom comprises all those tribes possessing what may properly be called an external skeleton; that is, a series of rings or hollow cases, of a hard texture, which enclose all the important organs of the body, and which, by their muscular connexions, allow of various kinds of movements, at the same time that they afford protection to all the softer tissues of which those organs are composed. The best idea that can be formed of this mechanical construction may be obtained by examining the body and the limbs of a lobster, in which it will be seen, that contrary to what obtains in vertebrated animals, the harder parts are external, and the muscles are within them, a construction allowing of very free movements of the limbs.

Nervous system.

(1091.) A remarkable degree of uniformity prevails with regard to the distribution of the nervous system in all these animals. The brain, which is situated above the œsophagus, but is still in the head, as in the higher classes of animals, is exceedingly small; and after sending out filaments of nerves to the different parts about the head, is connected with a double nervous cord, which encircles the œsophagus, and runs along the under side of the animal, being joined at intervals by nodules or ganglia, from which, as from new centres, other nervous threads radiate, and are variously distributed to the different vital organs, and to the limbs. Each of these nervous ganglia appears to perform the office of a subordinate brain in relation to the system of nerves which proceeds from it, and to the parts of the body supplied by those nerves, so that when the animal is divided into several portions, each portion seems to possess its own independent vitality. The form and structure of the digestive organs is very various; but jaws are always found, and their motion is lateral instead of vertical, as in vertebrated animals.

1. *Annelida.*

Annelida.

(1092.) The first class of articulated animals are the annelida, or worm-shaped animals. They are remarkable for possessing red blood, which circulates in a double system of complicated vessels, without any heart, or muscular ventricles. The body is soft, more or less elongated, and composed of a great number of segments. The foremost of these, which may be regarded as the head, contains the largest of the ganglia, or brain, the mouth, and the principal organs of the senses. The branchiæ are generally external, and sometimes uniformly spread on the surface of the body; and at other times are confined to the anterior divisions. Tufts of hair or bristles supply the place of feet. The mouth is either furnished with hard jaws, or else extended in the form of a tube.

(1093.) The leech, which is referable to this class, has a very capacious stomach, nearly of the size of the whole body, or rather a series of pouches, or dilatations proceeding from each side of the central cavity.[1] Tentacula situated on the head, are their principal organs of touch; and the small black points, observable in some tribes, have been regarded as organs of an imperfect kind of vision. The earth-worm has a remarkably complicated apparatus for circulation, consisting of a great number of dilatations of the dorsal vessel, forming a series of hearts.[2]

2. *Crustacea.*

Crustacea.

(1094.) The articulated form is more perfectly developed in the crustacea than in the annelida. Their blood is white, and is circulated by the aid of a muscular ventricle, or heart, situated in the back, propelling it through an arterial system; whence it returns by a system of veins, which collect in a trunk passing along the lower part of the abdomen. In some species the heart assumes a very elongated shape. There are always organs termed *antennæ*, or feelers, situated in front of the head; and these are generally four in number. The jaws are of complicated structure. It is only in a few species that an internal ear is met with, and it then consists of a sac full of fluid, in which a calcareous concretion is contained. The eyes are generally two in number, often placed at the end of pedicles, and consisting of a great number of facets, each provided with a separate cornea, retina, and branch of the optic nerve; and the whole constituting what is termed a composite eye. The branchiæ are of a pyramidal form, composed of plates, or filaments, or feathery tufts, generally situated at the base of the legs.

Lobster.

(1095.) The larger genera of this class, as the lobster, have a horny stomach, with strong teeth implanted in its coats, for the evident purpose of breaking and bruising the shells that are swallowed. All these animals cast off their shells several times in the progress of their growth, a new shell being successively formed of larger dimensions than the preceding, and adapted to the increased size of the animal.

3. *Arachnida.*

Arachnida.

(1096.) The third class of articulated animals, or the arachnida, have been separated from that of insects with which they had been before associated; being distinguished by the following peculiarities in their conformation and economy. They have a distinct circulation of the blood by means of an elongated dorsal vessel performing the office of a heart, propelling its blood into a system of arteries, and receiving it back again from a system of veins. They are without antennæ, but are provided with palpi. They have pulmonary cavities subservient to the respiration of atmospheric air. The head is united with the trunk without the intervention of any neck. The mouth is armed with jaws; and there are several simple eyes situated on the upper part of the head.

4. *Insects.*

Insects.

(1097.) Nothing can exceed the endless variety of forms displayed by this class of the animal creation. Their internal anatomy and economy, however, present many points which are common to the whole class. There is no other trace of a heart, than a long cylindrical tube extending along the back, and termed the *dorsal vessel;* but which seems to be closed on all sides, and neither to give out, nor to receive communicating branches of any sort. This vessel appears to contain a fluid, which is irregularly undulated backwards and forwards, by a kind of pulsation, or occasional contraction of one part of the canal, and dilatation of another. It had been supposed, in the absence of any visible blood-vessels, that nutrition in insects is performed by a kind of gradual transudation, or *imbibition*, as it has been termed. Professor Carus, however, has lately made the discovery of a distinct circulation in the vessels of the larvæ of several insects, and other observers have found a system of partial circulation in even later periods of insect life. But, in general, in the last stage of transformation, all these vessels, excepting the dorsal vessel, become obliterated.[1] There being neither branchiæ nor pulmonary organs where the nutritious fluids could receive the vivifying influence of the air, a complex mode of respiration is resorted to. Apertures are found in different parts, generally along the sides of the body, and which are called *spiracles* or *stigmata*. These are the commencements of elastic tubes, which remain continually open, and which are subdivided and ramified like the blood-vessels of other animals, for the purpose of conveying air to every part of the system. These tubes are termed *tracheæ.*

---

[1] See a description and delineation of this structure in the Bridgewater Treatise *on Animal and Vegetable Physiology,* ii. 103.

[2] Ibid. ii. 255.

(1098.) Insects are unprovided with glands for effecting secretions; that purpose being answered by means of long spongy vessels, which appear capable of absorbing the materials they require from the general cavity in which they float.

(1099.) The temperature of insects, like that of other animals said to be cold-blooded, varies with that of the surrounding medium; but is generally one or two degrees higher. In bee-hives and ant-hills, a much higher temperature prevails. This is proved by an elaborate series of experiments made on the temperature of insects, and its connexion with the functions of respiration and circulation, by Mr. Newport.[2]

(1100.) Their nervous system is formed upon the general model already described, (§ 1091.) The digestive organs admit of the greatest possible variety, according to the habits and particular kinds of food consumed. To specify all these diversities would far exceed the limits assigned to us in this work. The external organs connected with the limbs, the antennæ, the mouth, and the different functions of sense, fall more properly under the consideration of the naturalist, inasmuch as they furnish the best characters for the distinction of genera and species, and for perfecting their systematic classification. The subject is rendered infinitely more complex in consequence of the metamorphoses which the same insect undergoes in passing through the different stages of its existence, from the *egg* to the *larva,* the *nympha* and the *imago*, or the perfect insect. But for the history of these changes, we must again refer to the naturalist, to whose province it more strictly belongs to record them. We must content ourselves with mentioning in this place a few of the more striking peculiarities of internal conformation which are observable in some of the insect tribes.

Digestive organs. Ruminant stomachs.

(1101.) The first that we shall point out is, the remarkable structure of the digestive organs of the orthoptera, an order of insects which comprehend the blatta, or cockroach, and the mantis or leaf insect, the ear-wig, the locust, the grasshopper, and the cricket. Their stomachs bear some analogy to those of ruminant quadrupeds, in complication at least, if not in office. The first stomach, or crop, is membranous; to this succeeds a muscular stomach, or gizzard, the internal surface of which is armed either with scales, or with horny teeth. Around the pylorus there extend two or more blind pouches, furnished at their extremities with numerous vessels conveying bile. Many similar biliary ducts are inserted in the course of the intestinal canal. It has been strongly suspected that the insects in which these complex stomachs are found, actually possess the power of ruminating their food.

(1102.) The abdominal cavity of the working bee presents us with two stomachs, together with the intestine and the poison bladder. The anterior stomach in which the œsophagus opens, is the receptacle for the honey, which is occasionally returned into the mouth in order to be stored in the honey-cells, as a magazine of food for the winter. The next stomach is destined to contain the pollen, or material gathered from the antennæ of flowers. Its inner coat has a great number of circular folds. Wax is a secretion of a peculiar kind from the bee.

(1103.) The alimentary canal of the caterpillar, before transformation, consists of a straight and capacious tube, of which the anterior portion is somewhat dilated into what may be considered as the stomach; and of which the posterior portions forms a cloaca; the biliary vessels, which are four in number, and very long, are inserted very far behind. When the caterpillar is transformed into a butterfly, this alimentary canal is much diminished, both in its diameter and length; the first stomach, or crop, is situated on the side of the tube; there is next a second stomach full of irregular dilatations, a slender but long intestine, and a cœcum near the cloaca.[3]

(1104.) The nervous system undergoes corresponding changes during the transformations of insects, the ganglia uniting in several places, so that their number is much diminished.[4] The external senses of insects have for the most part a considerable range of action. Organs of vision are almost constantly present, but those of the other senses are but imperfectly known. The principal organs of touch are the *antennæ,* which probably also perform other offices relating to sensation, of which we have no certain knowledge.

Sect. VII.—*Comparative Physiology of Zoophytes.*

Zoophytes.

(1105.) The animals which occupy the lowest division in the scale of life, and constitute an approach to vegetable, namely, the class of zoophytes, present us with much simpler forms of organization than any of those which have passed under our review. Yet amongst these we may trace gradations in the mode in which the more refined organs of the animal economy successively disappear, and their functions are supplied by other parts, and also in the gradual simplification of those functions, till we appear to arrive at an approximation to mere vegetative existence. The great characteristic of the more perfect animals, the circulation of the fluids in vessels which distribute them to every part for the purposes of nutrition and secretion, is wanting in zoophytes; or if any traces of a circulation can be discovered, it is exceedingly partial and limited in degree. There is a well marked disposition in all the organs to assume a symmetrical arrangement about a common centre; being either disposed in radii proceeding from that centre, or arranged in a uniform manner round the circumference of a circle. In those instances in which a nervous system can be traced, which is the case only among the higher order of echinodermata, the disposition to assume this radiating form is particularly observable.

(1106.) Many amongst the lowest orders present us with the singular spectacle of compound animals, associated in great numbers for the purposes of a common defence and habitation, and having even nutrition in common. These more particularly constitute an approach to the vegetable kingdom.

1. *Echinodermata.*

(1107.) The zoophytes arranged in this division, which are chiefly the asterias, or star-fish, the echinus, and the holothuria, present us with some appearance of an external skeleton, or hard encasement, consisting of parts which are often articulated together, an imperfect vascular system, and the appearance of a system of nerves.

---

[1] The dorsal vessel of the sphinx ligustri is delineated in the Bridgewater Treatise *on Animal and Vegetable Physiology*, ii. 245.

[2] *Philosophical Transactions* for 1837, p. 25.

[3] These successive conformations of the digestive organs, in the *sphynx ligustri*, or privet hawkmoth, are delineated in the Bridgewater Treatise on *Animal and Vegetable Physiology*, ii. 217.

[4] Ibid. ii. 547.

Asterias. (1108.) The rays of the asterias are composed of numerous pieces, which have been compared to vertebræ, are slightly moveable upon one another, and allow of a slow flexion of the entire ray. It is hollowed below into a longitudinal groove, abounding in perforations for the passage of numerous rows of short tentacula, which perform the office of feet, for the progressive motion of the animal, and which also absorb water, and convey it into the general internal cavity for the purpose of respiration. The centre of the star is occupied by a large stomach, the entrance to which, or the mouth, is below, and which sends out two prolongations, or cœca, to each ray; these are ultimately ramified into minute vessels, suspended by a membrane which performs the office of a mesentery.

Echinus. (1109.) The structure of the echinus is still more complicated. The calcareous covering of the body has a globular shape, but is composed of several angular pieces joined together, and perforated by rows of lobes, through which the short feet, or tentacula, protrude. Besides these, there are a multitude of spines articulated to the surface of the shell, and subservient to voluntary motion. The mouth is armed with five teeth, inserted in a complicated apparatus of jaws, resembling a pentagonal lantern, provided with numerous muscles, and suspended over the great opening in the centre of the lower surface of the shell. The intestinal canal is of great length, and forms a spiral tube attached to the interior of the shell by a mesentery. A double vascular system extends the whole length of this canal, and is partly spread over the mesentery.

Holothuria (1110.) The holothuria resembles in its structure the echinus, but it has a cylindrical instead of a globular form. The respiratory organ is ramified like the branches of a tree, and fills and empties itself at the pleasure of the animal. The mouth has no teeth, and is only protected by a circle of calcareous plates. The intestine is very long, and makes many folds, being also attached to the sides by a mesentery. A partial circulation takes place in a double system of a very complicated arrangement of vessels, which has relation exclusively to the intestinal canal, and of which some of the branches are interlaced with the arborescent respiratory tubes already described.

2. *Entozoa.*

Entozoa. (1112.) Very little is known concerning the physiology of intestinal worms; the information that has been collected being chiefly of a negative kind. They have no visible respiratory organs, and no apparent nervous system or organs of sensation; and still less can we discover any traces of a circulation. The only very distinct organs are those belonging to the functions of nutrition and of reproduction. Some naturalists, indeed, allege that they have detected some filaments of nerves; but the real nature of these filaments is still very doubtful.

(1113.) The alimentary canal may in most intestinal worms be recognised without much difficulty; it is sometimes enclosed in an abdominal cavity, but at other times apparently passes through the solid parenchyma of the body. In some, as in the tænia, or tape-worm, we may discern ramified vessels for the distribution of the nourishment; but these are not seen in others. The simplest animal of this tribe is the globular hydatid, which consists altogether of a vesicular sac filled with a transparent fluid, and with an indistinct mouth; but without any other apparent external organ. This tribe of entozoa exhibit the simplest example of the gemmiparous mode of reproduction; the young appearing as gemmæ, or buds, which at certain periods spout from the homogeneous parenchyma composing the body of the parent, and by a sort of vegetative growth, gradually assume the form of the original animal, and are detached when capable of exercising an independent life.

Some of the entozoa, as the tænia, or tape-worm, are capable of being multiplied like plants, by division; each segment resulting from the division being converted into an independent animal, acquiring whatever parts may have been deficient, and after a time admitting of further subdivision, with a repetition of the same phenomena.

3. *Acalepha.*

(1114.) These are either fixed on rocks, or float in the sea; they exhibit more or less of a fibrous texture, and contain vessels which are excavated out of the substance of the body itself, and are not contained in any distinct cavity. Acalepha.

(1115.) The actinia, or sea anemone, is provided with numerous hollow tentacula surrounding the mouth and stomach. The space between the stomach and the outer skin is divided into compartments by vertical partitions, and the fluid contained in these compartments may be projected into the tentacula so as to render them turgid. Actinia.

(1116.) The medusa has a hemispherical form, and a gelatinous consistence. The mouth, which is situated in the centre of the flat disc below, is surrounded by fringed tentacula. It leads into a singularly-shaped cavity, which is the stomach, formed of four arches proceeding like radii from the centre, and terminating in tubes which are variously divided, and the branches derived from them freely communicating with one another by anastomoses. These are apparently for distributing the nourishment which has been prepared by the stomach, but not for any real circulation. There are four large cavities in the body which appear to be subservient to respiration. Medusa.

(1117.) In some species, forming the genus *rhizostoma* of Cuvier, there is no central mouth, but a canal commences by an open orifice from the extremity of each of the fringe-like processes of the tentacula, and these, uniting with others in their course upwards, form at length a single tube or œsophagus, which terminates in the central stomach already described. Rhizostoma.

Most of the animals of this order, which are found fixed on rocks, are propagated by means of spores or gemmules, constituting one of the modes by which the gemmiparous form of reproduction is effected. These gemmules are minute bodies, formed either on the surface or in some special internal organ of the parent, and which are immediately detached and swim with a spontaneous and independent motion in the circumambient fluid, by means of cilia or short filaments, which are in rapid and incessant vibration. They pursue these motions for a certain time till they find a convenient place for their future habitation, where, when they are once fixed, they generally remain ever after, growing to the dimensions and exercising all the functions of the parent animal. In the acalepha, which are not stationary, the gemmules retain their liberty of moving during the whole period of their existence.

4. *Polypi.*

(1118.) The organization of this numerous order of zoophytes, presents, in every essential particular, great uniformity, and bears a great analogy to that of the actinia. The gelatinous sac or tube, constituting the digestive cavity, is closed at one end, the opening at the other end being the mouth, which is surrounded by a circle of tentacula; and the nutritive fluid passing by imbibition through the coats of the general sac or stomach for the purpose of nourishment. The hydra may be taken as the type of this tribe of animals. It consists of a mere stomach provided with flexible tentacula for catching food and for progression. This sac may be inverted or turned inside out, without detriment to the animal, digestion being then performed by the new cavity, which is the result of the operation. These animals present the simplest examples of gemmiparous generation, (§ 777). Polypi.

No further discovery can be made respecting the organization of these animals, even by applying the microscope, which shews only a semitransparent substance interspersed with opaque grains. The greater number secrete on their outer surface a calcareous or a horny substance, which serves for their mechanical support, but at the same time fixes them on the spot to which they adhere.

Aggregate olypi.

(1119.) The most remarkable feature in their history is their disposition to congregate together in vast numbers, so as to compose by their united architecture whole rocks and even submarine mountains, rising from the bottom of the ocean. Some of these animal republics exhibit amongst the individuals thus associated together communications of nutritious vessels, so that the materials for the sustenance of each passes into the bodies of the neighbouring polypi, and is applied to the purposes of their economy. All these fixed polypi are propagated by spores or gemmules in the manner already described in our account of the stationary acalepha.

5. *Infusoria.*

nfusoria.

(1120.) These being all microscopic animalcules of extreme minuteness, it is scarcely possible to arrive at any exact knowledge of their internal organization or economy. Many, and probably all, are possessed of distinct organs for the reception of food, for reproduction, and for voluntary motion; but conjecture alone can fill up the imperfect outline, or suggest any plausible hypothesis as to their powers of sensation, which, however, we are unwilling to refuse to any being which appears to possess the properties and attributes of animality, especially since the splendid discoveries of Ehrenberg have made us acquainted with the complex organization observable in some of the minutest of this prodigiously diversified tribe of beings. It is remarkable, indeed, that those very animalcules, as the monads, which had been ranked by naturalists among the *agastrica*, or beings totally without alimentary cavities, are now found to have a very considerable number of stomachs, and to be entitled accordingly to the title of *polygastrica*.

It is chiefly amongst the various tribes of infusoria that the simpler modes of generation, such as that termed *fissiparous*, are exemplified. In the monas, for instance, a groove is seen to form around the equator of their globular bodies, which groove, gradually deepening, changes their form to that of an hour-glass, and the connecting ligament of the two portions being soon broken, the segments move away from one another, each commencing its independent existence, and being capable of performing all the functions of the undivided monad. In the bell-shaped vorticella, the division commences at the mouth or wide extremity of the bell, and gradually extends in a longitudinal direction towards the insertion of the stem, dividing the body into two equal portions, each being now a distinct and individual animal. The gonium divides itself into four instead of two portions, each portion being again subdivided into four others, the new animalcules assuming rapidly the dimensions and appearance of the one of which they originally formed a part. Other species are propagated by means of gemmules; and some of the infusoria are apparently oviparous.

CHAP. XXIII.—HISTORY OF PHYSIOLOGY.

History.

(1121.) The study of the history of any science furnishes to the mind a body of knowledge not merely ornamental or superfluous, but one that is fraught with instruction and utility, and is conducive to the just comprehension of the subject to which it relates. It is scarcely ever necessary, indeed, for the understanding of any proposition, that the student should follow the same laborious course and travel through the same tortuous mazes by which the discovery had originally been achieved; for the acquisition of any body of knowledge already systematized by the labours of our predecessors, is in general most readily attained by the synthetic method. But as soon as this point has been reached we can conceive no course of study more calculated to improve that knowledge, and to invigorate the faculties by which it may be extended and perfected, than reverting to the analytic process, and following the series of discoveries in the order in which they have actually occurred. From an historical survey of the successive steps by which science has proceeded from a rude origin to its present state of advancement, and which mark its varied progress and even occasional retrogressions at different periods, according to the prevailing disposition of the age, either to a servile submission to authority or to the hasty adoption of crude and visionary theories, we are enabled to derive most important rules for the conduct of the understanding in the search after truth.

The history of each particular branch of science may, indeed, be regarded as a separate chapter in the history of the human mind. It indicates the sources of its activity and of its strength, and also of its weakness and fallibility; it holds out the most powerful incentives to exertion; it exhibits much to admire and to emulate, and, at the same time, discloses enough to check pride and teach humility.

(1122.) The history of physiology must necessarily comprise a large portion of the history of anatomy, which consists in the mere knowledge of the organs and minute structure of the body, such knowledge being, in fact, the foundation on which the higher science of the philosophy of life is built. It is scarcely possible, indeed, to study mere organization, without extending our views to the functions that we see performed, and to the energies that are exerted by the living organs. Our object will therefore be in the present place, to inquire how far these higher qualities of mind have been displayed by the cultivators of this department of knowledge at different periods, so as to mark the progress of the philosophy of life, as contradistinguished from the more mechanical, though equally useful labours of the mere anatomist.

Earliest periods.

(1123.) The phenomena which constitute the subjects of physiological inquiry must, indeed, have attracted the attention of mankind long before any accurate knowledge had been acquired of the structure of the organs whose actions give rise to these phenomena. Life in its different forms must have been familiar to all; and every savage and warlike people must have been conversant with the diversified aspects of death, which they inflicted in such various modes. Speculations on the nature of the vital principle, and the physiological conditions on which it is dependent for its origin, maintenance, and decay, must have been formed and pursued in every state of society, removed but one degree from barbarism; and such speculations must have stimulated inquiry into the internal mechanism with which that principle is associated, and the hidden springs which regulate its course.

(1124.) Opportunities must frequently have occurred in the rudest ages, of observing the different parts of the structure of the bodies both of men and animals. The curiosity even of the savage could not fail to be attracted by the remarkable appearance of the internal organs, in the animals which he slaughtered for food, or prepared for sacrifice. Although deterred from the actual examination of the human body, by an instinctive repugnance, or superstitious terror, various casualties occurring in battle, or arising from accidents, would occasionally afford an insight into the human frame. Human bones, and sometimes entire skeletons, would often present themselves to those who revisited the fields of carnage. Thus would the principal bones, and the most conspicuous viscera of the human body, soon become known, and they would be designated by particular names. Evidence to this effect may be collected from the rudest and most ancient languages; from which we may infer that a certain progress must have been made in this kind of knowledge, long before it had been so arranged and methodized as to deserve the name of a science.

Amongst the Egyptians.

(1125.) The prevailing custom amongst most of the ancient nations, of consigning all dead bodies to destruction by fire, was one of the greatest obstacles to the advancement of anatomical and physiological knowledge. But opportunities were on the other hand afforded of learning the structure of certain animals, by the religious rites, during the celebration of which these animals were sacrificed, and especially by the examinations which were made by the priests of the yet palpitating entrails of their victims, for the purpose of prognosticating future events. Inferences were thus drawn by analogy as to the organization and functions of the human body. The Egyptians, indeed, who composed the most ancient nation of whose manners and customs we possess any authentic records, were supposed to have acquired considerable knowledge of the human structure from the practice of embalming the dead. This operation was performed by a particular class of men, and consisted in taking out a portion of the viscera, washing them with antiseptic fluids, and filling the cavities with aromatic substances. But as this process appears to have been conducted in the rudest manner, it required no skill in anatomy, and was but little calculated to improve the science. It was in the hands of a few persons only; and such was the contempt and abhorrence in which these persons were held by their countrymen, that whatever knowledge they might have acquired by the practice of their art, was not likely to be communicated to others.

The Greeks

(1126.) Whatever splendour may have attended the pride of power or extent of empire in these rude and unenlightened ages, the dawn of science was coeval only with that of liberty. The same energies by which man had thrown off the yoke of tyranny, animated them likewise with the desire of knowledge; and nations had no sooner emancipated themselves from despotism, than they began to emerge from barbarism and ignorance. The Greeks, who were the most free, were also the most polished of all the nations of antiquity, and far excelled them in every species of science and of art. So great was the ardour of their philosophers in the pursuit of knowledge, that they frequently travelled into distant countries to collect useful information, and impart it to their pupils. Even in the time of Homer, the Greeks seem to have possessed much general knowledge both of anatomy and physiology, as may be collected from the writings of that poet. He relates that the stone which was hurled at Æneas by Diomed, not only crushed the thigh-bone, but also tore the ligament of the acetabulum. Merion is represented as being wounded in one of the large veins which return the blood to the heart, or venæ cavæ; and Ulysses aimed a blow at the Cyclops at the part where the liver adheres to the diaphragm. It has even been supposed that Homer has purposely often wounded his heroes that he might have opportunities of displaying by the minuteness of his descriptions, his accurate acquaintance with anatomy.

Pythagoras.

(1127.) But though curiosity was roused, and a multitude of detached facts had been observed and collected, it was long before the proper methods of investigation were known, and the true principles of inquiry established. Although it appears that the studies of anatomy and physiology were prosecuted with considerable ardour in the school of Pythagoras, yet as they were regarded merely as a part of natural history, the information relating to these subjects was not sufficiently connected or concentrated to be embodied in one science. Alcmeon and Empedocles, who cultivated anatomy, belonged to this school; but the most remarkable of the pupils of Pythagoras, belonging to the Eleatic sect, was Democritus of Abdera, a man whose eccentric manners, as well as penetrating genius, and undisguised contempt for the follies of mankind, have procured him so much celebrity. He is said to have devoted considerable time to the dissection of animals, especially with a view to discover the origin and course of the bile. His fondness for seclusion, and his perseverance in a pursuit which appeared to his countrymen to be without any rational object, led them to suspect the soundness of his intellects; and Hippocrates was sent to visit him in his solitary abode. He found the philosopher seated on a stone, under the ample shade of a plane tree, with a number of books arranged on each side, one on his knee, a pencil in his hand, and several animals which he had been dissecting lying before him. His complexion was pale, his countenance thoughtful; at times he laughed, at times shook his head, mused for a while, and then wrote, then rose up and walked, inspected the animals, sat down, and wrote again. Hippocrates, who perceived the nature of his inquiries, observed him for some time in silent admiration, proclaimed to the bystanders the importance of his researches, and declared to them his regret that want of leisure from his own professional employments did not allow him to engage in similar pursuits.

Democritus.

Hippocrates.

(1128.) But it was only from men whose minds are capable of enlarged views, and can perceive the bearings and connexions of the several parts of the subjects they embrace, that a powerful impulse is given to science, such as to make it almost the creation of their hands, that it is raised to its proper rank among the departments of human knowledge. Such was the vigorous mind of Hippocrates; and so great was the improvement which medicine derived from his genius, that the foundation was thus laid for the more rapid progress of all the sciences connected with it in succeeding times. Hippocrates was born in the island of Cos, in the first year of the 80th olympiad, or 460 years before Christ; an æra which is therefore remarkable in the history of medical science. It appears that at that period a knowledge of medicine had been in a great measure hereditary in certain families, amongst whom the information which had descended from the successive generations was thus retained and augmented. This was the case in the family of Hippocrates, who is said to have been the fourteenth descendant from Esculapius, on his father's side; while his maternal ancestry could be traced to Hercules. He had been instructed in all the learning of those times; but particularly dedicated himself to the cultivation of medicine, which he formed into a distinct science, collecting and arranging all the information on the subject that was then known. Not satisfied with the knowledge which he could acquire in his native place, he travelled for several years through different parts of Greece and Asia Minor. He visited the temple of Diana at Ephesus, and was at the pains of transcribing and arranging the records of cases and of successful methods of cure, which it was the custom to deposit on tablets in these temples. On retiring to his native island, after the laborious proofs he had given of his diligence and ardour, he continued to exercise his profession, and enjoyed the highest and most extensive reputation. Such was the estimation in which his talents were held, that even princes were solicitous to allure him to their courts; but he was so strongly attached to his native country, that he resisted every temptation which the splendour or the favour of monarchs could hold out.

(1129.) Excepting one or two particular treatises, which bear his name, but the authenticity of which is dubious, the writings of Hippocrates are to be regarded rather as medical than physiological; but he seems to have been the first who formed a clear conception of the value of anatomy and physiology as the basis of medical reasoning. Originality of thought, combined with accuracy of observation, forms the characteristic feature of his writings; which contain, however, many traces of the Pythagorean philosophy, with which he seems to have been early imbued. He formed the bold conception of the existence of a principle, which he calls φυσις, or nature, exercising a general direction and superintendence over all the actions and movements of the body, and endowed for that purpose with a species of intelligence directed to beneficial ends. As subservient to this great and prime agent, he imagined that the functions were carried on by means of other subordinate powers or faculties; and also that they were subjected to the influence of the stars. He regarded the body as being composed of three kinds of substances, namely, solids, fluids, and spirits, and ultimately resolvable into the four primary elements of earth, water, air, and fire, the predominance of each of which in particular individuals gave rise to the prevailing temperaments, characterised by the peculiar combinations of the four qualities of dry, moist, cold, and hot. Hence arose his doctrine of temperaments, already noticed, (§ 862). The anatomical details which are interspersed throughout his works are numerous, but do not exhibit any profound knowledge of the subject, besides being in many instances incorrect. The confession which he made on his visit to Democritus shews that he had not devoted any considerable portion of his time either to physiology or to practical anatomy. It is very apparent, indeed, that he never dissected a human body; and much could not be learned from the occasional dissection of brutes. So far was he from having any idea of the real nature of the circulation of the blood, which some have done him the honour to suppose he had discovered, that he seems to have imagined that the arteries contained air, and he was at a loss to determine whether the veins took their origin in the liver, the heart, or the brain. He includes under the same name the ligaments, the tendons, and the nerves, and makes no distinction between their respective offices in the economy. But these imperfections were more to be imputed to the unavoidable disadvantages of the times, than to his own deficiency either of industry or of talent; for wherever he had opportunities of displaying these qualities, and of exerting the whole force of his original mind, he far surpassed all his cotemporaries. Hippocrates must indeed be regarded as the father of physiology, as well as of medicine; and his name will ever be cherished by posterity, as one of the most illustrious in the annals of science.

ocrates.

(1130.) Amongst the Athenian philosophers who paid attention to physiology, Socrates must not be passed over in silence; since he cultivated the science with a view to establish upon it, as upon the most solid foundation, the principles of natural theology. Plato, the friend and pupil of Socrates, likewise devoted a portion of his time to the study of animal structures, and indulged in a variety of fanciful speculations concerning the uses and functions of the vital organs.

lato.

ristotle.

(1131.) Aristotle, the tutor of Alexander the Great, whose transcendant genius embraced the whole domain of human science, prosecuted this, as well as every other branch of the history of nature, with an ardour and perseverance that have rarely been equalled, and never surpassed. Gifted with a mind of extraordinary acuteness and comprehension, he appears to have concentrated within it all the learning of his age, which, moulded and transformed by the power of his genius, assumed new forms of arrangement, yielded new products of generalization, and spread its luminous irradiation over every department of human knowledge. At the request of his pupil he undertook an extensive treatise on the natural history of animals; he was liberally furnished with specimens of all kinds, and empowered to command the services of numerous assistants, from every part of the vast empire of Alexander. He spared no labour in the prosecution of this undertaking, and in making the most profitable use of the resources thus placed at his disposal; and contributed in no small degree to the advancement of our knowledge of the animal economy in the diversified forms of life presented by nature. Yet with all the advantages he possessed, it would appear that his knowledge of human anatomy was exceedingly imperfect. He even acknowledges that the internal parts of the human body are but little known; and points out the probable advantages that might result from the examination of animals which have the nearest resemblance to the human species, for supplying these deficiences. But his work on the history of animals, περὶ ζωων ἱστοριας, is unrivalled by the magnitude of the field which it embraces, and by the vast information it contains. To him belongs the merit of arranging the facts in the order, not of their zoological, but their physiological relations; referring every organ to the functions it performs in the animal economy, and thus anticipating the very principle on which, in recent times, Hunter, Blumenbach and Cuvier have founded their more rational and philosophical views of comparative physiology.

The Ptolemies.

(1132.) The encouragement given by the Ptolemies, the successors of Alexander in Egypt, to every kind of learning, tended greatly to the advancement of anatomy and physiology. Permission was granted by these monarchs to dissect the human body, which none would otherwise have dared to attempt, in opposition to the prejudices of the Egyptians, which were no less violent against dissection than those of the Greeks.

Erasistratus.

(1133.) One of the earliest of the physiologists of this period was Erasistratus, the grandson of Aristotle, and the pupil of Chrysippus. Under the patronage of Nicanor, king of Sicily, he enjoyed frequent permission to dissect the bodies of those who were executed, and is even reported by *Celsus* to have had criminals delivered to him for the purpose of their being opened while alive, in order that the natural living state of the internal organs might be examined. This account, however, deserves to be regarded rather as a popular tale, which has no other foundation than irrational prejudices against dissection, and was propagated by idle credulity, and a passion for exaggerated scenes of horror. The works of Erasistratus are now lost; but from the quotations of later authors, he appears to have greatly advanced the knowledge of the structure of the human body, more especially by pointing out the circumstances in which it differs from that of other animals, whose anatomy had been previously studied as making the nearest approach to the organization of man.

Herophilus.

(1134.) Another no less distinguished anatomist of the same period was Herophilus of Chalcedon, who also flourished at Alexandria. He was the disciple of Praxagoras, and was considered as the founder of the medical school at Alexandria. He was much occupied in the dissection of human bodies, and directed his attention particularly to the nervous system. One of the sinuses of the brain, which he is said to have more particularly described, bears to this day the name of the *torcular of Herophilus*. He is stated to have been the first anatomist who taught osteology from the human skeleton. He distinguished the nerves from tendons and ligaments, with which they had, before his time, been confounded. He also paid minute attention to the varieties of the pulse, and thus laid a foundation for a knowledge of the important function of the circulation.

(1135.) Few physiologists of any note are recorded as having flourished from the time of Herophilus to that of Galen. The names of Lycus of Macedonia; of Marinus, who lived in the reign of Nero, have been transmitted to us as the author of some elaborate treatises on the muscles; and also of Rufus Ephesius, who wrote a work entitled *Onomasia*, which was considered as the best system of anatomical knowledge extant at that period.

Galen.

(1136.) Galen, the most celebrated and indeed the last of the physiologists of Greece, was born at Pergamos, in Asia

Minor, about 131 years before the Christian era. His father was imbued with the love of letters, and was anxious that his son should receive the benefit of a learned education, which the early promise he gave of superior talents shewed that he was well qualified to turn to advantage. He was placed under the tuition of the best philosophers of the time, and studied in all the schools with extraordinary diligence. His father died long before he could form any probable anticipation of the future fame of his son. It was two years after this event, that young Galen, who was now in his nineteenth year, first turned his attention to medical pursuits, of which he soon became passionately fond. As Alexandria was still the most celebrated school of medicine in the world, he travelled thither with a view of prosecuting his studies; in order to reap every advantage which foreign countries could afford, he visited in succession different parts of Asia Minor and the islands in the Ægean Sea. Anatomy was ever his favourite pursuit; but being debarred from the advantage of examining human bodies, the dissection of which had then been prohibited, even at Alexandria, he had recourse to that of such animals as were supposed to have the greatest resemblance in their structure to man. He has written very fully on every part of anatomy; so that his works may be considered as a system, exhibiting every thing which was known on the subject in his time. He was much impressed with the importance of anatomy as the basis of medicine and surgery, and enforces his opinion with singular acuteness and energy. This is evinced by the following passage in his second book of Academical Administrations:

"What can be more useful in wounds which are received in battle, in the extraction of darts, excision of bones, the reduction of luxations, the opening of fistulæ, than to be well acquainted with the anatomy of the limbs? It is of more use to be acquainted with the exterior than the interior parts of the body, as the shoulders, back, breast, the ribs, the belly, and the outward covering of the neck and head; for we are often required to cut into abscesses and sinuses. In the excision of bones it is necessary to cut and dissect; and if we do not know where the artery, vein, or nerve may be, we are more likely to be the cause of death than of health to the patient."

(1137.) Galen is entitled to great praise for having applied himself to the investigation of physiology in connexion with anatomy; so little had hitherto been known on this subject, that we cannot be surprised at the mixture of error which his works exhibit; but although he may often have proceeded on false principles and fallacious hypotheses, yet the reasonings themselves which he employs are always clear and conclusive. His account of the uses of the hand, for example, is remarkably perspicuous and correct. He succeeded in establishing by experiment the fact that arteries contain blood, and thus refuted the doctrines of the Alexandrian school that they are merely filled with air, which they serve to distribute throughout the body. It is interesting also to trace the effect which these subjects of contemplation produced on Galen's mind. After reviewing the structure of the hand and foot, and their adaptation to their respective functions, he breaks out into the following apostrophe, admirably characteristic of a mind imbued with the genuine spirt of piety:

"I esteem myself as composing a solemn hymn to the author of our bodily frame, and in this I think there is more true piety than in sacrificing to him hecatombs of oxen, or burnt-offerings of the most costly perfumes; for I first endeavour to know him myself, and afterwards to shew him to others, to inform them how great is his wisdom, his virtue, his goodness."

Dark ages.

(1138.) The great reputation which Galen had acquired, instead of promoting, tended rather to impede the progress of anatomy and physiology during several succeeding centuries. Where no hope was entertained of emulating the fame of one who was regarded as an infallible oracle, all motive to exertion was repressed. But other causes of a political nature also contributed to the decline of anatomy, as well as of other branches of learning, from the time of Galen to the downfall of the Roman empire, and during the ages of intellectual darkness which followed. Learning, however, still continued to be cultivated at Alexandria, until the capture of that city by the Saracens, in the year 640, when its magnificent library was burnt.

The Arabians.

(1139.) Anatomy and physiology began slowly to revive among the Arabians; but no addition seems to have been made by them to the knowledge which the Greeks had possessed on these subjects. The Arabian physicians were satisfied with what Galen had taught them; and as the rites of the Mahometan religion prohibited all contact with a dead body, an effectual bar was opposed to all improvement in anatomical or physiological knowledge. The work of Avicenna on anatomy is merely a compilation from Galen and other Greek authors; and whenever he ventures to differ from his authorities he is generally wrong. For more than a thousand years after the time of Galen, anatomical and physiological science may be considered as nearly stationary; for scarcely any discovery of the least importance was made during the whole of that period.

Avicenna.

Mundinus.

(1140.) The expeditions of the crusaders were the means of introducing into Europe some knowledge of the literature of the Arabians; and the light of science, after a long period of darkness and ignorance, began at length to dawn. In the fourteenth century, anatomy was revived by Mundinus, a Milanese, who had become acquainted with the writings of Galen through an Arabian translation, and who published a system of anatomy in 1315.

The fifteenth century.

(1141.) The destruction of the Greek empire by the Turks, in the succeeding century, tended to diffuse throughout the west of Europe, whatever portion had remained of the literature of the east. The learned of every profession fled from Constantinople, which had fallen into the hands of barbarians, and sought an asylum in Italy, where they disseminated the seeds of knowledge. The writings of Galen and of the ancients, could now be read in the original; their superiority to the Arabian authors was soon discovered; and such implicit deference was paid to their opinions, that for many ages no one would venture upon the slightest innovation. The improvement of anatomy was therefore exceedingly slow. It was promoted, however, by the exertions of eminent painters, such as Raphael, Albert Durer, Titian, and above all, Leonardo da Vinci, whose drawings evince considerable knowledge in that study.

The sixteenth century.

(1142.) The sixteenth century was more auspicious to the progress of anatomy, which was beginning to be cultivated with ardour in Germany and France, as well as in Italy. Berengarius of Carpi, professor at Bononia, acquired such reputation by his skill in dissection, that he was regarded as the restorer of this science. The structure of the ligaments and bones was successfully studied by Charles Stephens; that of the blood-vessels by Fernelius; and that of the muscles by Andernach. Sylvius was also at this time celebrated as a teacher of anatomy.

Vesalius.

(1143.) But the extravagant veneration of antiquity, that spell which has for so many ages held the medical world in thraldom, was at length broken by Vesalius, who boldly ventured to call in question the authority of Galen. This extraordinary man was born at Brussels in 1514, of a family which had for a long time cultivated medicine. He united to remarkable talents, a degree of ardour and perseverance which enabled him to overcome every difficulty; and his progress in the study of anatomy, for which he had very early shewn a partiality, was commensurate with these great qualities. He commenced his studies at Louvain, and prosecuted them in Italy. In a short time he made himself master of the Hebrew, Greek, and Arabic languages; so that before he had attained his twentieth year, he had already read the works of Galen and Avicenna in the original. Such was his zeal for anatomy, that it is reported he used to rob the gibbets, and dissect the bodies in his bedchamber. In a few years he excelled his teachers, Fernelius and Sylvius, who were esteemed the first anatomists of their time. He soon detected many errors in Galen, some of whose descriptions of parts had been taken from quadrupeds, and applied to man. These errors he ventured to disclose and to correct in his publications; but his boldness in appealing to nature from the authority of Galen, drew upon him the enmity of all the admirers of that great master. He was assailed from all quarters with the bitterest invectives; and Sylvius himself has not scrupled, in the heat of controversy, to brand him with the epithet of *Vesanus*, or madman, in allusion to his real name. The criticism which Vesalius had passed on Galen, was retorted by his enemies upon himself; and it must be confessed that in the plates which Vesalius published, some errors of the same kind were detected. But still their general accuracy was undeniable. The work of Vesalius was soon acknowledged to be unrivalled, and its author eventually enjoyed a complete triumph over all his opponents.

His fame reached the ears of Charles V., who appointed him his physician; but after being raised to that distinguished station, he was soon doomed to experience the inconstancy of fortune. Having obtained permission to examine the body of a Spanish gentleman, whom he had attended in his last illness, he began to lay open the chest, when the bystanders imagined they perceived a tremulous motion of the heart. This circumstance soon got wind, and probably with much exaggeration, reached the ears of the relations of the deceased, who, seized with horror, denounced Vesalius as a murderer; and coupling this charge with that of impiety, arraigned him at the tribunal of the Inquisition. Where superiority of knowledge was esteemed a crime, Vesalius, however unjustly he might be accused, was certain of condemnation. By the influence, however, of Philip II., who had then succeeded to his father Charles V., Vesalius was permitted to commute his punishment to a pilgrimage to the Holy Land, the merit of which, it was thought, might sufficiently atone for the heinousness of any crime. This journey he was accordingly obliged to perform; and on his return he was invited by the senate of Venice to teach anatomy, but he perished by shipwreck before he reached that city, when he was about fifty years of age.

(1144.) The impulse which had been given by Vesalius to the progress of anatomy, continued to operate; and many were the inquirers who pressed forward in the path in which he had so nobly led the way. The barriers to investigation had been removed; nature was open to inquiry; and men had only to observe and to think for themselves. Every year was now adding some new discovery; and it becomes no longer easy to trace the order of their succession, or to ascribe each to their proper authors. We shall endeavour, however, briefly to enumerate those which are most worthy of being noted.

allopius.

ustachius

(1145.) In the year 1561, Fallopius published, in Italy, his *Observationes Anatomicæ*, a work of much merit, and the fruit of great industry. About the same period also, Eustachius arrived at great eminence as an anatomist, and published a set of plates, which he himself engraved; their beauty and accuracy excite astonishment even in the present day.

abricius.

(1146.) *Fabricius ab Aquapendente*, a professor of anatomy at Padua, was also one of the most distinguished anatomists and physiologists of that period. He published a splendid volume on the formation of the fœtus, and bestowed much pains in investigating the mechanism of the motions of animals. He was the first who delineated and drew the attention of the public to the valves of the veins, which had, indeed, been imperfectly seen by Stephens, Sylvius, and Vesalius, and the existence of which had been denied by Fallopius and Eustachius. It was this discovery, perhaps, more than any other, which paved the way for that of the real course of the blood in its circulation; a discovery which was reserved for the illustrious *Harvey;* and which has justly rendered his name immortal. As it may be interesting to review the steps which led to this important physiological discovery, we shall retrace its history to a period somewhat more remote.

Discovery of the circulation.

(1147.) It is perfectly well ascertained, from an examination of the works of Galen, and of others who have copied from him, that the ancients had not the most distant notion of the real nature of the circulation. The blood was believed by them to have its origin in the liver, and to be undulated alternately in opposite directions in the veins; they imagined that the finer part of it transuded through the septum, or partition separating the cavities of the heart, from the right to the left side, where it mingled with the air received into the lungs, and forming a vital spirit, was moved by a sort of flux and reflux along the arteries.

Cœsalpinus

(1148.) On the revival of anatomy in Europe some vague notions of the pulmonary circulation appear to have suggested themselves to many eminent men. Vesalius demonstrated that the blood could not possibly pass from the right to the left ventricle through the septum of the heart. Realdus Columbus, who was professor of anatomy at Padua, and had been a pupil of Vesalius, distinctly traced the passage of the blood through the vessels of the lungs. The same fact had, however, been already discovered by Michael Servetus, who was born in Aragon in 1509, and who is more celebrated as a theologian than as a physiologist. Further progress was made by Andrew Cœsalpinus, an Italian physician, who speaks of a communication existing between the veins and arteries at their remote extremities, and notices the effect of the valves of the arteries and of the auricles as calculated to prevent a reflux of the blood; but he is quite at a loss to reconcile this observation with the common notions, which he had imbibed, and to which he still adhered, of the functions of these vessels. But notwithstanding these apparent approximations to the truth, it is probable that many ages would have elapsed before the complete discovery of the circulation, if some bold and penetrating genius, such as that of Harvey, had not arisen.

Harvey.

(1149.) This illustrious man was born in the year 1578; and the circumstances of his family gave him the advantage of a liberal education. After six years spent at Cambridge, where he was instructed in all the philosophy of the times; finding that the university furnished but very imperfect means of studying either anatomy or medicine, he repaired, at the age of twenty-one, to Padua. Here he became the pupil of Fabricius, who was at the time demonstrating to his students, with all the enthusiasm of a discoverer, the newly observed valvular structure of the veins. The attention of Harvey being thus directed to this remarkable conformation, he became anxious, on his return to England, to prosecute the inquiry into the purposes which were accomplished by it. He was obliged, for this purpose, to make many experiments on living animals; and these revealed to him the real course of the blood in its circulation; a discovery which ranks unquestionably as the noblest and most important ever made in Physiology. Harvey taught this new doctrine in his lectures about the year 1616; but did not publish any account of it till the year 1628. On its being made known to the world, it met with the most violent opposition; and so inveterate were the prejudices of the public, that the practice of Harvey was considerably diminished in consequence of his discovery. It was remarked that no physician who had passed the age of forty would admit the truth of a doctrine so much at variance with all the systems in which he had been educated. Envious of his growing reputation, many of his cotemporaries had recourse to all kinds of sophistry with the view of detracting from his merit. They at first vehemently contested the truth of the doctrine; but afterwards, when forced to admit it by the decisive evidence adduced in its support, they changed their ground of attack, and alleged that the merit of the discovery did not belong to Harvey, the circulation having been known even to the ancients. But vain were all the efforts of envy and detraction to lessen that fame, which will command the admiration of all future ages. The physiological researches of Harvey were not confined to the function of circulation; but extended also to that of generation, and to the evolution of the ovum, on which he made a series of very valuable observations.

Asselli.

(1150.) The beginning of the seventeenth century was an important era in anatomy, for it was also marked by another brilliant discovery, namely, that of the lacteals by Asselli in 1622. It appears, from the testimony of Galen, that Erasistratus had noticed white vessels on the mesentery of kids; but the observation was not followed up, and these vessels were supposed to have been merely veins. Asselli was born at Cremona, and was professor of medicine at Pavia. He observed on the mesentery of a dog numerous vessels, filled with a white fluid; he was immediately convinced that he had made an important discovery, and uttered in the fullness of his feelings, the exclamation "Ευρηκα." Perceiving similar vessels upon the surface of the liver, and entertaining some theoretical views concerning the functions of that organ, he too hastily concluded that the lacteals terminated in the liver. Asselli published an account of his discovery with coloured prints in 1627.

Pecquet.

(1151.) It was not till about thirty years after this discovery of Asselli, that the lacteals were traced by *Pecquet*, a French anatomist, into the receptaculum chyli, and thence into the thoracic duct, which he also followed to its termination in the great veins near the heart. These observations were published in the year 1651. All these discoveries were made in brutes; and it remained to be shewn, that similar structures existed in man. This was accomplished by Veslingius, who had already demonstrated the human lacteal vessels, in the year 1634; and the human thoracic duct in 1649. These parts were afterwards more fully investigated by Peirish and Vanhorne. Shortly afterwards, the general absorbents of the body were discovered by Olaus Rudbeck, a Swede, who was born at Avosa, in the year 1630. This discovery was also claimed by Thomas Bartholin, who was born at Copenhagen in the year 1616; but by his own account he had not seen these lymphatic vessels till December 1651, whilst Rudbeck had not only observed them, but had distinguished their peculiarities the year before; Rudbeck had also traced them to the thoracic duct, which Bartholin had failed to do. Dr. Joliffe, an English physician, has also contended for the honour of this discovery; but from a comparison of dates, the priority is clearly in favour of the Swedish anatomist. When we consider the minuteness of these vessels and the transparency of their coats, we are able to appreciate the difficulty of detecting their existence, and our surprise must cease at their having remained unknown for so many ages.

Rudbeck.
Bartholin.

(1152.) No discovery of equal importance to those we have mentioned has been made in anatomy since that period. Many parts of the body, which were unknown in Harvey's time, have indeed been brought to light; but the principal improvement has consisted in a more accurate knowledge of the composition and minute structure of the several organs. For this we are chiefly indebted to the invention of new anatomical processes both of investigation and of demonstration. Two principal means were employed in these researches; the one was the microscope, the other the practice of injections.

Malpighi.

(1153.) The microscope was first applied to the purposes of anatomical inquiry about the year 1661, by Malpighi, who was born near Bologna, in the year 1638. He examined, by the aid of this instrument, the minute organization of all the vital parts; and more particularly the glands. These researches into the intimate texture of the various parts of animals were prosecuted with great ardour by Leeuwenhock, a Dutch anatomist, about the year 1680. In exploring this new field of inquiry, which opened views so remote from common apprehension, his enthusiasm has often carried him beyond what was real, both in the power of the instrument, and in the results it afforded. But still much has been effected, and the boundaries of the science have been greatly enlarged by the skilful employment of the microscope.

Leeuwenhoek.

Vanhorne.

(1154.) The arts of preserving the parts of animals when dissected, by drying and varnishing them, and by other modes of preparation, had long been practised; and in these Vanhorne is said to have attained superior excellence. But the most valuable invention of this kind was that of injecting into the vessels certain fluids which would, after a time, become solid, and admit of the course of these vessels being easily traced. The injecting syringe used for this purpose was invented by De Graaf, a Dutch anatomist, about the middle of the seventeenth century; and soon after, the proper materials for injection were discovered by Swammerdam. The art of injection was carried to a very high degree of perfection by Ruysch; but with a degree of selfish illiberality which cannot be too strongly condemned, he kept secret the methods he employed.

De Graaf
Swammerdam.
Ruysch.

(1155.) The advancement of Physiology was greatly promoted both by the practice of this art, and by the dexterous employment of the microscope; and discoveries in this science have succeeded one another so rapidly from the period of their invention, that in giving an account of them, it is scarcely possible to preserve an unbroken narration; and it would be impossible, in this sketch, to recount the numerous minor improvements which have been made in our knowledge of this department of science from the epoch down to which we have now brought its history. Much error was still mingled with the acquisition of real knowledge on these subjects; and it has required the exertion of the more severe and scrutinizing spirit of inquiry which characterizes the philosophers of a later period, to winnow the grain from the chaff, and refine the pure metal from the superfluous ore which had been dug up along with it from the mine. Physiologists were slow in recognising the peculiarities which appertain to the vital powers, and those of the beginning of the eighteenth century long persisted in ascribing the phenomena of life to the operation of the same laws which regulate those of inanimate nature. Hence the history of physiology is occupied at that period, chiefly by the contentions which arose between the rival sects of chemists and mathematicians; each striving to apply to physiology the principles and methods of investigation which prevailed in their respective sciences. Much ingenuity was wasted in these unprofitable researches; for although some important fact was occasionally brought to light by the prosecution of elaborate inquiries, prompted by endeavours to support each favourite speculation, yet not one of these hypotheses could long maintain its ground, nor could it be said that a single general principle had been established.

(1156.) A new light was now thrown on the subject of physiology, which tended to dissipate the clouds of error in which it had been obscured by the dogmatical tenets of both the chemical and the mechanical sects; and to effect a complete renovation in the science. The new doctrine which thus superseded the former, originated in Stahl; who, although educated in the school of the chemists, soon shook off the trammels of his instructors, and with the vigour of

Stahl,
Hoffman,
and Boerhaave.

native genius began to reflect for himself. He perceived the futility of their doctrines, and strongly impressed with the wide differences observable between the phenomena presented by organized beings, and those which the same bodies exhibit when devoid of vitality, conceived that they were governed by some agency opposed to the ordinary physical powers of matter; and to this agent he gave the name of *anima*, (see §. 101), ascribing to it endowments allied to intelligence, which controlled all the changes in the system, and of which the operations were always directed to salutary ends. This hypothesis, gratuitous and unphilosophical as it was, had the beneficial effect of directing the attention of physiologists to the phenomena which peculiarly characterise the living state, and prepared them for the study of the laws of these vital phenomena. Much praise is also due to Hoffmann, who, although too hasty in his conclusions to inspire confidence in their correctness, appears to have been amongst the earliest of the followers of Stahl, who entertained proper views of the principles and objects of physiology. Boerhaave was celebrated at this time for the extent of his information, the soundness of his judgment, and his talent in the art of instruction. His doctrines had extensive influence in the schools of medicine; but being destitute of the solid support of facts, they did not long survive their propounder.

Haller.

(1157.) But the great founder of modern physiology is unquestionably Haller, whose labours in this field of inquiry are so prodigious in extent, and so fruitful in results, that the publication of his Elements, to which it may be perceived we have had occasion in the course of this treatise perpetually to refer, must be considered as forming an important era in the history of the science.

Whytt, Cullen, Hunter, Bichat, &c.

(1158.) The attention of physiologists was beginning to be more particularly directed to the functions of the nervous system; and the labours of Whytt at this period had tended much to give it this impulse. Amongst the host of names which claim our notice as having contributed their share in the rapid progress of discovery, since this time, we can point out only a few of the most illustrious. William Hunter, the Monros, and Cullen, are amongst those most eminent for the services which they have rendered to physiology; but perhaps the largest contributor to the mass of facts collected in modern times was John Hunter. The merits of Bichat were also of the first order; and considering how early his career was cut short by the hand of death, the additions which he has made to the stock of facts, and the influence which his opinions have had on the progress of the science, must excite astonishment. Germany and Italy, as well as France, have been prolific in ardent devotees and successful cultivators of physiology; and although it might be invidious to point out particular names, we should be sorry to omit those of Spallanzani, Blumenbach, Soemmerring, Meckel, Gmelin, and Müller; nor should the justly earned fame of Cuvier be passed over in silence, even in this brief and imperfect retrospect of the benefactors of our race, for such we must esteem all those who enlarge the sphere of human knowledge, and thereby confer the most solid accession to the power and happiness of man.

PIA Mater, a thin membrane which covers the brain, and is in immediate contact with it. See Anatomy.

PIACENZA. See Piazenza.

PIANO-FORTE, a well-known modern instrument, in which the immediate sonorous bodies are wires of brass and steel. It has completely usurped the place of the old harpsichord, upon which it is a great improvement. Of late it has undergone many modifications, which are too numerous to be noticed here. The merit of its invention is disputed by the Italians and the Germans. Count G. R. Carli, in his works printed at Milan in 1784–1794, states (in vol. xiv. p. 405), that the piano-forte was invented in 1718, by Bartolommeo Cristofori of Padua, during his stay in Florence. The count speaks indignantly of the forgetfulness of the Italians regarding their own inventions: "Della quale inventione ci siamo scordati a segno, che l'abbiam creduta una nuova cosa, allorchè ci venne dalla Germania e dall' Inghilterra, accogliendola come una singolare produzione di quelle felici regioni, destinate ad illuminarci con i lumi presi dagl' Italiani." On the other hand, the Germans assert that it was invented about the year 1717, by C. A. Schrœter, a German organist, and that it was afterwards improved by Silbermann, G. A. Stein, and others. The English makers have, of late years, gained great repute by their excellent piano-fortes. Amongst the best may be mentioned those made by the Broadwoods, and by Clementi, Erard, and Collard. Those of Broadwood are distinguished by a rich soft tone, well suited for accompanying the voice. Erard's possess a more powerful and brilliant tone, and are better suited for the public performer of piano-forte sonatas, concertos, &c. The horizontal piano-fortes are those most used, as being the best. The origin of the vertical piano-forte may be found in Père Mersenne's *Harmonicorum libri xii.* 1652, folio; in which there is an engraving of a similarly formed instrument of an ancient date. We consider the modern extreme extension of the compass of the piano-forte, both grave and acute, as detrimental to the best effects of the instrument. On this subject, and as to the true powers of the piano-forte, see the article Music, vol. xv. pp. 644, 645. An Italian writer informs us, that in the beginning of the present century he had played upon many piano-fortes of a compass of *six octaves and a half*, made by Antonio Gherardi of Parma.

PIAS, or Bias, a town of Asiatic Turkey, supposed to be the site of the ancient Issus, near which was fought the celebrated battle that decided the fate of the Persian empire. Not many years since it was the residence of a powerful and warlike chief, who rebelled against the grand signior, plundered caravans, and laid the neighbouring countries under contribution. The Turkish ruler, provoked by these outrages, fitted out a fleet, which took the town of Pias, and reduced it to a heap of ruins.

PIASANSKOI, Verschnei, a village of Asiatic Russia, in the government of Tobolsk, near the Frozen Sea. There is another village of the same name, twenty-eight miles to the north of it, and four hundred and sixty miles north of Turuchansk.

PIASTUS, a native of Poland, was originally a wheelwright, and the son of Cossisco, a citizen of Cruswitz. He flourished in the year 830, when, on the extinction of the family of Popiel, great disputes arose about his successor, and Cracow was afflicted with a severe famine. During this extremity, when the people were dying in the streets, the credulous historians of the time relate that two pilgrims, or two angels in human form, having been hospitably entertained by Piastus, they promised him the crown of Poland; and being ordered by the pilgrims to distribute among the multitude his only remaining little cask of the common liquor of the country, he piously obeyed their instructions, and the cask was found inexhaustible. The people in astonishment cried out, "a miracle;" and as it appeared to the electors that this was a declaration of Heaven in favour of Piastus, they resolved on elevating him to the vacant throne.

Though we make but little account of the marvellous means by which it is said that the hospitable wheelwright ascended the ducal throne of Poland, it would be presumptuous entirely to omit a fact attested by all the writers upon this subject. It seemed proper therefore to take notice of it, but we leave it to the reader's judgment to attach what faith he pleases, or none at all, to the story. Being now raised to the supreme dignity, he was not intoxicated with his prosperity. His natural charity, benevolence, and sweetness of disposition, remained; nothing being altered but his power of doing good. He was truly called the father of his people; the injured never returned unredressed, nor merit unrewarded. Piastus wiped the tear from the eyes of the widow; and was himself the guardian of the orphan, the general patron of the poor and distressed. His excellent inclinations served him instead of great abilities; and the happiness which his people enjoyed made them forget that their prince was not born a statesman and a warrior. Several intestine commotions arose during his administration, all which he quelled by the mildness and clemency of his nature; for his nobility were ashamed of rebelling against a sovereign who devoted his whole life to render his people happy. He removed the court from Cruswitz, a city which he detested, because it was the scene of Popiel's crimes and tragical end, and fixed his residence at Gnesna, where he died beloved, esteemed, and even adored, by his subjects. It is in memory of this excellent prince that all the natives of Poland who have since been promoted to the ducal or regal dignity were called Piastes, in contradistinction to the foreigners.

PIATNITZKA, a village of Asiatic Russia, in the government of Tobolsk, twenty-eight miles north-north-west of Eniseisk.

PIAUHY, a large province of Brazil, is bounded on the east by the Serra Hibiappaba, which separates it from the province of Seara; on the south by the Serra of Piauhy, which separates it from Pernambuco; on the north by the Atlantic Ocean; and on the west it is separated from Maranham by the river Parnahiba. Although classed amongst the inland provinces, it has about eighteen leagues of coast, its form being almost triangular, whilst on the southern side, where it borders on Pernambuco and Goyaz, it expands to upwards of one hundred leagues in width. It stretches from the Atlantic Ocean inland, that is, from north to south, about one hundred and twenty leagues; so that if we estimate its average breadth at fifty leagues, its area will be equal to that of England and Wales. Originally it formed a comarca of Maranham; but in the year 1718 it was erected into a separate province, although it did not receive resident governors until forty years after that period. Originally Piauhy was explored and subdued on account its pastures, and not for the sake of slaves or from its possessing mines of the precious minerals or metals, for in these it appears to be deficient. Domingos Affonso, its conqueror, was the most extensive grazier in Pernambuco, and at his death bequeathed thirty of his large fazendas to the Jesuits, in trust for specified objects of charity; but on the expulsion of the order the trust fell into the hands of the crown. These estates, with three others added by the Jesuits, continue to be administered by government for the purpose intended by the original donor. The number of fazendas in the province is very great; as early as the year 1724 they amounted to no less than four hundred. It is to Piauhy that the neighbouring provinces of Pernambuco, Maranham, Bahia, and Minas Geraes look chiefly for their supply of cattle. A flourishing fazenda produces annually nearly one thousand calves; but after deductions for tithes and herdsmen, it is only able to export from two hundred and fifty to three hundred oxen. The cows are always reserved for breeding and home consumption; the rest are accounted for by the plague of flies, vampire-bats (from which the folds afford no security), jaguars, snakes, poisonous herbs (of which there are many kinds), and, above all, by drought, which frequently converts all the grass in the country into standing hay; and when that is consumed, the cattle perish by thousands.

Piauhy occasionally suffers greatly from drought, but the evils consequent thereupon are much ameliorated by the presence of several trees which yield abundance of grateful and wholesome juices. Travellers have sometimes owed their lives to the *imbuzeiro*, a remarkable tree, which is found in the most arid regions of Brazil. "Bulbs," says Southey, "about a palm in diameter, and full of water, are attached to its shallow roots. Arruda names this tree *spondia tuberosa*. Its fruit is smaller than a hen's egg, and, under a tough skin, contains a succulent pulp of a grateful flavour, at once acid and sweet. The Brazilians make a dainty of its juice with curds and sugar. The people of Piauhy make a beverage from the *buriti*, one of the loftiest and most beautiful of the palm tribe, but which grows only in moist or swampy places. Its fruit is about the size and shape of a hen's egg, covered with red scales arranged spirally; under these is an oily pulp of the same vermilion colour. The liquor which they prepare from it is said to be nutritious and palatable; but if drunk in excess it has the singular property of tinging the skin and the white of the eyes, without appearing to affect the general health." Another tree of great importance to a country like Piauhy, where drought is the great evil, is the *piqui*, which prospers in a dry and sandy soil, and produces abundantly a wholesome oily fruit, the size of an orange, to which the inhabitants are very partial. It grows to the height of fifty feet, having a proportional girth; and the timber is useful for ship-building. Some parts of the country have been redeemed from a desert state by tanks being formed on the rivers which dry up in summer. By thus laying in a store of water during the season when the streams are at the fullest, the herdsmen were enabled to establish fazendas, where otherwise it would have been certain destruction to the cattle to allow them to range.

The capital of this province, which, till the year 1762, bore the name of Mocha, received from king Joze, along with the title of city, the appellation of Oeyras, in honour of the great minister, the first count of that name. It is situated on a small stream, which, three miles lower down, falls into the Caninde, a confluent of the great Parnahiba, with which it unites twenty miles below. The town is small, and only remarkable from its being the capital of the province. It contains a church and two chapels; and the houses, although not numerous, are said to be commodiously and even elegantly constructed. The greater part of the inhabitants are Europeans, and, including the surrounding district, amount to fourteen or fifteen thousand.

A larger and much more important town than the capital, is St Joam da Barra da Parnahiba, situated seventy-five leagues north of Oeyras. It is built on sandy ground, five leagues from the sea, on the right bank of the eastern and largest branch of the river from which it takes its name. This is the seaport of the province, but the river, although navigable for barks of considerable tonnage more than a hundred leagues up, has diminished in depth so much near its embouchure, that vessels which used to ascend to the town are now under the necessity of mooring two leagues below it. The entrance is besides rendered dangerous by shoals and a heavy surf. Parnahiba contains some houses of one story above the ground floor, which are not seen in any other town in the province. This place is badly supplied with water, and fevers prevail to some extent; but its advantageous position on the great stream which traverses the western limits of the province, as well as its being the only seaport, secures it a considerable trade, and it is a great dépôt for cotton and hides. The surrounding country produces also excellent melons, and the tobacco raised in the south-western part of the province is preferred even to that of Bahia. There are several other towns, the principal of which is Piracuruca, situated on a river of the same name, and lying on the line of road from Villa Vicoza to Pernambuco. It carries on a considerable trade in cotton, and mandioc is cultivated to some extent. The river Piauhy, from which the province derives its name, originates in the southern frontier, and, running northward through pasture lands, enters the Caninde fifty miles below the capital, after a course of 140 miles. There are no serras of any consequence, nor any large forests, in this province. It consists, indeed, of vast grassy plains, little wooded, but in which numerous tall herbs attest the bounty of the sun. The population may be estimated at 50,000. (R. R. R.)

PIAZENZA, Placentia, or Plaisance, one of the four districts composing the duchy of Parma, in Italy, and which contains ten cantons. The capital is the city of the same name. It stands on the right bank of the Po, about a furlong from the stream. It is the see of a bishop, is situated in a rich and beautiful district, is surrounded by walls, which are rather adapted for promenades than for defence, and has a citadel, garrisoned by Austrian troops. The streets are straight and long, especially the one called the Stradone, which is very magnificent. The cathedral is a fine specimen of Gothic architecture, and has a gilded cupola. The city contains 2000 houses, two hundred of which are called palaces, and 16,500 inhabitants, whose chief occupation consists in preparing silk and weaving it, and trading in wine, oil, and cheese. Long. 9. 37. 12. E. Lat. 45. 2. 4. N.

PIAZIDA, a river of Asiatic Russia, which rises in the government of Tomsk, and falls into the Frozen Ocean after a course of 300 miles. Long. 87. 14. E. Lat. 73. 30. N.

PIAZINSKOI, a lake of Asiatic Russia, in the government of Tobolsk, 252 miles north of Turuchansk.

PIAZZA, a town of the island of Sicily, in the intendancy of Calatanisetta and district of Noto. It is a fine town, situated on a hill, in a healthy situation, 100 miles from Palermo, the Plutia of Diodorus. It contains 2424 houses, with 13,000 inhabitants, who cultivate the fertile soil near them, and carry on a great trade in its production. Near to it is the Lake of Pergusa, the scene of the rape of Proserpine.

Piazza, in building, popularly called *piache*, an Italian name for a portico, or covered walk, supported by arches. The word literally signifies a broad open place or square; and hence it was also applied to the walks or porticoes around them.

PIBROCH, says Dr Beattie, in his Essay on Music, is a species of tune peculiar to the Highlands and Western Isles of Scotland. It is performed on a bagpipe, and differs totally from all other music. Its rhythm is so irregular, and its notes, especially in the quick movement, so mixed and huddled together, that a stranger finds it almost impossible to reconcile his ear to it, so as to perceive its modulation. Some of these pibrochs, being intended to represent a battle, begin with a grave motion resembling a march, then gradually quicken into the onset; run off with noisy confusion and turbulent rapidity, to imitate the conflict and pursuit; then swell into a few flourishes of triumphant joy; and perhaps close with the wild and slow wailings of a funeral procession.

PIC DE L'ETOILE, Le, a small island in the South Pacific Ocean, so named by M. Bougainville in 1768, from its shape. It is one of the group called by Cook the New Hebrides. Long. 169. E. Lat. 14. 29. S.

PICA, or Pye, had formerly the same sense as *ordinal*, meaning a table or directory, pointing out the order in which the devotional services appointed for different occasions were to be performed. Accordingly we are told it is derived from ϖι, a contraction of ϖιναξ, *a table;* and by others from *litera picata*, a great black letter at the beginning of some new order in the prayer. The term was used in a similar sense by officers of civil courts, who called their calendars or alphabetical catalogues, directing to the names and things contained in the rolls and records of their courts, the *pyes*.

Pica, or *Picus, John*, prince of Mirandola and Concordia, was born in the year 1463, under the pontificate of Pius II. He was the youngest son of John Francis of Mirandola, and Julia, a lady of the noble family of Boiardo. Some of the credulous historians of the time have related, that at his birth a globe of fire was seen to rest upon his mother's bed; portending, say they, by its shape the perfection of his genius, and by its element the celestial turn of his mind. As soon as he was capable of receiving instruction, he was placed by his mother's care under the most able masters, and very early distinguished himself by the vigour of his application, and the strength of his memory, of which such prodigies are related as would be very difficult to credit, were we not assured, by some modern instances, of the perfection to which that faculty may be carried. At the age of fourteen he was, by the direction of his mother, who was desirous that he should assume the clerical functions, sent to Bologna, at that time the principal resort of those who studied the pontifical law. After spending two years there, he became disgusted with this pursuit; although such was his industry, even at that early age, that he compiled an epitome of the pontifical epistles or decretals. His disposition, however, led him strongly to the pursuit of philosophy, and excited an eager curiosity to penetrate the secrets of nature and science. With this view he travelled over Italy and France, visited the most celebrated schools of each, and studied under the most famous teachers of both countries.

After seven years spent in this course of instruction, and at the age of twenty-three, he went to Rome, and, after the fashion of the scholars of that time, brought himself into notice by publicly proposing literary questions for disputation. This sort of challenge was very common in that age, and, when printing was scarcely practised, and the name of a man of learning less rapidly extended than it is now, was almost the only method that a person of superior attainments could adopt to make himself known. Mirandola proposed nine hundred questions, or, as they were called, *Conclusiones*, in dialectics, mathematics, natural philosophy, and divinity; drawn not only from the stores of the Latin and Greek, but from the mysteries of the Hebrews and the arcana of the Chaldeans and Arabians. In addition to the endless topics of metaphysics, theology, and the ordinary subjects of disputation, into which he entered very profoundly, the *Conclusiones* involved the ancient and obscure philosophy of Pythagoras, Trismegistus, and Orpheus; the doctrines of the Cabbala, or mystical interpretation of the sacred writings, according to the Hebrews, taught by Origen and Hilarius; and the extent, uses, and learning of natural magic, which was vindicated from the vulgar reproach of impiety and necromancy. Seventy-two new physical and metaphysical dogmas of the author's invention were likewise proposed and defended. These propositions, according to the ostentatious practice on these occasions, were fixed in the most public places in Rome; and the proposer engaged to defray the expenses of any one who should come from a distance for the purpose of disputing with him. This challenge did not bring forward any disputants, but exposed Mirandola to much envy and jealousy, particularly from the professors of science at Rome, who felt the reflection that would be thrown upon their credit by their declining a competition which they durst not encounter.

Unable to injure his fame as a scholar, they made a much more dangerous attack upon the soundness of his faith. Thirteen questions were selected, which were charged with the terrible suspicion of heresy, and contempt of the ordinances of the church; a suspicion very readily listened to by the church when directed against great learning, which the increasing influence of philosophy and letters began to make her watch with extreme jealousy. Mirandola repelled this attack by publishing his *Apologia*, or Defence of the accused propositions, which, if he did not effectually clear away the suspicions he had incurred, tended to confirm his enemies in their dread of his learning and powers; and it must be owned that, overlooking the misapplication of talents to such subjects, the *Apologia* exhibits a command of profound and well-digested learning and keen argument, truly astonishing at the age of twenty-three. This work, and the discussions it contained of certain delicate points, added to some hints of the limit of pontifical control in matters of faith, were so disagreeable to Pope Innocent VIII. that he interdicted the reading both of the Apology and the disputed questions. The love of glory, however, was not Mirandola's only passion. His youth, splendid accomplishments, and the graces of his person, for which he is said to have been remarkable, attracted the admiration and caresses of many distinguished Roman ladies, who united the love of letters to that of pleasure, a taste very common amongst the Italian ladies of that age. The young philosopher yielded to the force of these allurements, or rather, according to the account of his nephew and biographer, Francisco di Mirandola, eagerly followed the bent of his disposition, naturall y inclined to obey the attractions of beauty.

But this life of pleasure, however suitable to his condition and inclinations, was of a short continuance. Irritated by the restless persecutions of his enemies, and obliged perpetually to defend himself against the imputation of heresy, the most formidable calumny which in that age any man could have to contend with, he detached himself from vicious pleasures, and regulated his manner of life by rigidly observing the laws of abstinence imposed by Christianity; for being a firm adherent of the Christian doctrines, the charge of infidelity and the vigilance of his enemies made him the more solicitous to guard against the appearance of disobeying them. From this time becoming wholly devoted to learning, he soon acquired such celebrity that the most eminent scholars from all parts of Italy came to visit him for conversation or instruction. As a proof of the sincerity of his reformation, he committed to the flames five books of elegiac poetry which he had composed upon the subject of his amours, together with numerous pieces in Tuscan verse, which had been addressed to his various mistresses. There is perhaps reason to lament that the zeal of the new convert could not be satisfied without this sacrifice. It must, however, be considered that the spirit of religion at that period exacted many sacrifices from the professors of Christianity, which the lenient temper of these times does not call for. An example of this severity is to be met with amongst the works which still remain of Mirandola, and at the end of which, in the folio edition published by his nephew, we find a learned and entertaining comment, in the Italian language, upon a composition of his friend Girolamo Benivieni, entitled *Una Canzone de Amore secundo la mente et opinione de' Platonici*, a poetical treatise upon love, explaining the doctrines of the Platonists. The author, Girolamo, informs the reader, in a short preface, that he had determined to suppress this poem and comment, out of regard to his friend's character and his own, deeming it unbecoming a professor of Christianity, in treating of celestial and divine love, "to treat of it as a Platonist, and not as a Christian;" but that having lent it to some of his friends for their perusal, an imperfect and erroneous copy was printed, which obliged him, but not until after the death of Mirandola, to publish it correctly. He takes care to allege, in excuse of himself, however, that he has apprised the reader of his plan by the title of the poem, and warned him, in all places where Plato's opinions depart from those of Christ, that the doctrines of a Gentile and a heathen are not entitled to the least weight compared with the reasonings of the Christian theologists, "and particularly the irrefragable arguments of the angelic doctor St Thomas of Aquino."

The first fruit of Mirandola's devotion to sacred literature was the Heptaplus, or Comment upon the Six Days of the first chapter of Genesis, which was written in 1491. Two years afterwards he published a treatise in ten chapters, *De Ente et Uno;* the object of which was to reconcile the doctrines of Plato and Aristotle, and to demonstrate that the disputes of their respective followers originated in a misconception of the opinions of these philosophers relative to the *Ens* and the *Unum*, at that time a subject of mighty strife amongst the learned. This treatise was held in high estimation by both sides. It was the last work of consequence which the author lived to complete; but he had laid the plan of a vast and comprehensive work, of which his early death prevented the execution. This was no less than to confound the seven enemies of the Christian church, by examining and refuting all their errors. In the prosecution of this design, he had, before his death, composed and perfected twelve books against astrology, the most popular and the most pernicious superstition which then infested the world. Paulus Jovius, bishop of Nocera, has left a testimony to the merits of this work, which is above all other encomiums. "In this excellent though unfinished work, Mirandola attacked the astrologers with such erudition and keenness, and so ably exposed the absurdity and vanity of the whole art of divination, that he seems to have deterred the professors of the occult sciences from writing."[1]

This great design, as well as many others which Mirandola had formed, particularly that of a more complete essay towards reconciling the opinions of Plato and Aristotle, was frustrated by his death. From the time that he left Rome, which was soon after the publication of the *Apologia*, Mirandola generally resided either at Ferrara or at Florence. The friendship of the Prince of Ferrara, and its vicinity to his paternal seat, attracted him to the former place; but Florence was the most agreeable to him, on account of the society of literary men which it afforded, and particularly that of Politian and Lorenzo de' Medici, with whom he entertained a close friendship. Besides these two illustrious men, his society was cultivated by other eminent scholars, amongst whom was the learned and unfortunate Hieronymus Savanarola, and Hermolaus Barbarus. Petrus Crinitus, the pupil of Politian,[2] mentions him as excelling all his companions in the erudition and eloquence of his conversation. The same author has left us an account of Pica's laborious studies; for when Politian had expressed in his presence high admiration of his great genius and learning, Mirandola with singular modesty answered, that he deserved no praise except for his assiduous application: "Gratulandum potius, intelligite, assiduis vigiliis atque lucubrationibus, quam nostro ingenio plaudendum."[3]

His library is likewise celebrated by the same writer, and is said by Francisco di Mirandola to have cost seven thousand pieces of gold. His accomplishments were not confined to subjects of abstruse literature; in his youth he was much attached to music, in which he acquired such skill, that some of his melodies were publicly received, and held in great esteem. It might also be concluded, from an anecdote related by Petrus Crinitus, that he was not unacquainted with physic; for, according to that author, when Hermolaus Barbarus was seized at Rome with a dangerous fever, Mirandola sent him from Florence a medicine prepared by himself. No man ever testified a more sincere devotion for learning and philosophy, to the contempt of all other qualifications, than the Prince of Mirandola. He possessed a very large estate, which he bestowed almost entirely upon works of charity, except what was spent in collecting books, and entertaining and providing for literary men. At length, however, about three years before his death, he made over to his nephew Francisco his principality and possessions in Mirandola, and obtained a confirmation of the grant from Maximilian, the Roman emperor, to whom that principality was subject. He reserved to himself only enough to purchase a small estate near Ferrara, where he spent the remainder of his life, except when he resided at Florence, in elegant and learned retirement. His mother, under whose care he received his education, had destined him for the church; and he was often urged by his friends to embrace the sacred profession, with the certainty of the highest honours and emoluments; but nothing could induce him to quit the life which he had chosen for himself. He died of a fever, at Florence, in the year 1494, in the thirty-first year of his age, on the same day that Charles IX. of France entered the city on his famous expedition into Italy. That monarch, hearing of Mirandola's illness as he approached the city, sent two of his own physicians to his assistance; but, in spite of their aid, the violence of his disorder put an end to his existence in thirteen days.

[2] P. Crinitus *De Honesta Disciplina*, lib. iii. c. 2, lib. v. c. 1, and lib. ii. c. 2.

[3] *Ibid.* lib. ii. c. 2.

With respect to the works of this author, something has already been said, and little more remains to be observed. The *Conclusiones* afford a very complete specimen of the learning of the age, and of what were deemed the most valuable purposes to which learning could be applied. However useless and unprofitable these purposes may appear to us, it will not be denied by any one who has the curiosity to look into the *Conclusiones*, that the mass of learning possessed by the proposer of them must have been prodigious, when it is recollected, that at the time he proposed them, he was no more than twenty-three years of age. For there is not the least reason to suppose, that a person whose works prove him to have been a man of profound learning, and who, in an age and nation distinguished by some of the brightest scholars that ever appeared, was ranked by their unanimous judgment amongst the first, should have challenged the discussion of any of the proposed subjects, without being well provided with the knowledge necessary for such a debate. The manner in which the questions were propounded leaves little room to doubt that the author was deeply versed in the respective subjects they embrace; and the Apology for the accused propositions, particularly those *de Salute Origenis* and *de Magia atque Cabbala*, discover familiarity with the writings of the Fathers, as well as with the Greek and Hebrew classics.

John Pica di Mirandola has been represented by some writers, whose ideas are taken from the encomiums of his contemporaries, as a mighty prodigy of learning and genius. The distaste which the present times entertain towards the subjects upon which he wrote renders it very difficult, upon a review of his works, to believe these encomiums well founded. But, making allowance for this change of opinion, it may be fairly concluded that he was, in reality, a man of very extraordinary powers.

PICARD, John, an able mathematician, and one of the most learned astronomers of the seventeenth century, was born at Flêche, and became priest and prior of Rillie in Anjou. Going to Paris, he was in 1666 received into the Academy of Sciences in quality of astronomer. In 1671, he was sent, by order of the king, to the castle of Uraniburg, built by Tycho Brahé, in Denmark, in order to make astronomical observations there; and thence he brought the original manuscripts written by Tycho Brahé, which are of the greater value as they differ in many places from the printed copies, and contain a book more than has yet appeared. He made important discoveries in astronomy, and was the first who travelled through several parts of France to measure a degree of the meridian. His works are, 1. A Treatise on Levelling; 2. Fragments of Dioptrics; 3. Experimenta circa Aquas effluentes: 4. De Mensuris; 5. De Mensura Liquidorum et Aridorum; 6. A Voyage to Uraniburg, or astronomical observations made in Denmark; and, 7. Astronomical Observations made in several parts of France. These, and some other of his pieces, are contained in the sixth and seventh volumes of the Memoirs of the Academy of Sciences.

PICARDS, a religious sect which arose in Bohemia in the fifteenth century. Picard, the author of this sect, and from whom it has derived its name, drew after him, as has been generally said, a number of men and women, pretending that he would restore them to the primitive state of innocence in which man was created; and accordingly he assumed the title of the *New Adam*. With this pretence he taught his followers to give themselves up to all impurity, saying that therein consisted the liberty of the sons of God; and that all those not of their sect were in a state of bondage. He first published his notions in Germany and the Low Countries, and, persuading many people to go naked, he gave them the name of *Adamites*. After this he seized upon an island in the river Lausnecz, some leagues from Thabor, the head-quarters of Zisca, where he fixed himself and his followers. His women were common, but none were allowed to enjoy them without his permission; so that when any man desired a particular woman, he carried her to Picard, who gave him leave in these words, "Go, increase, multiply, and fill the earth." At length, however, Zisca, general of the Hussites, scandalized at their abominations, marched against them, made himself master of their island, and put them all to death except two, whom he spared that he might learn their doctrine. Such is the account which various writers, relying on the authorities of Æneas Sylvius and Varillas, have given of the Picards, who appear to have been a party of the Vaudois, who fled from persecution in their own country, and sought refuge in Bohemia. It is indeed doubtful whether a sect of this denomination, chargeable with such wild principles and such licentious conduct, ever existed; and it is certainly astonishing that Mr Bayle should adopt the reproachful representations of the writers just mentioned; for it appears probable, at least, that the whole is a calumny invented and propagated in order to disgrace the Picards, merely because they deserted the communion and protested against the errors of the church of Rome. Lasitius informs us, that Picard, together with forty other persons, besides women and children, settled in Bohemia in the year 1418. Balbinus the Jesuit, in his *Epitome Rerum Bohemicarum* (lib. ii.), gives a similar account, and charges against the Picards none of the extravagances or crimes ascribed to them by Sylvius. Schlecta, secretary of Ladislaus, king of Bohemia, in his letters to Erasmus, in which he gives a particular account of the Picards, says that they considered the pope, cardinals, and bishops of Rome, as the true Antichrists, and the adorers of the consecrated elements in the eucharist as downright idolaters; that they denied the corporeal presence of Christ in this sacrament; that they condemned the worship of saints, prayers for the dead, auricular confession, the penance imposed by priests, the feasts and vigils observed in the Catholic church; and that they confined themselves to the observance of the Sabbath, and of the two great feasts of Christmas and Pentecost. From this account it would appear that they were no other than the Vaudois; and M. de Beausobre has clearly shown that they were both of the same sect, though under different denominations. Besides, it is certain that the Vaudois were settled in Bohemia in the year 1178, where some of them adopted the rites of the Greek, and others those of the Latin church. The former were pretty generally adhered to till the middle of the fourteenth century, when the establishment of the Latin rites caused great disturbance. Upon the commencement of the national troubles in Bohemia, on account of the opposition to the papal power, the Picards more publicly avowed and defended their religious opinions; and they formed a considerable body in an island by the river Launitz or Lausnecz, in the district of Bechin, and, recurring to arms, were defeated by Zisca.

PICCOLOMINI, Alexander, archbishop of Patrass, was a native of Sienna, where he was born about the year 1508, being descended of an ancient and illustrious family, which came originally from Rome, but afterwards settled at Sienna. He composed with success for the theatre; but he was more distinguished for his genius, than for the purity of his manners, and his regard to virtue. His charity was great, and chiefly exerted in relieving the necessities of men of letters. He left behind him a number of works in Italian, the most remarkable of which are, 1. Various Dramatic Pieces, which laid the first foundation of his character as a writer; 2. A Treatise on the Sphere; 3. A Theory of the Planets; 4. A Translation of Aristotle's Art of Rhetoric and Poetry, in 4to; and, 5. A System of Morality, published at Venice, 1575, in 4to, translated into French by Peter de Larivey, and printed at Paris, 1581, in 4to. These, with a variety of other works, prove his extensive knowledge in natural philosophy, mathematics, and theology. He was the first who made use of the Italian language in writing upon philosophical subjects. He died at Sienna on the 12th of March 1578, at the age of seventy.

Piccolomini, *Francis*, of the same family with the preceding, was born in the year 1520, and taught philosophy with success for the space of twenty-two years, in the most celebrated universities of Italy, and afterwards retired to Sienna, where he died in 1604, at the age of eighty-four. This city went into mourning on the occasion of his death. His works are, 1. Some Commentaries upon Aristotle, printed at Mayence, 1608, in 4to; and, 2. Universa Philosophia de Moribus, printed at Venice, 1583, in folio. He laboured to revive the doctrine of Plato, and endeavoured also to imitate the manners of that philosopher. He had as his principal rival the famous James Zabarella, whom he excelled in facility of expression and neatness of discourse, but to whom he was much inferior in point of argument, because he did not examine matters to the bottom as the other did, passing too rapidly from one proposition to another.

Piccolomini, *James*, whose proper name was *Ammanati*, took that of *Piccolomini* in honour of his patron Pius II. He was born in a village near Lucca, in 1422. He became Bishop of Massa, and afterwards of Frescati; was made a cardinal in 1461, under the name of Cardinal of Pavia; and died in 1479, at the age of fifty-seven, of an indigestion, occasioned by eating too freely of figs. His works, which consist of some Letters, and a history of his own time, were printed at Milan in 1521, in folio. His history, entitled *Commentaries*, commences with the 14th of June 1464, and ends with the 6th of December 1469. They may very properly be considered as a sequel to the Commentaries of Pope Pius II., which end with the year 1463.

PICKERING, a market-town of the north riding of the county of York, 222 miles from London, and six from York. It is situated in a mountainous district, and it had formerly a castle. The church is very large. There is a good market, which is held on Monday. The population amounted in 1801 to 1994, in 1811 to 2332, in 1821 to 2746, and in 1831 to 2555.

PICKET, an out-guard posted in advance of an army, to give notice of the approach of an enemy.

Picket, a kind of punishment so called, where a soldier stands with one foot upon a sharp-pointed stake; the time of his standing being limited according to the nature of the offence of which he has been found guilty.

PICKETS, in fortification, are stakes sharpened at one end, and sometimes shod with iron, being used in laying out the ground. They are about three feet in length, but when used for pinning the fascines of a battery they are made from three to five feet in length.

Pickets, in artillery, are about five or six feet in length, and shod with iron, being used to pin the lines, in laying out the boundaries of the park.

Pickets, in the camp, are also stakes of about six or eight inches in length, being used to fasten the tent cords in pitching the tents; also stakes of about four or five feet in length, driven into the ground near the tents of the cavalry, to tie the horses to.

PICO, one of the Azores, is so called from some lofty mountains on the island; or rather from one very high mountain, terminating, like Teneriffe, in a peak, and reputed by some writers to be equal to it in height. See Azores.

PICTET, Benedict, a celebrated divine, descended of a distinguished family. He was born at Geneva in 1655; prosecuted his studies with great success; and after having travelled into Holland and England, he taught theology in his own country, with an extraordinary reputation. The university of Leyden, after the death of Spantreina, solicited him to come and fill the place of that eminent person; but he thought that his own country had the best right to his services, and for this generosity on his part he received its thanks through the members of council. A languishing disorder, occasioned by excessive fatigue, hastened his death, which happened on the 9th of June 1724, at the age of sixty-nine years. This minister had much sweetness and affability in his manner; and the poor found in him a comforter and a friend. He published in Latin and French a great number of works, which are much esteemed in Protestant countries. The principal of these are, 1. A System of Christian Theology, in Latin, in three vols. 4to, the best edition of which is that of 1721; 2. Christian Morality, printed at Geneva, 1710, in eight vols. 12mo; 3. the History of the Eleventh and Twelfth Centuries, intended as a sequel to that of Sueur, printed in 1713, in two vols. 4to; 4. Several controversial treatises; 5. A great number of tracts on morality and piety, amongst which we must distinguish the Art of Living and Dying Well, published at Geneva, 1705, in 12mo; 6. Some Letters; 7. Sermons, from 1697 to 1721, in four vols. 8vo; with a vast number of other pieces, the names of which it would be tedious to mention, but which, as M. Sennebier says, "all show evident marks of piety and good sense."

PICTOU. See Nova Scotia.

PICTS, the name of one of those nations who anciently possessed the north of Britain. It is believed by some writers that they were so called from their custom of painting their bodies; an opinion which Camden supports with considerable erudition. It is certainly liable, however, to many objections; for as this custom prevailed amongst the other ancient inhabitants of Britain, who used the *glastum* of Pliny and the *vitrum* of Mela for the same purpose, it may be asked why the name of *Picti* was confined by the Romans to only one tribe, when it was equally applicable to many others? Why should they designate them only by an epithet, without ever annexing their proper name; or why should they impose a new name upon this people alone, when they gave their proper names to all the other tribes which they had occasion to speak of? As these questions cannot be answered in any satisfactory manner, it is plain that we must look for some other derivation of the name.

The Highlanders of Scotland express the name of this once famous nation by the term *Pictich;* a word familiar to the ears of the most illiterate, who could never have derived it from the Roman authors. But the word *Pictich* signifies *pilferers* or *plunderers;* and the appellation was probably imposed upon this people by their neighbours, or assumed by themselves, some time after the reign of Caracalla, when the unguarded state of the Roman province, on which they bordered, afforded them frequent opportunities of making incursions, and committing depredations therein. Accordingly the name appears to have been unknown until the end of the third century. Eumenius the Panegyrist is the first Roman author who mentions this people under their new name of *Pictich,* or, with a Latin termination, *Picti.* But when we say that this name may have probably been assumed for the reason just now mentioned, we must observe, that, in those days of violence, the character of robber was not attended with any disgrace. If a person of this description had the address to lay his schemes well, and to execute them successfully, he was rather praised than blamed for his conduct, providing he made no encroachments upon the property of his own tribe, or that of any of its allies. Nor is this any peculiar stigma upon the Picts; for other nations of antiquity, in the same rude state, thought and acted as they did in such circumstances.[1]

Concerning the origin of the Picts, authors are very much divided in opinion. Boethius derives them from the Agathyrsians, Pomponius Lætus from the Germans, Bede from the Scythians, Camden and Father Innes from the ancient Britons, Stillingfleet from a people inhabiting the Cimbrica Chersonesus, and Keating and O'Flaherty, on the authority of the Cashel Psalter, from the Thracians. But the most probable opinion is, that they were the descendants of the ancient Caledonians. Several very cogent reasons have been urged in support of this opinion by Pinkerton and others; and the words of Eumenius, "Caledonum, *aliorumque* Pictorum, silvas," plainly imply that the Picts and Caledonians were one and the same people. But the question arises here, Of what race were the ancient Caledonians? Were they of Celtic origin, or were they of northern or Scythian descent, a branch of that great family which everywhere overran and occupied the territories possessed by the Celts? Each of these opinions has found its advocates, and has been supported by much erudition and ingenuity; but, without entering into the discussion of a subject so little interesting to the generality of readers, it may be sufficient to state, that the preponderance of evidence and authority is clearly in favour of the latter hypothesis, which Pinkerton has rendered as clear as any matter of this kind can be expected to be made.

As there has been great difference of opinion about the origin of the Picts, so there has likewise been much dispute about their language. There are several reasons which, according to some, make it plain that their tongue was the Gaelic or Celtic; and these reasons are considered as a further confirmation of their having been of Caledonian origin. Through the eastern and north-eastern coasts of Scotland, which were possessed by the Picts, we meet with an innumerable list of names of places, rivers, mountains, and other natural objects, which, it is said, are manifestly Gaelic. From a very old register of the priory of St Andrews,[2] it appears, that in the days of Hungus, the last Pictish king of that name, St Andrews was called *Mukross;* and that the town now called *Queensferry* had then the name of *Ardchinneachan.* But both these words are claimed as Gaelic. The former, we are told, signifies the heath or promontory of boars; and the latter, the height or peninsula of Kenneth. In the list of Pictish kings published by Father Innes, most of the names are apparently Gaelic, and in many instances the same with the names in the list of Scottish or Caledonian kings published by the same author. But Innes understood nothing of that language, and certainly his nomenclature is as little to be relied on as some of his etymologies. Besides, he forgets that the predominance of the Celts at a period long anterior to the settlement of the Picts, and the traces of their language still to be found in the names of places and natural objects, are points which, as far as we know, have never been seriously disputed. This, however, does not prove that the Picts were a branch of the great Celtic family, and there is no good evidence to show that they ever spoke the language of that people. On the contrary, it seems highly probable that they were of German or Scandinavian origin; and although almost no remains of their language now exist, it may be proved negatively, as indeed Pinkerton has done, that it could not have been Celtic.

The Picts of the earliest ages, as appears from the joint testimony of all writers who have examined the subject, possessed only the eastern and north-eastern coast of Scotland. On one side, the ancient Drumalbin, or that ridge of mountains reaching from Lochlomond, near Dumbarton, to the Moray Frith, was the boundary of the Pictish dominions. Accordingly we find in the life of St Columba, that, in journeying to the palace of Brudius, king of the Picts, he travelled over Drumalbin, the *Dorsum Britanniæ* of Adomnan. On the other side, the territory of the Picts was bounded by the Roman province. After Britain was abandoned by the Emperor Honorius, the Picts and the Saxons were by turns masters of those countries which lie between the Frith of Forth and the river Tweed. We learn from Bede, that when he finished his Ecclesiastical History, the Saxons were masters of Galloway. The Picts, however, soon afterwards made a conquest of that country; so that, before the extinction of their monarchy, all the territories bounded on the one side by the Forth and the Clyde, and on the other by the Tweed and the Solway Frith, fell into their hands.

The history of the Picts, as well as that of all the other ancient inhabitants of Britain, is involved in great obscurity. The Irish historians give us a long list of Pictish kings, who reigned over Pictavia for the space of twelve or thirteen centuries before the Christian era. After them, Innes, in his Critical Essay, gives us a list of above fifty, of whom no less than five are said to have swayed the sceptre, each for a whole century. It is probable that these writers confounded the history of the Picts with that of their ancestors the ancient Caledonians. In any other view, their accounts of this people are highly fabulous, and undeserving of serious attention. The Picts, as has already been observed, were probably not known by that name before the third century; at least the first mention of them is made by Eumenius the Panegyrist, in the passage already referred to. Further, Adomnan, abbot of Iona, is the first author who expressly mentions any Pictish king; and the next after him is the Venerable Bede. We are informed by these two writers that St Columba converted Brudius, king of the Picts, to the Christian faith. But St Columba landed in Britain in the year of our era 565. Before that period we have no general record from which to ascertain so much as the name of any Pictish king. The history of *Drust* or *Drost,* who is said to have reigned over the Picts in the beginning of the fifth century, when St Ninian first preached the gospel to that nation, has all the appearance of fiction.[1] His having reigned a hundred years, and his putting an end to a hundred wars, are stories which exceed all the bounds of probability.

---

[1] See Thucydides, lib. iii. p. 3; and Virgil, *Æn.* vii. 745 and 749.

[2] Dalrymple's Collections, p. 122.

Brudius, the contemporary of St Columba, is therefore the first Pictish king mentioned by any writer of authority. But what figure his ancestors made, or who were his successors on the throne of Pictavia, cannot be ascertained. Bede informs us, that, during the reign of one of them, the Picts killed in battle Egfred, king of Northumberland, and destroyed the greater part of his army. The same author mentions another of their kings called *Naitan*, for whom he had a particular regard. It was to this Naitan that Ceolfrid, abbot of Wiremouth, wrote his famous letter concerning Easter and the Tonsure;[2] a letter in which Bede himself is supposed to have had a principal hand. Roger Hoveden and Simon of Durham mention two other Pictish kings, *Onnust* and *Kinoth;* the former of whom died in 761, whilst the latter flourished about the year 744, and gave an asylum to Alfred of Northumberland, who about that time was expelled from his kingdom. The accounts given by the Scottish historians, of several other Pictish kings, cannot be depended on; nor are the stories told by the British historians, Geoffroy of Monmouth and the author of the *Eulogium Britanniæ*, worthy of much greater credit.

Towards the close of the ninth century, the Pictish nation was totally subdued by, or rather amalgamated with, the Scots, in the reign of Kenneth Macalpin. Since that time their name has been lost in that of the conquerors, with whom they were incorporated; but they seem to have been treated by the Scottish kings with great lenity, so that for some ages afterwards they commanded great respect. The prior of Hogulstead, an old English historian, relates, that they made a considerable figure in the army of David the Saint, in his disputes with Stephen the king of England. In a battle fought in the year 1136, by the English on one side, and the Scots and Picts on the other, the latter insisted on their hereditary right of leading the van of the Scottish army, and were indulged in that demand by the king.

The principal seat of the Pictish kings was at Abernethy. Brudius, however, as appears from the accounts given by Adomnan, in his life of St Columba, had a palace at Inverness, which was probably near the extremity of his territory in that quarter; for there is no good reason to believe, with Camden, that this king had any property in the Western Isles, or that he made a gift of Iona to St Columba when he visited the saint in that island.

With respect to the manners and customs of the Picts, there is no reason to suppose that they were any other than those of the ancient Caledonians, of which many particulars are related by the Greek and Roman writers who have occasion to speak of those nations. Upon the decline of the Roman empire, cohorts of barbarians were raised, and Picts were invited to enter the service by Honorius; and when peace was everywhere restored, they were named *Honoriaci*. Those of them who served under Constantine opened the passes of the Pyrenean mountains, and let the barbarous nations into Spain. From this period may be dated the civilization of their manners, which happened after they had, first by themselves, and afterwards with the assistance of the Scots, ravaged the Roman province. This brought them in contact with civilization, and they profited by the collision.

PICTS' *Wall*, in *Antiquity*, a wall begun by the Emperor Hadrian, on the northern boundaries of England, to prevent the incursions of the Picts and Scots. It was at first made only of turf strengthened with palisades, but the Emperor Severus, coming in person into Britain, built it of solid stone. This wall, part of which still remains, began at the entrance of the Solway Frith, in Cumberland, and running north-eastward, extended to the German Ocean.

PICTURE, a piece of painting, or a subject represented in colours, on wood, canvass, paper, or some other substance. See PAINTING.

PICTURESQUE literally signifies that which is capable of, or fitted for, pictural delineation. Picturesque beauty, says an able writer on that subject, refers to such beautiful objects as are suited to the pencil. This epithet is chiefly applied to the works of nature, though it will often apply also to works of art. Those objects are most properly denominated picturesque which are disposed by the hand of nature with a mixture of varied rudeness, simplicity, and grandeur. A plain neat garden, with little variation in its plan, and no striking grandeur in its position, displays too much of art, design, and uniformity, to be called picturesque. "The ideas of neat and smooth," says Mr Gilpin, "instead of being picturesque, in fact disqualify the object in which they reside from any pretensions to picturesque beauty. Nay, farther, we do not scruple to assert, that roughness forms the most essential point of difference between the beautiful and the picturesque; as it seems to be that particular quality which makes objects chiefly pleasing in painting. I use the general term *roughness;* but, properly speaking, roughness relates only to the surfaces of bodies; when we speak of their delineation, we use the word *ruggedness.* Both ideas, however, equally enter into the picturesque, and both are observable in the smaller as well as in the larger parts of nature; in the outline and bark of a tree, as in the rude summit and craggy sides of a mountain."

PICUMNUS and PILUMNUS were two Roman deities, who presided over the auspices required before the celebration of nuptials. Pilumnus was supposed to patronize children, as his name seems in some manner to indicate, "quod pellat mala infantiæ." The manuring of the land was first invented by Picumnus, for which reason he is also called *Sterquilinius.* Pilumnus was also invoked as the god of bakers and millers, because he was said to have first invented the art of grinding corn.

PIEDMONT, or PIEMONT, a principality and principal province of the continental states of the Sardinian monarchy, forming the north-western portion of Italy. It was separated from Sardinia by the French in the year 1798, and in 1802 incorporated with France. On the fall of Napoleon in 1814 it was restored to the king of Sardinia, and the duchies of Milan and Montferrat have been annexed to it. It is now divided into twenty-six districts. Piedmont, in a narrower sense, borders on the Valais and Savoy to the north, on France to the west, on Nice and Genoa to the south, and on the Sardinian Milanese and Montferrat to the east. These limits comprise an area of 6575 square miles, and contain a population of 1,400,000 souls. If we include the Sardinian Milanese and Montferrat, its superficial extent is above 12,000 square miles, and the inhabitants amount to 2,322,000. It forms a continuation of the plain of Lombardy, somewhat narrowed, and more closely bounded by the mightiest ranges of the Alps and Apennines; the former on the north and west, the latter on the south. The principal river is the Po, which runs through its centre, dividing it into two nearly equal parts; and it receives here nearly all its early tributaries, which, from being in the vicinity of their mountain sources, are liable to sudden and destructive inundations. The climate, of course, varies according to the elevation of the surface. In the mountainous regions in the north and west the snow and ice remain during a great portion of the year. In the plains the climate is temperate during winter, and the excessive heats of summer are tempered by the vicinity of the Alps. The soil generally is very fertile, the plains traversed by the Po being particularly prolific, and in a high state of cultivation. They yield in abundance corn, wine, oil, fruits, rice, and hemp. But the staple product is silk, the breeding of the silk-worm being nowhere in Italy carried to the same extent; and the produce is also reckoned the finest in quality. It produces yearly 22,000,000 *lire* worth of silk, most of which is exported in the raw state. Another important branch of industry is the breeding of cattle, the pastures being both extensive and rich. The hills are in general covered with vineyards, the produce of which is very abundant, but generally of inferior quality. Olives, almonds, chestnuts, and in smaller quantities figs, oranges, and lemons, are raised here. The northern, western, and southern districts supply the central region with wood. The Piedmontese are industrious and frugal, and are all Catholics, with the exception of about 20,000 Waldenses and a few Jews. They have some silk, linen, and woollen manufactures, and thousands of them are seen travelling about Italy, France, and Germany as pedlars. The capital of Piedmont is Turin. This province derives its name from its situation at the foot of the mountains.

---

[1] According to Camden, this conversion happened about the year 630, in the southern Pictish provinces; whilst the northern, which were separated by mountains, were converted by St Columba.

[2] We are told by some authors that St Columba taught the Picts to celebrate Easter always on a Sunday between the 14th and 20th of March, and to observe a different method of tonsure from the Romans, leaving an imperfect appearance of a crown. This occasioned much dispute, till Naitan at length brought his subjects to the Catholic rule. In that age many of the Picts went on a pilgrimage to Rome, according to the custom of the times; and amongst the rest we find two persons mentioned in the Antiquities of St Peter's Church. *Asterius*, count of the Picts, and *Syra*, with some of his countrymen, performed their vow.

PIEDMONTE, a town of Italy, in the province Terra di Lavoro, and the kingdom of Naples. It is situated at the foot of the mountain Matese, and has wide streets, well-built houses, seven churches, a hospital, and 4640 inhabitants, who make woollen cloths, paper, and iron ware.

PIER, in building, denotes a mass of stone, opposed by way of fortress to the force of the sea or a great river, for the security of ships which lie at harbour in any haven.

PIERCY Island, a small island near the east coast of New Zealand, a little to the east of Cape Brett.

PIERHEAD, a promontory on the north-east coast of New Holland, and the west point of Thirsty Sound.

PIERIDES, in fabulous history, the daughters of Pierus, a Macedonian prince, who, presuming to dispute with the muses for the prize of poetry, were turned into magpies. The name of *Pierides* was also given to the muses, from Mount Pieris in Thessaly, which was consecrated to them; or, according to others, from Pieris, a Thessalian poet, who was the first who sacrificed to them.

PIERINO del Vaga, an eminent Italian painter, the son of poor parents, and a native of Tuscany, was born about the year 1500. He was placed apprentice with a grocer in Florence, and got some instructions from the painters to whom he was sent with colours and pencils; but an artist named Vaga taking him to Rome, he was called *Del Vaga*, from living with him, his real name being Buonacorsi. He studied anatomy and the other sciences necessary for his profession, and had somewhat of everything that was good in his compositions. After Raffaelle's death, he united with Julio Romano and Francisco Penni in finishing the works in the Vatican which were left imperfect by their common master; and, to confirm their friendship, he married Penni's sister. He gained the highest reputation by his performances in the palace of Prince Doria at Genoa; but the multiplicity of his occupations, and the vivacity of his imagination, exhausted his spirits in the flower of his age; and he died in the year 1547.

PIETISTS, a religious sect which sprung up amongst the Protestants of Germany, being a kind of mean between the Quakers of England and the Quietists of the Catholic church. They despised all sorts of ecclesiastical polity, all scholastic divinity, and all forms and ceremonies, and gave themselves up to contemplation and a mystic theology. Many gross errors are charged on the Pietists, in a book entitled *Manipulus Observationum Antipietisticarum;* but these have much of the air of polemical exaggeration, and are certainly not at all just. Indeed there are Pietists of various kinds; some running into gross illusions, and carrying their errors to the overturning of the greater part of Christian doctrine, whilst others are only visionaries, and a few are very honest and good, though perhaps misguided, people. Having become disgusted with the coldness and formality of other churches, they were charmed with the fervent piety of the Pietists, and attached to their party, without giving in to the grossest of their errors.

PIETRA Mala, a market-town of Italy, in the vicariate of Firenzuolo, and the grand duchy of Tuscany. It stands on the great road from Florence to Bologna, twenty-four miles to the north-west of the former city. It is remarkable from its vicinity to the mountain Raticosa, from which there issues constantly, on some parts of its surface, a flame, which does not produce those effects that commonly arise from volcanic eruptions. It burns both clear and bright, rises several feet above the earth, and is visible at a considerable distance. Various opinions and conjectures have been formed by naturalists concerning the causes and nature of this phenomenon, but none has been considered as satisfactory.

PIETRA Percia, a town of the island of Sicily, in the intendancy of Calatinata, and district of Noto. It is situated on a steep inland mountain, near the river Salso, seventy-four miles from Palermo, and is a healthy place, containing 8290 inhabitants.

PIETRI de Fusi, a town of Italy, in the province Principato Ulteriore, and the kingdom of Naples. It contains 4890 inhabitants, who grow some excellent wine.

PIETY is a virtue which denotes veneration for the Deity, and love and tenderness to our friends. This distinguished virtue, like many others, received amongst the Romans divine honours, and was made one of their gods. Acilius Glabrio first erected a temple to this divinity, which he built upon the spot on which a woman had fed with her own milk her aged father, who had been imprisoned by order of the senate, and deprived of all aliments.

PIGEON. See Ornithology.

Pigeon *Island*, in Dusky Bay, New Zealand, a little to the south of Facile Harbour. This is also the name of another island in the Eastern Seas, near the coast of Canara. Long. 74. 5. E. Lat. 14. 2. N.

PIKE. See Ichthyology.

PILATE, or Pontius Pilate, was governor of Judæa when our Lord was crucified. Of his family or country we know little, though it is believed that he was a native of Rome, or at least of Italy. He was sent to govern Judæa in the room of Gratus, in the year 26 or 27 of the common era, and he governed this province for ten years, that is, from the twelfth or thirteenth to the twenty-second or twenty-third year of Tiberius. He is represented, both by Philo and by Josephus, as a man of an impetuous and obstinate temper, and, as a judge, accustomed to sell justice, and to pronounce any sentence that was desired, provided he was paid for it. The same authors mention his rapines, his injuries, his murders, the torments he inflicted upon the innocent, and the persons he put to death without any form of process. Philo, in particular, describes him as a

Pilate.

man who exercised excessive cruelty during the whole time of his government, disturbed the repose of Judæa, and gave occasion to the troubles and revolt which followed. St Luke (xiii. 1, 2, et seq.) acquaints us that Pilate had mingled the blood of the Galileans with their sacrifices, and that the matter having been related to our Lord, he said, "Suppose ye that these Galileans were sinners above all the Galileans, because they suffered such things? I tell you, nay; but except ye repent, ye shall all likewise perish." It is not known upon what particular occasion Pilate caused these Galileans to be slain in the temple whilst they were sacrificing; for this is the meaning of the expression about mingling their blood with their sacrifices. Some think they were disciples of Judas the Gaulonite, who taught that the Jews ought not to pay tribute to foreign princes, and that Pilate had put some of them to death even in the temple; but there is no proof of this fact. Others are of opinion that these Galileans were Samaritans, whom Pilate cut to pieces in the village of Tirataba,[1] as they were preparing to go up to Mount Gerizim, where a certain impostor had promised to discover to them treasures; but this event did not happen before the year 35 of the common era, and consequently two years after the death of Jesus Christ. At the time of our Saviour's passion, Pilate made some faint endeavours to rescue him out of the hands of the vindictive Jews. He knew that they had delivered him up, and pursued his life with so much violence, solely out of malice and envy (Matt. xxvii. 18). His wife, also, who had been disturbed the night before with frightful dreams, sent to tell him that she desired him not to meddle in the affair of that just person (*ibid.* 19). He attempted to appease the wrath of the Jews, and to give them some satisfaction, by scourging our Lord (John, xix. 1; Matt. xxvii. 26). He also tried to take him out of their hands by proposing to deliver him or Barabbas, on the day of the festival of the passover. Lastly, he had a mind to discharge himself from pronouncing judgment against him by sending him to Herod king of Galilee (Luke, xxiii. 7, 8). But when he saw that all this would not satisfy the Jews, and that they even in a manner threatened him, saying he could be no friend to the emperor if he let him go (John, xix. 12, 15), he caused water to be brought, and having washed his hands before all the people, publicly declared himself innocent of the blood of Jesus, in whom he found no fault (Matt. xxvii. 23, 24); though at the same time this miserable juggler with conscience delivered him up to his soldiers that they might crucify him. His conduct, however, was sufficient to justify Jesus Christ, as Calmet observes, and to show that the governor held him to be innocent; but it was not enough to vindicate the conscience and integrity of a judge, whose duty it was to assert the cause of oppressed innocence, as well as to punish the guilty and criminal. He ordered to be inscribed on our Saviour's cross an abstract as it were of his sentence, and the motive of his condemnation, "Jesus of Nazareth, king of the Jews," which was written in Latin, Greek, and Hebrew. Some of the Jews found fault with it, and remonstrated with Pilate, alleging that he ought to have written "Jesus of Nazareth, who pretended to be king of the Jews." But Pilate could not be prevailed on to alter it, and gave them this peremptory answer, that what he had written he had written.

Towards evening, he was applied to for leave to take down the bodies from the cross, that they might not continue there the following day, which was the passover and the sabbath-day (John, xix. 31). This he allowed, and granted the body of Jesus to Joseph of Arimathea, that he might pay to it his last duties (*ibid.* 33). Lastly, when the priests, who had solicited the death of our Saviour, came to desire him to set a watch upon the sepulchre, lest his disciples should steal him away by night, he answered them, that they had a guard, and might place it there themselves (Matt. xxvii. 65). This is the substance of what the gospel tells us concerning Pontius Pilate.

Justin Martyr, Tertullian, Eusebius, and several other succeeding writers, both ancient and modern, assure us that it was formerly the custom for Roman magistrates to prepare copies of all verbal processes and judicial acts which took place in their several provinces, and to send these to the emperor. Pilate, therefore, in compliance with this custom, having sent intelligence to Tiberius of what had passed relating to Jesus Christ, the emperor wrote an account of it to the senate, in a manner which gave reason to infer that he thought favourably of the religion of Jesus Christ, and showed that he had no serious objection to their decreeing him divine honours. But the senate was not of the same opinion, and so the matter dropped. It appears, from what Justin says of these acts, that the miracles of Jesus Christ were mentioned there, including even the circumstance of the soldiers having divided his garments amongst them. Eusebius insinuates that they spoke of his resurrection and ascension. Tertullian and Justin refer to these acts with so much confidence, that we cannot suppose them to have written without authority. However, neither Eusebius nor St Jerome, who were both inquisitive and intelligent persons, nor any other author who wrote afterwards, seems to have seen these acts, at least not the true and original acts; for as to those which we have now in great number, they are not authentic, being neither ancient nor uniform. There are also some pretended letters of Pilate to Tiberius, giving a history of our Saviour; but they are universally allowed to be spurious.

Pilate being a man who, by his excessive cruelties and rapine, had disturbed the peace of Judæa during the whole time of his government, was at length deposed by Vitellius, the proconsul of Syria, in the 36th year of Jesus Christ, and sent to Rome to give an account of his conduct to the emperor. But though Tiberius died before Pilate arrived at Rome, yet his successor Caligula banished him to Vienne in Gaul, where he was reduced to such extremity that he put himself to death with his own hands. The Evangelists call him governor, although in reality he was only procurator of Judæa.

With regard to Pilate's wife, the general tradition is, that she was named Claudia Procula or Proscula; and in relation to her dream, some are of opinion, that as she had intelligence of our Lord's apprehension, and knew by his character that he was a righteous person, her imagination, being struck with these ideas, had naturally produced the dream we read of; but others think that this dream was sent to her providentially, for the clearer manifestation of our Lord's innocence.

Pilatre de Rozier.

PILATRE DE ROZIER, FRANCIS, was born at Metz on the 30th of March 1756. He was first apprentice to an apothecary there, and afterwards went to Paris in quest of further improvement. He applied himself to the study of natural history and physics, and had already acquired some reputation, when the discovery of Montgolfier astonished the learned world. On the 25th of October 1783, he attempted an aerial voyage, accompanied by the Marquis of Arlande. He performed several other excursions in this way with brilliant success, in the presence of the royal family of France, of the king of Sweden, and of Prince Henry of Prussia. He then resolved to pass into England by means of his aerial vehicle, and for that purpose he repaired to

---

[1] Josephus, *Antiq. Jud.* lib. xviii. c. 5.

Boulogne, whence he rose about seven o'clock in the morning on the 15th of June 1785; but in half an hour after he set out, the balloon took fire, and the aeronaut, with his companion M. Romaine, were crushed to death by the fall of the machine. See Aeronautics.

PILCHARD. See Ichthyology.

PILE, in *Heraldry*, an ordinary in the form of a wedge, contracting from the chief, and terminating in a point towards the bottom of the shield.

Pile, amongst the Greeks and Romans, was a pyramid built of wood, upon which were laid the bodies of the deceased, to be burned. It was partly in the form of an altar, and differed in height according to the quality of the person to be consumed. Probably it might originally have been considered as an altar, upon which the dead were consumed as a burnt-offering to the infernal deities. The trees made use of in the erection of a funeral pile were such as abounded in pitch or rosin, and consequently were most combustible; if they used any other wood, it was split that it might the more easily catch fire. Round the pile were placed cypress boughs, to prevent the noisome smell.

Pile, in building, means a large stake rammed into the ground in the bottom of rivers, or in marshy land, for a foundation to build upon.

Pile is also a term amongst architects, signifying a mass of building.

Pile-Engine, a machine for driving the piles upon which the piers of bridges are founded. See Mechanics.

PILEUS, in Roman antiquity, was the ordinary cap or hat worn by the freedmen at public shows and sacrifices. It was one of the common rewards assigned to such gladiators as were slaves, in token of their obtaining freedom.

PILGRIM, one who travels through foreign countries to visit holy places, and to pay his devotion to the relics of saints. The word is formed from the Flemish *pelgrim*, or the Italian *pelegrino*, which signifies the same; and these were originally formed from the Latin *peregrinus*, a stranger or traveller.

PILGRIMAGE, a kind of religious discipline, which consists in taking a journey to some holy place in order to pray before the relics of some saint. Pilgrimages began to be made about the middle ages of the church; but they were most in vogue after the end of the eleventh century, when every one was smitten with a desire of visiting places of devotion, not excepting kings and princes themselves; and even bishops made no difficulty of being absent from their churches on the same account.[1]

Dr Johnson, in his *Rasselas*, gives us some observations on pilgrimage, which are so much to the purpose that we think we cannot do better than lay them before our readers. "Pilgrimage, like many other acts of piety, may be reasonable or superstitious according to the principles upon which it is performed. Long journeys in search of truth are not commanded. Truth, such as is necessary to the regulation of life, is always found where it is honestly sought: change of place is no natural cause of the increase of piety, for it inevitably produces dissipation of mind. Yet since men go every day to view the fields where great actions have been performed, and return with stronger impressions of the event, curiosity of the same kind may naturally dispose us to view that country where our religion had its beginning; and I believe no man surveys those awful scenes without some confirmation of holy resolutions. That the Supreme Being may be more easily propitiated in one place than in another, is the dream of idle superstition; but that some places may operate upon our own minds in an uncommon manner, is an opinion which hourly experience will justify. He who supposes that his vices may be more successfully combated in Palestine, will perhaps find himself mistaken; yet he may go thither without folly: he who thinks they will be more freely pardoned, dishonours at once his reason and religion."

PILKALLEN, a town of the province of East Prussia, and the capital of a circle of the same name, which extends over 410 square miles, and, in two cities and seven parishes, contains 22,100 inhabitants. The town is situated on a small river, and has 120 houses, with 1490 inhabitants. Long. 22. 54. 57. E. Lat. 54. 45. 19. N.

PILKINGTON, Lætitia, a sprightly and once noted writer, was the daughter of Dr Van Lewin, a physician of Dublin, where she was born in the year 1712. She was married when very young to the Rev. Matthew Pilkington, a poet of no inconsiderable merit; and the two wits, as is often the case, lived very unhappily together, and were at length totally separated. The story is told at large in her Memoirs. After this separation, Mrs Pilkington came to London, and lived for some time on the productions of her pen. She was, however, thrown into the Marshalsea for debt; and being set at liberty, opened a pamphlet shop. She at length raised a handsome subscription for her Memoirs, which are written with great sprightliness and wit; containing several anecdotes of Dean Swift, with whom she was intimate, as well as many pretty little pieces of her own poetry. This ingenious person died at Dublin in 1750.

Pilkington, a township in the parish of Prestwick, of the hundred of Salford, in Lancashire, 180 miles from London and four from Manchester. It is chiefly inhabited by cotton manufacturers. The population amounted in 1801 to 5786, in 1811 to 7353, in 1821 to 8976, and in 1831 to 11,006.

PILLAR, Cape, a high cape on the south-east coast of Van Diemen's Land, on the north-eastern shore of Storm Bay. Long. 148. 8. E. Lat. 43. 12. S.

PILLARS, in antiquarian topography, are large single stones set up perpendicularly. Those of them which are found in this country were the work of the Druids; but as they are the most simple of all monuments, they are unquestionably more ancient than even Druidism itself. They were placed as memorials recording different events; as remarkable instances of God's mercies, of contracts, singular victories, boundaries, and sometimes sepulchres. Various instances of these monuments erected by the patriarchs occur in the Old Testament. Such was that raised by Jacob at Luz, afterwards by him named *Bethel;* and such also was the pillar placed by him over the grave of Rachel. They were likewise marks of execrations and magical talismans. These stones, from having long been considered as objects of veneration, were at length idolatrously worshipped by the ignorant and superstitious; wherefore, after the introduction of Christianity, some had crosses cut upon them, which was considered as taking them out of the category of works devoted to the service of the devil. Vulgar superstition of a later date has led the common people to regard them as persons transformed into stone for the punishment of some crime, generally that of sabbath-breaking. This notion, however, is not confined to single stones, but is also told of whole circles; as the monuments called the *hurlers* in Cornwall, and *Rolloric stones* in Warwickshire. The former are by the vulgar supposed to have once been men, who were thus transformed as a punishment for playing on the Lord's day at a game called *hurling;* the latter are believed to consist of a pagan king and his army.

---

[1] It deserves to be remarked here, that in the year 1428, under the reign of Henry VI. abundance of licenses were granted by the crown of England to captains of English ships, for carrying numbers of devout persons to the shrine of St James of Compostella, in Spain; provided, however, that those pilgrims should first take an oath not to carry with them any thing prejudicial to England, nor to reveal any of its secrets, nor to take out with them any more gold or silver than what should be sufficient for their reasonable expenses. In this year there went out from England, on the same pilgrimage, from London 280, Bristol 200, Weymouth 122, Dartmouth 90, Yarmouth 60, Jersey 60, Plymouth 40, Exeter 30, Poole 24, Ipswich 20; in all 926 persons.

PILLAU, a city of the province of East Prussia, in the circle of Fischausen. It stands on a tongue of land on the bank of a strait by which the Frisch Haff is connected with the Baltic Sea. It is regularly fortified, and defended by a fortress. The harbour is secure, and admits ships of 200 tons burden, and about 1000 vessels yearly enter and depart. It contains about 200 very large and anciently-fashioned houses, with 3600 inhabitants. It has considerable trade in ship-building, in the fishery, in distilleries and breweries, in corn, and in timber. Long. 19. 48. 21. E. Lat. 54. 38. 18. N.

PILLERE, a small town of Hindustan, in the district of Gurrumcundah, ninety-five miles west-north-west from Madras. Long. 79. 5. E. Lat. 13. 32. N.

PILLIBEET, a town of Hindustan, in the province of Delhi, and district of Bareily. It was a great emporium of commerce in the time of Hafiz Rehmut. After the Rohilla country was laid waste by the nabob of Oude, its commerce was annihilated; but since its cession to the British it has greatly revived.

PILLORY (*collistrigium,* that is, *collum stringens; pilloria,* from the French *pilleur,* meaning *depeculator;* or *pelori,* derived from the Greek πυλη, *janua,* a door, because one standing on the pillory puts his head as it were through a door, and ὁραω, *video*) is an engine made of wood, to punish offenders, by exposing them to public view, and rendering them infamous.

PILOT, an officer who superintends the navigation of a ship, squadron, or fleet, either upon the sea-coast or upon the main ocean. It is, however, more particularly applied by our mariners to the person charged with the direction of a ship's course on or near the sea-coast, and into the roads, bays, rivers, havens, and creeks, within his respective district.

PILSEN, a city of the Austrian kingdom of Bohemia, the capital of a circle of the same name, which extends over 1474 square miles, comprehending fifteen cities, fourteen towns, 669 villages, and 28,500 houses. The city stands at the junction of the rivers Bradawta and Beraunta, and contains 546 houses, and about 8000 inhabitants, who conduct some cloth manufactories, and considerable internal trade in hardware made from mines of iron in its neighbourhood. Near to them are also extensive alum works, both belonging to the city. The place is one of historical celebrity, from having been the scene of the insurrection of Wallenstein against the imperial government in the Thirty Years' War. Long. 13. 18. 45. E. Lat. 49. 44. 38. N.

PILUM, a missive weapon used by the Roman soldiers, and in a charge hurled against the enemy. Its point, we are told by Polybius, was so long and small, that after the first discharge it was generally so bent as to be rendered useless. The legionary soldiers made use of the *pilum,* and each man carried two. The *pilum* underwent many alterations and improvements, insomuch that it is impossible to describe it with any precision. Julius Scaliger laboured much to give an accurate account of it, and would have esteemed success on this head amongst the greatest blessings of his life. Marius made a material improvement on the *pilum;* for during the Cimbrian war, he so contrived it, that when it stuck in the enemy's shield it bent down at an angle in the part where the wood was connected with the iron, and thus became useless to the person who received it.

PILWARA, a town of Hindustan, in the province of Ajmere, and district of Oudipore, belonging to the ranah. Long. 74. 25. E. Lat. 25. 19. N.

PIMENTO, JAMAICA PEPPER, or *Allspice,* a species of *myrtus.* The pimento trees grow spontaneously, and in great abundance, in many parts of Jamaica, but more particularly on hilly situations near the sea, on the northern side of that island, where they form the most delicious groves that can possibly be imagined.

"This tree is purely a child of nature, and seems to mock all the labours of man in his endeavours to extend or improve its growth; not one attempt in fifty to propagate the young plants, or to raise them from the seeds, in parts of the country where it is not found growing spontaneously, having succeeded. The usual method of forming a new pimento plantation (in Jamaica it is called a *walk*), is nothing more than to appropriate a piece of woodland, in the neighbourhood of a plantation already existing, or in a country where the scattered trees are found in a native state, the woods of which being fallen, the trees are suffered to remain on the ground till they become rotten and perish. In the course of twelve months after the first season, abundance of young pimento plants will be found growing vigorously in all parts of the land, being without doubt produced from ripe berries scattered there by the birds, whilst the fallen trees, &c. afford them both shelter and shade. At the end of two years it will be proper to give the land a thorough cleansing, leaving such only of the pimento trees as have a good appearance, which will then soon form such groves as those already described, and, except perhaps for the first four or five years, require very little attention afterwards.

"Soon after the trees are in blossom, the berries become fit for gathering; the fruit not being suffered to ripen on the tree, as the pulp in that state, being moist and glutinous, is difficult to cure, and when dry becomes black and tasteless. It is impossible, however, to prevent some of the ripe berries from mixing with the rest; but if the proportion of them be great, the price of the commodity is considerably injured.

"It is gathered by the hand; one labourer on the tree, employed in gathering the small branches, will give employment to three below, who are generally women and children, in picking the berries; and an industrious picker will fill a bag of 70 lbs. in the day.

"The returns from a pimento walk in a favourable season are prodigious. A single tree has been known to yield 150 lbs. of the raw fruit, or one hundredweight of the dried spice, there being commonly a loss in weight of one third in curing; but this, like many other of the minor productions, is exceedingly uncertain, and perhaps a very plentiful crop occurs but once in five years."

PIN, in commerce, a little necessary instrument made of brass-wire, and chiefly used by women in fastening and adjusting their dress. In the year 1543, by statute 34 and 35 of Henry VIII. c. 6, it was enacted, "That no person shall put to sale any pinnes but only such as shall be double headed, and have the heads soldered fast to the shank of the pins, well smoothed, the shank well shapen, the points well and round filed, cauted, and sharpened." From the above extract it should appear that the art of pin-making was then but of recent invention, being probably introduced from France; and consequently our manufactories must since that period have wonderfully improved.

Though pins are apparently simple, their manufacture is, however, not a little curious and complex. When the brass wire of which the pins are formed is first received at the manufactory, it is generally too thick for the purpose of being cut into pins. The first operation, therefore, is that of winding it off from one wheel to another with great velocity, and causing it to pass between the two, through a circle in a piece of iron of smaller diameter. The wire being thus reduced to its proper dimensions, is straightened by drawing it between iron pins fixed on a board in a zigzag manner, but so as to leave a straight line between them. Afterwards it is cut into lengths of three or four yards, and then into smaller ones, every length being sufficient to make six pins; and each end of these is then ground to a point. When the wire is thus pointed, a pin is taken off from each end, and this is repeated until it has been cut into six pieces. The next operation is that of forming the heads, or, as they term it, *head spinning;* which is done by means of a spinning-wheel, one piece of wire being thus with astonishing rapidity wound round another, and the interior one being drawn out, leaving a hollow tube between the circumvolutions. It is then cut with shears, every two circumvolutions or turns of the wire forming one head; and these are softened by throwing them into iron pans, and placing them in a furnace until they are red hot. As soon as they are cold, they are distributed to children, who sit with anvils and hammers before them, which they work with their feet by means of a lathe, and taking up one of the lengths, they thrust the blunt end into a quantity of the heads which lie before them, and catching one at the extremity, they apply them immediately to the anvil and hammer, and by a motion or two of the foot the point and the head are fixed together in much less time than it can be described, and with a dexterity only to be acquired by practice; the spectator being in continual apprehension for the safety of their finger-ends. The pin is now finished as to its form, but still it is merely brass. It is therefore thrown into a copper containing a solution of tin and the lees of wine. Here it remains for some time, and when taken out assumes a white though dull appearance. In order, therefore, to give it a polish, it is put into a tub containing a quantity of bran, which is set in motion by turning a shaft that runs through its centre, and thus by means of friction it becomes perfectly bright. The pin being complete, nothing remains but to separate it from the bran, which is performed by a mode exactly similar to the winnowing of corn; the bran flying off and leaving the pin behind fit for immediate sale.

PINACIA, amongst the Athenians, were tablets of brass inscribed with the names of all those citizens in each tribe who were duly qualified and willing to become judges of the court of Areopagus. These tablets were cast into a vessel provided for the purpose, and the same number of beans, a hundred being white and all the rest black, were thrown into another. Then the names of the candidates and the beans were drawn out one by one, and they whose names were drawn out together with the white beans were elected judges or senators. In Solon's time there were only four tribes, each of which chose a hundred senators; but the number of tribes being afterwards increased, that of senators and judges was also increased to so many hundreds more.

PINAGRA, a town and fortress of the south of India, in the district of Baramahal, ninety-five miles east by south from Seringapatam. Long. 78. 8. E. Lat. 12. 6. N.

PINCHBECK, a factitious metallic substance, or an alloy of three parts of zinc and four of copper.

PINDAR, the most celebrated lyric poet that Greece produced, was a native of Thebes in Bœotia, and born B. C. 518, forty years before the expedition of Xerxes. He was the contemporary of Æschylus, but younger than Simonides, and somewhat older than Bacchylides. It was scarcely to be expected that the early years of such a distinguished poet should pass without some extraordinary event taking place, and it is accordingly stated that he was exposed on a desert mountain, and that he was fed by bees. Whether his father's name was Diophantus or Scopelinus is uncertain, but he was of the humble profession of a player on the flute, which he at first intended that his son should pursue. Finding, however, that his talents entitled him to occupy a higher position in the drama of life, he placed him under Lasus of Hermione, a poet who then enjoyed a high reputation. Although he lived in one of the most eventful periods of Grecian history, it does not appear that he took any active part in the political struggles of his country. It has been even doubted whether his feelings in favour of the liberty of Greece were so ardent as to induce him to oppose the progress of the Persians. Before the battle of Platæa a seditious movement had taken place in Thebes, and a strong party had joined the Persians. In a passage of the poet written at this period, Polybius imagines he can satisfactorily discover that Pindar was the advocate of this step, and of course visits him with not unmerited reproach. Stobæus, however, gives this same passage more fully, and it there appears that the poet recommends peace, not in reference to the Persians, but to his fellow-citizens, who were tearing one another to pieces in civil broils. But a still stronger proof that Polybius had taken a prejudiced view of his character, is found in the circumstance that the poet wrote a dithyrambic poem after the battle of Platæa, in which he spoke so warmly in admiration of Athens, that the prevailing party amongst his countrymen took umbrage at it, and visited him with punishment. The Athenians, on the other hand, erected a statue to his honour. Again we find him comparing the victories of Hiero at Cumæ and Himera to the most illustrious engagements of the Greeks against the Persians. It is impossible, therefore, to doubt that he joined heartily in support of Greek independence, though he does not seem to have thought that a monarchical government, justly and mildly administered, was unworthy of respect. Of his private history nothing farther is known, except that he died at an advanced age, probably about the year B. C. 439. According to one tradition, he died whilst he was resting on the bosom of his young disciple Theoxenus, after he had taken part in the active exercises of the gymnasium. He was the writer of many poems, but they have all perished except some fragments, and those hymns which he composed in honour of the conquerors at the solemn games of Greece. They are divided into four books, of which the first contains those who had conquered at the Olympic games, and consists of fourteen odes; the second, addressed to the conquerors of the Pythian games, contains twelve odes; the third, addressed to the Nemean conquerors, contains eleven odes; and the fourth, celebrating the Isthmian conquerors, contains eight odes. It is difficult to believe that the reputation of Pindar was founded upon the poetry which has come down to us, and indeed his dithyrambic hymns are spoken of as his finest productions. He is no doubt distinguished by a warm and enthusiastic genius, and by bold and figurative expressions; but the abruptness of his transitions, and the numerous allusions to persons and things now altogether unknown, and which, if known, would not interest the reader, very much diminish the pleasure with which his poetry is read. Still the opinion of Horace must for ever place him in the foremost rank of lyric poets.

> Fiery, immense, profound he flowes
> As from a mountaine tumbling goes
> A torrent fed with showers, flyes o'er
> The well-knowne limits of the shore.
> Apollo's bayes are due to him,
> Whether new words swolne to the brim,
> He (bold) through dithyrambics throw,
> Where every new word doth loosely flow;
> Whether gods, kings, or gods' allies
> He chant, who by a just surprise,
> The Centaurs vanquish'd, and supprest
> Chimæra's dreadful flaming crest.
>
> *Hawkins' Translation,* 1625.

The oldest edition of this poet is that of Aldus, Venice, 1513, in 8vo. The best editions are those by Erasmus Schmid, Wittenburg, 1616, in 4to; by Heyne, Göttingen, 1773; by Aug. Böckh, Leipzig, 1811–1822, particularly valuable for criticism and metre; by Thiersch, with a German translation, Leipzig, 1820, in 8vo; Pindari Carmina commentario perpetuo illustravit L. Dissen, Goth., 1830, in 8vo; Schneider de Vitâ et Scriptis Pindari, Strasburg, 1774, in 8vo.

PINDAR RIVER, a small river of Northern Hindustan, in the province of Serinagur, which afterwards joins the Alcananda.

PINDTARUK, a small village of Hindustan, in the Gujerat peninsula, situated in a sandy plain. There is a spring of pink-coloured water in the vicinity, which is celebrated amongst the natives as a place of pilgrimage.

PINEDA, JOHN, an historian of some note, was descended of a noble family, and born at Seville. He entered into the society of the Jesuits in 1572, and taught philosophy and divinity in several colleges, but devoted his time chiefly to the study of the Holy Scriptures. That he might render this study the more easy, he made himself master of the oriental languages. Of his writings we have, 1. Commentaries upon the book of Job, two vols. in folio; 2. Commentaries upon Ecclesiastes; 3. A general History of the Church, in Spanish, four vols. in folio; and, 4. A History of Ferdinand III. in the same language, in folio. He died in 1637, much regretted by the members of his society, and by the public in general.

PINEROLO, one of the provinces into which the continental part of the kingdom of Sardinia, in Italy, is divided. It is bounded on the north and north-west by Susa, on the east by Turin, on the south by Saluzzo, and on the west by France. It extends over 550 square miles, and contains one city, forty-six towns and villages, with 125,000 inhabitants. A portion of the Cottian Alps is comprehended in this province, in which are found the four valleys of Lucerna, Perosa, San Martino, and Pragelato, which were inhabited by the Waldenses. The district is well watered by several streams, the principal of which, the Clusone, receives the other river. Though for the most part mountainous, the valleys are productive, and there is sufficient corn raised for the consumption of the inhabitants, whilst silk, chestnuts, and turpentine serve the purpose of exchange for the few foreign commodities that are needed. The capital of the province is the city of the same name. It is situated at the foot of the Alps, and is the see of a bishop, whose sumptuous cathedral, with six monasteries and five nunneries, are the most distinguished objects. It contains 11,500 inhabitants, who spin wool and silk, manufacture goods of both materials, and trade also in corn, wine, cattle, and charcoal. It was formerly the residence of the Dukes of Savoy, most of whom were buried in it. Long. 7. 8. E. Lat. 44. 53. N.

PINES, ISLAND OF, in the South Pacific Ocean, near the southern point of New Caledonia. It is about eighteen leagues in circumference. Long. 167. 32. E. Lat. 22. 38. S.

PINET, ANTONY DU, an ecclesiastical writer, who lived in the sixteenth century, and was a native of Besançon, in France. He was strongly attached to the Protestant religion, and a bitter enemy to the church of Rome. His book, entitled La Conformité des Eglises Reformées de France et de l'Eglise Primitive, printed at Lyons, 1564, in 8vo, and the notes which he added to the French translation of the Fees of the Pope's Chancery, which was printed at Lyons in 8vo, 1564, and reprinted at Amsterdam in 1700, in 12mo, plainly discover his sentiments. The last-mentioned work he published under the title of La Boutique du Pape, in Latin and French, with some notes taken from decrees, councils, and canons, in order to ascertain the discipline anciently observed in the church. In the epistle dedicatory he assumes the tone of a declared enemy of the court of Rome. His translation of Pliny's Natural History, printed at Lyons in two vols. folio, 1566, and at Paris, 1608, was formerly much read. Though it contains many errors, it is nevertheless very useful, especially for those who do not understand the Latin, on account of the translator's researches, and a great number of marginal notes. Pinet also published at Lyons, 1564, in folio, Plans of the principal Fortresses in the World.

PING-LIANG, a city of China, of the first rank, in Shensee, in a fruitful and well-watered district. Long. 106. 18. E. Lat. 35. 35. N.

PINGLO, a city of China, of the first rank, in the province of Quangsee, situated amongst mountains, and on a river which is scarcely navigable from the number of waterfalls which interrupt its course. Long. 110. 4. E. Lat. 24. 22. N.

PINION, in *Mechanics*, an arbor or spindle, having in the body of it several notches, which catch the teeth of a wheel that serves to turn it round; or it is a lesser wheel that plays in the teeth of a larger.

PINNACE, a small vessel navigated with oars and sails, and having generally two masts, which are rigged like those of a schooner.

PINNACLE, in *Architecture*, the top or roof of a house, terminating in a point. This kind of roof amongst the ancients was appropriated to temples; their ordinary roofs being all flat, or made in the platform fashion.

PINOS, an island of the Atlantic, situated near the south coast of Cuba, from which it is separated by a channel sixteen leagues in length by six in breadth. It abounds in pastures, which are covered with herds of goats and other animals; and it is likewise noted for the size of its trees. Although Pinos possesses several very secure and well-sheltered roads, and is of tolerable size, being forty-two miles in length and thirty-four in breadth, yet it is only inhabited by a few fishermen. Long. 82. 45. W. Lat. 21. 38. N.

PINSK, a city of Russia, in the government of Minsk, the capital of a circle of its own name. It is situated on the river Pina, surrounded with deep morasses, and is built in the style of all the old Polish towns. It contains several Greek and Catholic churches, and had a very large collegiate establishment of the Jesuits. It contains 4500 inhabitants, of whom many are Jews, and carries on a considerable trade in the finest red leather. It is 767 miles from St Petersburg. Long. 25. 45. E. Lat. 52. 8. N.

PINTOR, PETER, a physician, was born at Valentia in Spain, in the year 1420, and became physician to Alexander VI. whom he followed to Rome, where he practised with great success. He left behind him two works of considerable merit; 1. Aggregator Sententiarum Doctorum de Curatione in Pestilentia, printed at Rome in 1499, folio; and, 2. De Morbo Fœdo et Occulto his Temporibus Affligenti, printed at Rome in 1500, 4to, black letter, a book extremely scarce, and which traces the *lues venerea* to the year 1496. Pintor died at Rome in the year 1503, aged eighty-three.

PINUS, the PINE-TREE, was one well known to the ancients, and has been described and celebrated both by their philosophers and their poets. Pliny enumerates no less than six species of trees of this genus; and it is mentioned by Virgil in his Eclogues, his Georgics, and his Æneid; by Horace in his Odes, by Ovid in his Metamorphoses, by Statius, and by Catullus.

There are generally reckoned fourteen species of this genus, of which the most remarkable are the following:—

1. The *pinea*, *pineaster*, or wild pine, which grows naturally on the mountains in Italy and the south of France. It grows to the size of a large tree; the branches extend to a considerable distance; and whilst the trees are young, they are fully garnished with leaves, especially where they are not so close as to exclude the air from those within; but as they advance in age, the branches appear naked, and

all those which are situated below become unsightly in a few years; for which reason they are now much less esteemed than formerly.

2. The *pinus pinea*, or stone pine, is a tall evergreen tree, a native of Italy and Spain. It delights in a sandy loam, although, like most others, it will grow well in almost any land. Respecting the uses of this species, Hanbury tells us that the kernels are eatable, and by many prefer-red to almonds.

3. The *rubra*, commonly called the *Scotch fir* or *pine*, is common throughout Scotland, whence its name; though it is also found in most of the other countries of Europe. M. Duhamel mentions his having received some seeds of it from St Domingo in the West Indies; and thence concludes, that it grows indifferently in the temperate, frigid, and torrid zones. The wood of this tree is the red or yellow deal, which is the most durable of any of the kinds yet known

4. The *pinus picea*, or yew-leaved fir, is a tall evergreen, and a native of Scotland, Sweden, and Germany. This species includes the silver fir and the balm of Gilead fir. The first of these is a noble upright tree. The balm of Gilead fir has of all the sorts been most coveted, on account of the great fragrance of its leaves; though this is not its only good property; for it is a very beautiful tree, naturally of an upright growth, and the branches are so ornamented with their balmy leaves, as to exceed any of the other sorts in beauty. The silver fir is very hardy, and will grow in any soil or situation; but it always makes the greatest progress in rich loamy earth. The balm of Gilead fir must be planted in deep, rich, good earth; nor will it live long in any other. The soil may be a black mould, or of a sandy nature, if it be deep enough, and if the roots have room enough to strike freely.

5. The *pinus abies*, or European spruce fir, a native of the northern parts of Europe and of Asia, includes the Norway spruce and long-coned Cornish fir. The former of these is a tree of as much beauty whilst growing, as its timber is valuable when propagated on that account.

6. The *pinus Canadensis*, or American and Newfoundland spruce fir, a native of Canada, Pennsylvania, and other parts of North America, includes three varieties; the white Newfoundland spruce, the red Newfoundland spruce, and the black Newfoundland spruce. These, however, differ so little, that one description may serve for them all. They are of an upright growth, though they do not shoot so freely or grow so fast with us as the Norway spruce. The leaves are of the same green, and garnish the branches in the same beautiful manner, as those of that species; only they are narrower, shorter, and stand closer. The greatest difference is observable in the cones; for these are no more than about an inch in length, and the scales are closely placed. In the cones, indeed, consists the difference of these three sorts; those of the white species are of a very light brown colour, those of the red species more of a nut-brown or reddish colour, and those of the black species of a dark or blackish colour.

7. The *pinus balsamea*, or hemlock fir, a native of Virginia and Canada, possesses as little beauty as any of the fir tribe; though, being rather scarce in proportion, it is deemed valuable. It is called by some the *yew-leaved fir*, from the resemblance of the leaves to those of the yew-tree. It is a tree of low growth, with but few branches; and these are long and slender, spreading abroad without order.

8. The *pinus orientalis*, or oriental fir, a native of the East, is a low but elegant tree. The leaves are very short, and nearly square. The fruit is exceedingly small, and hangs downward; and the whole tree makes an agreeable variety with the other kinds.

9. The *strobus*, or North American white pine. This grows sometimes to the height of a hundred feet and upwards, and is highly valued on account of its beauty. The bark of the tree is very smooth and delicate, especially when young; the leaves are long and slender, five growing out of one sheath; and the branches are pretty closely garnished with them, thus making a fine appearance.

10. The *pinus tæda*, or swamp-pine, is a tall evergreen tree, being a native of the swamps of Virginia and Canada. There are several varieties of this genus.

11. The *pinus cedrus*, ranked by Tournefort and others under *larix*, and famous for its duration, is that popularly called by us the *cedar of Lebanon*, by the ancients *cedrus magna* or the *great cedar;* also *cedrelate*, κεδρελατη; and sometimes the Phœnician or Syrian cedar, from the country where it grows in its greatest perfection. It is a coniferous evergreen, of the larger sort, bearing roundish cones of smooth scales, standing erect, the leaves being small, narrow, and thickly set. They sometimes counterfeit cedar by dyeing wood of a reddish hue; but the smell discovers the cheat, that of true cedar being very aromatic. In some places the wood of the cajou tree passes under the name of cedar, on account of its reddish colour and its aromatic smell, which somewhat resemble those of sandal. Cedar-wood is reputed almost immortal and incorruptible; a prerogative which it owes chiefly to its bitter taste, which the worms cannot endure. For this reason it was that the ancients used cedar tablets to write upon, especially for things of importance, as appears from the expression of Persius, *Et cedra digna locutus.* A juice alluded to by Horace was also drawn from cedar, with which the ancients smeared their books and writings, or other matters, to preserve them from rotting; and by means of which it was that Numa's books, written on papyrus, were preserved entire to the year 535, as we are informed by Pliny.

Solomon's temple, as well as his palace, were both constructed with this wood. That prince gave Hiram, king of Tyre, several cities for the cedars he had furnished on these occasions. Cortes is said to have erected a palace at Mexico, in which were 7000 beams of cedar, most of them 120 feet in length and twelve feet in circumference, as we are informed by Herrera. Some tell us of a cedar felled in Cyprus 130 feet in length and eighteen in diameter. It was used for the mainmast in the galley of King Demetrius. Le Bruyn assures us, that the two largest he saw upon Mount Lebanon measured, one of them fifty-seven palms, and the other forty-seven, in circumference. In the temple of Apollo at Utica there were cedar-trees near two thousand years old; which yet were nothing to the beam in an oratory of Diana at Saguntum in Spain, said to have been brought thither two hundred years before the destruction of Troy. Cedar is of so dry a nature that it will not endure to be fastened with iron nails, from which it usually shrinks; so that they commonly fasten it with pins of the same wood.

It is remarkable that, as far as has yet been discovered, this tree is not to be found as a native in any other part of the world than Mount Libanus. What we find mentioned in Scripture of the lofty cedars can be nowise applicable to the common growth of this tree; since, from the experience we have of those now growing in England, as also from the testimony of several travellers who have visited the few trees remaining on Mount Libanus, they are not inclined to grow very lofty, but, on the contrary, extend their branches very far; a circumstance with which the allusion made by the Psalmist agrees very well, when, describing the flourishing state of the people, he says, "They shall spread their branches like the cedar-tree."

12. There is another species, namely, the *larch-tree*, which the old botanists ranked under *larix*, with deciduous leaves and oval obtuse cones. It grows naturally upon the Alps and Apennines, and of late has been very much propagated in Britain. See PLANTATION.

PIOMBINO, an ancient principality in Italy, now one of the provinces of the grand duchy of Tuscany. It is 136 square miles in extent, and contains one city and eleven villages, with 13,900 inhabitants. The princely house, though mediatized, continues to hold the proprietorship, as before 1815. It is a marshy and very unhealthy tract of country. The capital is the city of the same name, situated on the Bay of Fullonica. It is slightly fortified towards the sea only, and contains 1200 inhabitants, mostly occupied in the fisheries. Long. 10. 25. 42. E. Lat. 42. 55. 27. N.

PIONEERS, in the art of war, are persons who are ordered in from the country, to march with an army, for the purpose of mending the roads, working on intrenchments and fortifications, and forming mines and approaches.

PIOVE di Sacco, a town of Austrian Italy, in the province of Milan and delegation of Padua. It is situated on the Canal of Fiumecello, and contains 790 houses, and 5640 inhabitants, engaged in making silk goods and tanning leather. Long. 11. 57. 11. E. Lat. 45. 17. 21. N.

PIP, or Pep, a disease amongst poultry, consisting of a white thin skin or film, which grows under the tip of the tongue, and hinders their feeding. It usually arises from want of water, or from drinking puddle-water, and eating filthy meat. It is cured by pulling off the film with the fingers, and rubbing the tongue with salt. Hawks are particularly liable to this disease, from their feeding on stinking flesh.

PIPE, a musical instrument, various in kind. (See the articles Music and Organ.) Without entering into useless details regarding the ancient ἄυλοι and *tibiæ*, we may mention that Strutt, in his Sports and Pastimes of the People of England, gives representations of the pipe and tabor, as used in England in the fourteenth century to accompany a dancing dog, a cock on stilts, a horse rearing, &c. From the drawings we cannot ascertain the nature of the pipe represented. We may, however, suppose it to have been similar to the *galoubet* used in France, along with the tabor, from a very remote period. This *galoubet* is a small instrument of the flageolet kind. Its use, for more than the last two centuries, has been confined to Provence. It has only three finger-holes, and is played with the left hand, whilst the right beats the tabor, which is attached to the performer. The compass of the *galoubet* is two octaves and a tone from D on the third line of the treble clef up to E in *altissimo*. Great skill is required to bring out all the sounds of its compass. Some of the players on this small and imperfect instrument are said to be so dexterous as to be able to perform upon it very difficult pieces of music composed for other instruments, such as the violin, &c. It is always accompanied by the tabor, which is a small drum of a cylindrical form, and rather longer and narrower in its relative proportions than the common drum.

Pipe, in building and other employments or arts, a canal, or conduit, for the conveyance of water and other liquids. Pipes for water, water-engines, and the like, are usually of lead, iron, earth, or wood; the latter being usually made of oak or elder. Those of iron are cast in forges, and their usual length is about two feet and a half; several of these being commonly fastened together by means of four screws at each end, with leather or old hat between them to stop the water. Those of earth are made by the potters, and are fitted into one another, one end being always made wider than the other. To join them the closer, and prevent their breaking, they are covered with tow and pitch; their length being usually about that of the iron pipes. The wooden pipes are trees bored with large iron augres, of different sizes, beginning with a less, and then proceeding with a larger successively; the first being pointed, the rest being formed like spoons, increasing in diameter from one to six inches and more. See Boring.

Pipe, *Pipa*, in *Law*, is a roll in the exchequer, called also the *great roll.*

Pipe-Office is an office in which a person, called the *clerk of the pipe*, makes out leases of crown-lands, by warrant from the lord-treasurer, or commissioners of the treasury, or the chancellor of the exchequer. The clerk of the pipe also makes out all accounts of sheriffs, &c. and gives the accountants their *quietus est.*

Piper, *Pepper*, a genus of plants belonging to the *diandria* class. There are twenty species of *piper*, of which the most remarkable is the *siriboa*, with oval, heart-shaped, nerved leaves, and reflexed spikes. This is the plant which produces the pepper so much used in food. It is a shrub, the root of which is small, fibrous, and flexible; and it rises into a stem, which requires a tree or prop to support it. Its wood has the same sort of knots as the vine; and when it is dry, it exactly resembles the vine-branch. The leaves, which have a strong smell and a pungent taste, are of an oval shape; but they diminish towards the extremity, and terminate in a point. From the flower-buds, which are white, and are sometimes placed in the middle and sometimes at the extremity of the branches, are produced small berries resembling those of the currant-tree. Each of these contains between twenty and thirty corns of pepper. They are commonly gathered in October, and exposed to the sun seven or eight days. The fruit, which was green at first, and afterwards red, when stripped of its covering assumes the appearance it has when we see it. The largest, heaviest, and least shrivelled, is the best.

The pepper plant flourishes in the islands of Java, Sumatra, and Ceylon, and more particularly on the Malabar coast. It is not sown, but planted; and great nicety is required in the choice of the shoots. It produces no fruit until the end of three years; but bears so plentifully the three succeeding years, that some plants yield between six and seven pounds of pepper. The bark then begins to shrink; and the shrub declines so fast that in twelve years' time it ceases bearing.

The culture of pepper is not difficult. It is sufficient to plant it in a rich soil, and carefully to pull up the weeds that grow in great abundance round its roots, especially the first three years. As the sun is highly necessary to the growth of the pepper plant, when it is ready to bear, the trees that support it must be lopped, to prevent their shade from injuring the fruit. When the season is over, it is proper to crop the head of the plant. Without this precaution there would be too much wood, and little fruit.

The *piper amalago*, or black pepper, and the *piper inequale*, or long pepper of Jamaica, with some other species, are indigenous, and known by the names of *joint-wood*, or *peppery elders*. The first bears a small spike, on which are attached a number of small seeds of the size of mustard. The whole of the plant has the exact taste of the East India black pepper. The long-pepper bush grows taller than the amalago. The leaves are broad, smooth, and shining; and the fruit is similar to the long pepper of the shops, but smaller. The common people in Jamaica season their messes with the black pepper. To preserve both, the fruit may be slightly scalded when green, then dried, and wrapped in paper.

PIPERS, a musical term, now applied to performers on the bagpipe. Thus we have Northumbrian pipers, Irish pipers, Calabrian pipers, Scottish pipers, &c. The bagpipe seems to be one of the most ancient of musical instruments. It had various names in ancient times and in different countries. Boccacio introduces it as a fashionable instrument in his Decameron; and, from the accounts of the household expenses of our British monarchs, we find that the bagpiper was a court-musician in the olden time. In Strutt's Sports and Pastimes of the People of England, we find a bagpipe player on stilts, from an illuminated manuscript of the thirteenth century, in the reign of Henry III.; and another bagpiper of the same century, with a girl dancing upon his shoulders. Some of the most curious representations of bagpipers and their instruments (*chori* or *cori*) are given by Gerbert *De Cantu et Musica Sacra*, plates thirty-three and thirty-four of the second volume.

PIPLEY, a small town of Hindustan, in the province of Orissa and district of Mohurbunge. It is situated on the eastern bank of the Subanreeka River, about ten miles from the sea. It was with this port, which was considered one of the best in Bengal, that the English were permitted to trade by Shah Jehan; but the trade was afterwards transferred to the Hooghly River. The floods have now washed away part of the town, and formed a dangerous bar in the river, in consequence of which the merchants have removed to Ballasore. Pipley is twenty-two miles north-east from Ballasore. Long. 87. 25. E. Lat. 21. 42. N.

PIPLEY, a town in the province of Orissa and district of Cuttack, thirty miles south from Cuttack. Long. 86. 8. E. Lat. 20. 8. N.

PIPLOUD, a town and large mud fort of the Mahratta territories, in the province of Khandesh, thirty-one miles north-east from Boorhanpoor. Long. 76. 35. E. Lat. 21. 44. N.

PIQUET, or PICKET, a celebrated game at cards, much in use throughout the polite world. It is played between two persons, with only thirty-two cards; the deuces, threes, fours, fives, and sixes, being set aside.

In reckoning at this game, every card goes for the number it bears, as a ten for ten, only all court cards go for ten, and the ace for eleven; and the usual game is one hundred up. In playing, the ace wins the king, the king the queen, and so down.

Twelve cards are dealt round, usually by two and two; which done, the remainder are laid in the middle. If one of the gamesters finds he has not a court card in his hand, he is to declare he has *carte-blanche*, and tell how many cards he will lay out, and desire the other to discard, that he may show his game, and satisfy his antagonist that the carte-blanche is real; for which he reckons ten.

Each person discards, or lays aside a certain number of his cards, and takes in a like number from the stock. The first of the eight cards may take three, four, or five; the dealer all the remainder, if he pleases. After discarding, the eldest hand examines what suite he has most cards of; and reckoning how many points he has in that suite, if the other have not so many in that or any other suite, he tells one for every ten of that suite. He who thus reckons most is said to win the point.

The point being over, each examines what *sequences* he has of the same suite, that is, how many tierces, or sequences of threes, quartes or fours, quintes or fives, sixiemes or sixes, and so on. For a tierce they reckon three points, for a quarte four, for a quinte fifteen, for a sixieme sixteen, and so forth. And the several sequences are distinguished in dignity by the cards they begin from. Thus ace, king, and queen are called *tierce major;* king, queen, and knave, *tierce to a king;* knave, ten, and nine, *tierce to a knave*, &c.; and the best tierce, quarte, or quinte, in other words, that which takes its descent from the best card, prevails, so as to make all the others in that hand good, and destroy all those in the other hand. In like manner, a quarte in one hand sets aside a tierce in the other.

The sequences being over, the players proceed to examine how many aces, kings, queens, knaves, and tens, each holds, reckoning for every three of any sort, three; but here, too, as in sequences, he that with the same number of threes has one that is higher than any the other has, for instance, three aces, has all his others made good thereby, and his adversary's all set aside. But four of any sort, which is called a *quatorze*, always sets aside three.

All the game in hand being thus reckoned, the eldest proceeds to play, reckoning one for every card he plays above a nine, and the other follows him in the suite; and the highest card of the suite wins the trick. However, unless a trick be won with a card above a nine (except the last trick), nothing is reckoned for it, though the trick serves afterwards towards winning the cards; and he who plays last does not reckon for his cards unless he wins the trick.

The cards being played out, he who has most tricks reckons ten for winning the cards. If they have tricks alike, neither reckons anything. The deal being finished, and each player having marked up his game, they proceed to deal again as before, cutting afresh each time for the deal. If both parties be within a few points of being up, the carte-blanche is the first thing that reckons, then the point, then the sequences, then the quatorzes or threes, then the tenth cards.

He who can reckon thirty in hand by carte-blanche, points, quintes, &c. without playing, before the other has reckoned anything, reckons ninety for them; and this is called a *repique*. If he reckons above thirty, he reckons so many above ninety. If he can make up thirty, part in hand and part play, ere the other has told any thing, he reckons for them sixty. And this is called a *pique;* whence the name of the game. He who wins all the tricks, instead of ten, which is his right for winning the cards, reckons forty; and this is called a *capot*.

Mr Demoivre, who has made this game the object of mathematical investigation, has proposed and solved the following problems. 1. To find at piquet the probability which the dealer has for taking one ace or more in three cards, he having none in his hand. He concludes from his computation, that it is twenty-nine to twenty-eight that the dealer takes one ace or more. 2. To find at piquet the probability which the eldest has of taking an ace or more in five cards, he having no ace in his hand; the answer is two hundred and thirty-two to ninety-one, or five to two nearly. 3. To find at piquet the probability which the eldest hand has of taking an ace and a king in five cards, he having none in his hand; the answer is, the odds against the eldest hand taking an ace and a king are three hundred and thirty-one to three hundred and fifteen, or twenty-one to twenty nearly. 4. To find at piquet the probability of having twelve cards dealt to, without king, queen, or knaves, which case is commonly called *cartes-blanches;* the odds against cartes-blanches are seventeen hundred and ninety-one to one nearly. 5. To find how many different sets, essentially different from one another, one may have at piquet before taking in; the answer is, 28,967,278. This number falls short of the sum of all the distinct combinations, by which twelve cards may be taken out of thirty-two, this number being 225,792,840; but it must be considered that in that number several sets of the same import, but differing in suite, might be taken, which would not introduce an essential difference amongst the sets.

PIRÆUS PORTUS, in *Ancient Geography*, a celebrated port to the west of Athens, consisting naturally of three harbours or basins, which lay neglected till Themistocles put the Athenians on making it a commodious port; the Phalerus, a small port, and not far from the city, being what they used before that time.

The Piræus, as Athens flourished, became the common emporium of all Greece. Hippodamus, an architect, celebrated as the inventor of many improvements in housebuilding, besides other monuments of his genius, was employed to lay out the ground. Five porticoes, which, communicating with one another, formed the *Long Portico*, were erected by the ports. Here was an *agora* or market-place, and, farther from the sea, another called *hippoda-*

mia. Beside the vessels were dwellings for the mariners. A theatre was opened, temples were raised, and the Piræus, which surpassed the city in utility, began to equal it in dignity. The cavities and windings of Munychia, natural and artificial, were filled with houses; and the whole settlement, comprehending Phalerus and the ports of the Piræus, with the arsenals, the storehouses, the famous armoury of which Philo was the architect, and the sheds for three hundred, and afterwards four hundred, triremes, resembled the city of Rhodes, which had been planned by the same Hippodamus. The ports, on the commencement of the Peloponnesian war, were secured with chains. Centinels were stationed, and the Piræus was carefully guarded.

The Piræus was reduced with great difficulty by Sylla, who demolished the walls, and set fire to the armoury and the arsenals. In the civil war it was in a defenceless condition. Calenus, lieutenant of Cæsar, seized it, invested Athens, and ravaged the territory of the state. Strabo, who lived under the Emperors Augustus and Tiberius, observes, that the many wars had destroyed the long walls, with the fortress of Munychia, and had contracted the Piræus into a small settlement by the ports and the temple of Jupiter Saviour. See Athens.

PIRANO, a city of the Austrian government of Trieste, in the district of Capo d'Istria. It stands on a tongue of land in the Bay of Trieste, and contains 895 houses, with 6800 inhabitants, who are chiefly employed in the fisheries, or in making salt on the lagunes in their vicinity. Long. 13. 29. 4. E. Lat. 45. 29. 22. N.

PIRATE, πειρατης, a sea-robber, or an armed ship which roams the seas without any legal commission, and seizes or plunders every vessel she meets indiscriminately, whether friends or enemies.

PIRHALA, a town of Hindustan, in Lahore, tributary to the Afghan sovereigns of Caubul. It lies fifty-five miles east from the Indus. Long. 71. 48. E. Lat. 32. 25. N.

PIRNA, a city of the kingdom of Saxony, in the circle of Meissen, and the capital of a bailiwick of its own name, which comprehends eleven cities and towns, and 170 villages, with 36,250 inhabitants. The city is situated upon the banks of the Elbe, is surrounded with walls, and contains three churches, an orphan-house, an hospital, and 500 houses, with about 6000 inhabitants. It suffered much in the campaign of 1813, when it was the centre of the operations between the French and the allied armies; but it rapidly recovered, and is now the seat of considerable manufactures of cotton goods, and has a good trade on the river Elbe, both in building vessels and in conveying goods. A little above the city is the fine castle of Sonnenstein, now occupied as a lunatic asylum.

PIROMALLI, Paul, a Dominican of Calabria, was sent as a missionary to the East. He remained a long time in Armenia, where he had the happiness to bring back to the church many schismatics and Eutychians, and even the patriarch himself, who had before thrown every obstacle in his way. He afterwards passed into Georgia and Persia, then into Poland, in quality of nuncio to Pope Urban VIII., in order to appease the disturbances which had been occasioned there by the disputes of the Armenians, who were very numerous in that country. Piromalli united them in the profession of the same faith, and the observance of the same ceremonies. On his return to Italy he was taken by some corsairs, who carried him prisoner to Tunis. As soon as he was ransomed he went to Rome, and gave an account of his mission to the pope, who conferred upon him some signal marks of his esteem. His holiness intrusted him with the revisal of an Armenian bible, and sent him again into the East, where he was promoted, in 1655, to the bishopric of Nashirvan. After having governed that church for nine years, he returned to Italy, and took charge of the church of Bassignano, where he died three years afterwards, in 1667. His charity, zeal, and other virtues, did honour to the episcopal office. There are extant of his writings, 1. Some works of Controversy and Theology; 2. Two Dictionaries, the one a Latin-Persian, and the other an Armenian-Latin; 3. An Armenian Grammar; and, 4. A Directory, which is of great use in correcting Armenian books.

PIRON, Alexis, a French poet, was born at Dijon in July 1689, where his father was an apothecary, and where he passed more than thirty years in idle and destructive dissipation. He was at length obliged to quit the place of his nativity, in order to avoid the reproaches of his fellow-citizens, on account of an ode which he had written, and which gave them great offence. His relations not being able to give him much assistance, he supported himself at Paris by means of his pen, the strokes of which were as beautiful and fair as those of an engraver. He lived in the house of M. de Belleisle as his secretary, and afterwards with a financier, who, however, did not know that he had a man of genius under his roof. His reputation as a writer commenced with some pieces which he published for the entertainment of the populace, and which showed strong marks of original invention; but what fully established his character in this way was his comedy entitled *Métromanie*, which was the best that had appeared in France since Regnard's Gamester. This performance, in five acts, well conducted, and replete with genius, wit, and humour, was acted with the greatest success upon the French stage in 1738. Piron, however, had a sufficient stock of self-conceit; and what helped to increase it, and make him fancy himself superior to the most celebrated of his contemporaries, was the circumstance that, on account of his original humour, of which he had an uncommon share, his company was more courted than that of Voltaire, who was otherwise too lively, captious, and crabbed. Piron's mischievous ingenuity was partly the cause which excluded him from the French Academy. "I could not," said he, "make thirty-nine people think as I do, and I could less think as thirty-nine do." He called that celebrated society "les invalides du bel esprit," and yet he often endeavoured to become one of those invalids. He died on the 21st of January 1773, at the age of eighty-three. He had prepared for himself the following characteristic epitaph:

Ci gît Piron, qui ne fut rien,
Pas même académicien.

A collection of his works appeared in 1776, in seven vols. 8vo and nine vols. 12mo. The principal pieces are, The School of Fathers, a comedy acted in 1728 under the title of Ungrateful Sons; Callisthenes, a tragedy, the subject of which is taken from Justin; The Mysterious Lover, a comedy; Gustavus and Ferdinand Cortez, two tragedies, some scenes of which discover an original genius, but the versification neither pleases the ear nor affects the heart; Métromanie, a comedy; The Courses of Tempe, an ingenious pastoral, in which the manners both of the town and country are pleasantly drawn; with some odes, poems, fables, and epigrams. In this last kind of poetry he was very successful, and he may be placed after Marot and Rousseau; but there was no occasion for loading the public with seven volumes of his works. The half of that number might have sufficed; for, excepting Métromanie, Gustavus, the Courses of Tempe, some odes, about twenty epigrams, three or four fables, and some epistles, the rest are but indifferent, and have no claim to any extraordinary merit.

PISA, a portion of Italy, once an independent state, but now one of the provinces of the grand duchy of Tuscany. It forms the north-west portion of that duchy, except a small part of Arovalle, and the whole sea-coast to the cape of the Apennines, which divides it from Maremma. In it is included also the Isle of Elba with its dependencies, and the ancient duchy of Piombino. It extends over 2614 square miles, is divided into three districts, and contains 345,000 inhabitants. The capital is the city of the same name, situated near the mouth of the river Arno, in a marshy and unhealthy district, arising from its being enclosed on all sides by the moisture of Paduli del Lupo, Paduli di Stagno, and of the water of the Serchio. It is surrounded with thick walls, now converted into promenades, for which purpose they are better adapted than for defence. It is the see of an archbishop, whose cathedral and palace are magnificent structures; the tower of the former has attracted much attention, and been called the hanging tower, because it considerably declines from the perpendicular. There is a university, founded in 1309, which at present is resorted to by about 300 students, and has a library of 60,000 volumes. It is frequented by invalids, on account of some warm baths on Monte Giuliano, near the city. Pisa contains 2000 houses, and about 18,000 inhabitants, who make some linen and woollen cloths, some silk goods, with glass, paper, white lead, vitriol, and alabaster articles, but depend mostly on the invalid visitors. Long. 10. 18. 10. E. Lat. 43. 43. 7. N.

PISCADORE or Ponghou Islands, a cluster of small islands in the North Pacific Ocean, in the channel of Formosa, about six leagues from the west coast of that island. According to Pérouse, they are a heap of rocks, which assume all kinds of shapes, and are totally barren, but have a good and sheltered harbour. The Chinese maintain a garrison here. They are situated between the island of Formosa and the port of the island of Emouy, and extend from 23. 10. to 23. 40. N., about twenty-four miles; the westernmost is in 119. 27. E. long.

PISCINA, in *Antiquity*, a large basin in a public place or square, where the Roman youth learned to swim, and which was surrounded with a high wall, to prevent filth from being thrown into it. This word is also used for a lavatory amongst the Turks, placed in the middle court of a mosque or temple, where the Mussulmans wash themselves before they offer their prayers.

PISISTRATUS, the son of Hippocrates, was descended from one of the most illustrious families of Athens, which claimed to derive their origin from Codrus, and through him traced their pedigree to Nestor and the Pylian kings. At the time that he began to take part in the political affairs of his country, there were three factions struggling for power; those of the Lowlands, Highlands, and Coast. Megacles, chief of the great family of the Alcmæonidæ, took the lead of the Coast party, whilst Pisistratus headed the democratical faction of the Highlanders. Solon had tried to calm their passions by the wisdom of his laws, but the contending parties had refused to submit; and when he returned, after an absence of several years, he found much confusion, and everything tending towards a state of anarchy. Pisistratus was determined to secure to himself the chief authority in the government; and by pretending to the people that he was in danger of his life, he obtained a guard for the security of his person, and it was not long before he made himself master of the citadel. He thus became what was afterwards called Tyrant of Athens, B. C. 560; though Herodotus expressly states, that all the laws continued in force, and that the constitutional powers of the magistrates were not in the least restricted. Solon used to say, that were it not for his ambition, there would not be a man better disposed, or a more worthy citizen, in Athens. Though Solon was no doubt deeply mortified that his countrymen were unable to maintain the political constitution which he had formed for them, it does not appear that he broke off all connection with Pisistratus. He took the wiser course of trying to direct his measures for the benefit of his country, and assisted him in the administration of the commonwealth. How long Pisistratus continued to maintain himself in power is not stated, but he was at last driven into exile, by the two parties of Megacles and Lycurgus uniting their strength. A dispute between the victors induced Megacles to propose an accommodation with Pisistratus, upon condition that he should marry his daughter; and this was at once acceded to. A quarrel, however, with Megacles again took place, and Pisistratus was obliged to retire to Eretria in Eubœa. Here he continued to increase his influence, till a favourable opportunity presented itself of regaining his former position. It was in the eleventh year of his second banishment that he returned, when the Athenians flocked to his standard, and, in the words of Herodotus, preferred tyranny to liberty. He defeated the Alcmæonidæ, and entered Athens, promising safety to all who returned quietly to their homes. Some of the leaders were of course banished, but the great body of the people seem to have benefited by the change. He was kind to the poor, and introduced many laws and regulations which were highly advantageous to his country. He was a lover of learning, and is said to have been the first who arranged the poems of Homer as we now have them. Cicero speaks of his eloquence in the highest terms. He continued to direct the administration of Athens till his death, B. C. 527, thirty-three years after his first usurpation, of which time he ruled seventeen years. He left two sons, Hippias and Hipparchus, who succeeded to his power.

PISMIRES, or Ants. See Ants.

PISO, Lucius Calpurnius, surnamed the Frugal, on account of his parsimony, was descended of the illustrious family of the Pisos, which gave so many great men to the Roman republic. He was tribune of the people in the year 149 before Christ, and afterwards consul. During his tribuneship he published a law against the crime of concussion or extortion, entitled *Lex Calpurnia de pecuniis repetundis*. He happily ended the war in Sicily. To reward the services of one of his sons, who had distinguished himself in that expedition, he left him by his will a golden crown, weighing twenty pounds. Piso joined to the qualities of a good citizen the talents of a lawyer, an orator, and an historian.

PISSASPHALTUM, or Asphaltum, *Earth-pitch*, a fluid, opaque, mineral body, of a thick consistence, strong smell, readily inflammable, but leaving a residuum of grayish ashes after burning. It arises out of the cracks of the rocks in several parts of the island of Sumatra, and some other places in the East Indies, where it is much esteemed in paralytic disorders. There is a remarkable mine of it in the island of Bua.

PISSELÆUM Indicum, *Barbadoes Tar*, a mineral fluid of the nature of the thicker bitumens, and of all others that which most approaches, in appearance, colour, and consistence, to the true pissasphaltum, though it differs from it in other respects. It frequently occurs in many parts of America, where it is found trickling down the sides of mountains in large quantities, and sometimes floating on the surface of the waters. It has been greatly recommended internally in coughs and other disorders of the breast and lungs.

PISTACIA, Turpentine-tree, *Pistachia-nut* and *Mastich-tree*, a genus of plants belonging to the diœcia class. Pistachia-nuts are moderately large, containing a kernel of a pale greenish colour, covered with a reddish skin. They have a pleasant, sweet, unctuous taste, resembling that of almonds; and they abound with a sweet and well-tasted oil, which they yield in great abundance on being pressed after bruising them. They are reckoned amongst the analeptics, are wholesome and nutritive, and are by some esteemed very proper to be prescribed by way of restoratives, eaten in small quantity, to people emaciated by long illness.

PISTIL, amongst botanists, the little upright column which is generally found in the centre of every flower. According to the Linnæan system, it is the female part of generation, the office of which is to receive and secrete the pollen, and produce the fruit. It consists of three parts; the germen, stylus, and stigma. See Botany.

PISTOJA, a city of the duchy of Tuscany, in Italy, the capital of a district, called a vicariate, of the same name, in the circle of Florence. It stands on the river Ombrone, and is defended by walls and ditches. It is the see of a bishop, whose cathedral is abundantly furnished with holy relics. It contains many churches and monasteries, and 1100 houses, with 9160 inhabitants, who make some woollen cloth, some ironmongery and fire-arms. Long. 10. 32. 45. E. Lat. 45. 47. N.

PISTON, in pump-work, is a short cylinder of metal or other solid substance, fitted exactly to the cavity of the barrel or body of the pump. See Hydrodynamics.

PISUM, Pease, a genus of plants belonging to the diadelphia class. See Horticulture.

PITCAIRNE, Archibald, a physician of great eminence, was born at Edinburgh on the 25th of December 1652. His father, Alexander Pitcairne, who was engaged in trade, and became one of the city magistrates, derived his lineage from the ancient family of Pitcairne of Pitcairne in the county of Fife. His mother, whose name was Sydserf, belonged to a good family in the county of Haddington, descended from Sydserf of Ruthlaw. After having been initiated in classical learning at Dalkeith school, he was sent to the university of Edinburgh in 1668, being then sixteen years of age. In 1671 he took the degree of A. M. It was the wish of his family that he should devote himself to the study of divinity: but for the office of a minister he seems to have had no vocation; and his father, not without some degree of reluctance, permitted him to direct his next views to the profession of law. To this new pursuit he betook himself with all the ardour of a young and ambitious mind; but his intensity of application produced such an effect upon his health, that the physicians, apprehensive of his being visited with consumption, advised him to try the effect of a residence in the south of France.

On his arrival at Paris, he found his health so much improved, that he judged it unnecessary to visit Montpellier; and after having formed some pleasant acquaintances among his young countrymen engaged in the study of physic, he determined to prosecute his own studies without seeking for any other school. They however persuaded him that Paris could not boast of any able professors of law; and he was easily induced to listen to their advice of relinquishing all thoughts of the bar.

> Scire potestates herbarum usumque medendi
> Maluit, et mutas agitare inglorius artes.

After he had for several months attended the hospitals, his father deemed it expedient to recall his wandering footsteps. He accordingly returned to Scotland; and being in this state of preparation for any one of the learned professions, divinity, law, or physic, he continued to enlarge his fund of knowledge, and to cultivate his excellent talents. The mathematical sciences were however his favourite pursuit; and this propensity is supposed to have been fostered by his intimacy with David Gregory, who became professor of mathematics at Edinburgh, and afterwards Savilian professor of astronomy at Oxford. Of his learned friend Dr Gregory, who belonged to a very remarkable family, he has made honourable mention in his works. In this department of study, we are informed, "he made a great progress in a short time; and meeting with the lately invented method of infinite series, he made some improvements thereon, which were afterwards published by Dr Wallis."[1] He is further said to have perceived the necessary connexion between physic and geometry, and thus to have fixed his choice unalterably upon that profession.

He now applied himself to the study of botany, pharmacy, and materia medica, in which branches he could at that time receive no public instruction in Edinburgh. It appears to have been the usual method to attend the private instructions of some established practitioner. In the year 1675 he returned to Paris; and having prosecuted his studies with great ardour and success, he took the degree of M. D. at Reims on the 13th of August 1680. He entered upon his professional career in his native city; and of the Royal College of Physicians, incorporated by a charter bearing date the 29th of November 1681, he was one of the original fellows. His talents and learning were such as could not fail to attract the attention of those among whom he lived. He was a scholar and a wit, as well as a man of science; and he so completely deserted the beaten track of medical speculation, that he was soon regarded as no ordinary character.

After his first settlement in Edinburgh, he married Margaret the daughter of Colonel James Hay of Pitfour. She bore him a son and a daughter; but the mother and her children did not long survive, and he devoted an elegiac poem to her memory. He continued to rise in professional reputation; and this was greatly encreased by the publication of his "Solutio Problematis de Inventoribus," which was printed at Edinburgh in 1688, and again at Leyden in 1693. The object of this tract is to vindicate to Harvey the honour of having discovered the circulation of the blood; an honour of which many attempts had been made to deprive him. According to the notion of Vander Linden, and various other writers, this great fact in the animal economy was known to Hippocrates; but their opinion is very scientifically refuted by Dr Pitcairne. There seems to be much more reason to believe that the unfortunate Servetus "had imperfect glimmerings of that light which afterwards Dr Harvey communicated with so bright a lustre to the learned world."[2]

An attempt to found a medical school in the university had been made in the year 1685. The first professor in that faculty was Sir Robert Sibbald, who was appointed on the 24th of March. Dr Halket and Dr Pitcairne were appointed on the 9th of September; but it has not been ascertained that they read any lectures. Of the estimation in which Pitcairne was held, we find a more striking proof in the circumstance of his being invited by the curators of the university of Leyden to accept a professorship of physic. Of this invitation he did not hesitate to avail himself; and his inaugural oration was delivered on the 26th of April 1692.[3] The oration, we are informed, was highly applauded, and the ordinary salary of his professorship was augmented by one half. We however learn from a passage in Bayle's correspondence, that his lectures were too abstruse, and contained too large an infusion of geometry, to be altogether popular.[4] In this university "he continued little more than a year, during which he read lectures on the works of Bellini, such as were then published. While he was professor here, he printed several dissertations which were drawn from his lectures: in these he attempts to explain the circulation of the blood, and some of the principal parts of the animal œconomy mechanically, as had been done by Bellini, whom he places next to Harvey upon the bench of inventors of physic." Lorenzo Bellini, who was a professor in the university of Pisa, testified his gratitude by dedicating to Pitcairne a collection of his Opuscula.[1] One of his pupils at Leyden was Dr Mead, who always retained the highest regard for his master.

[3] Archibald Pitcarnii, M. D. et Regii Collegii Medicorum Edinburgensium Socii, Oratio, qua ostenditur Medicinam ab omni Philosophorum Secta esse liberam, habita Lugduni Batavorum die 26 Aprilis CIƆIƆCXCII. cum ordinariam Facultatis Medicæ Praxeosque docendæ Professionem solenniter auspicaretur. Lugd. Bat. 1692, 4to. This oration was reprinted in 1695, and again in 1696. He inserted it in both editions of his Dissertationes Medicæ.

[4] Œuvres Diverses de Bayle, tom. iv. p. 732

Before he quitted Edinburgh, he had made an engagement to marry a daughter of Sir Archibald Stevenson, one of the king's physicians. In the course of the year 1693 he accordingly returned, with the intention of fulfilling his promise, and immediately resuming his academical duties; but the reluctance of the parents to part with their daughter, placed him in a situation of embarrassment, as he was neither disposed to relinquish the professorship nor the young lady. He however adopted the former alternative; and having married Elizabeth Stevenson, he resigned his chair, and finally settled in Edinburgh, where he speedily found himself engaged in very extensive practice. He acquired the reputation of a very skilful practitioner, and indeed his name became more celebrated than that of any other physician then residing in Great Britain. In addition to his more ordinary employment, he received frequent consultations from England, and even from Holland.

With this extensive practice his time was so much occupied, that it did not leave him any abundant leisure for other pursuits. He however continued to gratify his taste by the composition of Latin verses, which were alike calculated to please his friends, and to expose his enemies. His satirical propensities, added to his unrivalled success in a lucrative profession, rendered his enemies somewhat numerous. The violence of his prejudices as a Jacobite and an episcopalian must have had no tendency to recommend him to the best supporters of the existing government. But his friends were likewise numerous; and he pursued his career with great alacrity, and apparently with a great disregard of personal animadversion.

He was fiercely attacked in a little volume, published under the title of "*Apollo Mathematicus;* or the Art of Curing Diseases by the Mathematicks, according to the Principles of Dr Pitcairn: a work both profitable and pleasant, and never published in English before. To which is subjoined a Discourse of Certainty, according to the Principles of the same Author.". Printed in the year 1695, 8vo. This sarcastic work, according to the statement of Dr Oliphant, was the production of Dr, afterwards Sir Edward Eyzat.[2] It was speedily followed by "Tarrugo Unmasked; or an Answer to a late Pamphlet intituled *Apollo Mathematicus*, by George Hepburn, M.D. and Member of the Colledge of Phisicians at Edinburgh. To which is added by Doctor Pitcairne, the Theory of the internal Diseases of the Eye demonstrated mathematically." Edinb. 1695, 4to. This title bears an allusion to "Tarugo's Wiles, or the Coffee-House, a Comedy," written by Thomas Sydserf, or St Serfe, and printed at London in the year 1668. The author of the first tract escaped without any censure from the College of Physicians, of which he was likewise a fellow; but Dr Hepburn, who had been Pitcairne's pupil, and who then resided in Haddington, was not treated with the same degree of forbearance. On the 7th of November a committee was appointed to examine his pamphlet, and on the 3d of December he was suspended from the exercise of his right to sit and vote as a fellow. The proceedings against him appear to have been very arbitrary and irregular: "though a day was allowed him to answer a libel to be given him, and six free days to see it, yet before any libel was given him, or the day of compearance come," they hastened to pass a vote of suspension. During the interval, namely on the 18th of November, Dr Pitcairne had tendered a protest against the admission of certain fellows, one of whom was Eyzat, as having been conducted in an irregular manner. It was then referred to a committee, who on the 22d delivered a report, "that the protestation given in and subscribed by Dr Pitcairn was a calumnious, scandalous, false, and arrogant paper;" and the meeting having unanimously approved of this report, did thereupon suspend him "from voting in the college, or sitting in any meeting thereof." It was even proposed to prohibit him from the practice of physic. At the meeting which suspended Dr Hepburn, four fellows, Melville, Eccles, Oliphant, and Smelholme, were ordered "to compear next day, to hear and see themselves suspended, for adhering to the protestation presented by Dr Pitcairn." The object of all this indecent violence was to deprive them of the right of voting at the ensuing election; "but they having presented a bill of advocation, and obtained a sist for some days, in which the day of election was included, that project was baulked." A double election ensued: Dr Trotter was re-elected president by his adherents, while the opposite party elected Sir Archibald Stevenson. The meeting was attended by one of the bailies; and Pitcairne was removed by the town-officers, after having protested against this unwarrantable interference. He and his friends withdrew to Stevenson's house, and there elected the president and other office-bearers for the ensuing year. These violent animosities produced several applications to the privy council and the court of session. Another fierce contention arose from the question of publishing a Dispensatory, which had been prepared under the sanction of the college. Stevenson's party opposed its publication, on the ground of its being "barely a transcript of the London one, ill copied, and worse explained." Dr Pitcairne was attacked in a virulent pamphlet, which charged him with the inconsistency of having written a commendatory preface to a book which he afterwards represented as worthless.[3] On the 31st of January 1700 an overture towards reconciliation was made to him and other six fellows who had been suspended. Another pacific resolution was passed on the 7th of January 1703; but only three of the seven were disposed to avail themselves of this second opportunity. On the 4th of January 1704 an act of oblivion was proposed by the president, Dr Dundas, and was received with unanimous approbation. It was confirmed at two subsequent meetings, held on the 11th and 12th of the same month. After this period Pitcairne resumed his seat in the college; but after the 6th of March 1706 he was not present at any of their meetings, and was repeatedly fined for non-attendance.[1]

---

[1] Laurentii Bellini Opuscula aliquot, ad Archibaldum Pitcarnium, Professorem Lugduno-Batavum, in quibus præcipue agitur de Motu Cordis, &c. Lugd. Bat. 1737, 4to. There are several editions of an earlier date. A long and remarkable dedication, "Viro meritissimo Archibaldo Pitcarnio," is dated at Florence on the 20th of March 1693. It commences thus: "Rapiunt me mores tui, vir meritissime; tua enim illa te gerendi ratio, qua me per literas compellare voluisti, ad omnem optimi et magni viri speciem est ita comparata, ut per universum vitæ meæ spatium vix quicquam mihi contigerit, quod fuerit tam apte factum ad genium meum." In this dedication he introduces Pitcairne's letter, dated at Leyden on the 22d of June 1692.

[2] Oliphant's Short Discourse to prove the Usefulness of Vomiting in Fevers, pref. Edinb. 1699, 8vo. See likewise *Melius Inquirendum*, or, an Answer to Dr Olyphant's Discourse of the Usefulness of Vomiting in Fevers, p. 18. Edinb. 1699, 8vo. Here the authorship of Apollo Mathematicus is not denied by the answerer, who is sufficiently known to have been Dr Eyzat. He is designated in the title of Dr Andrew Brown's Epilogue to the five Papers lately past betwixt the two Physicians, Dr O. and Dr. E. containing some Remarks, pleasant and profitable, concerning the Debate, and the Usefulness of Vomiting and Purging in Fevers. Edinb. 1699, 8vo. He is more directly mentioned in a facetious letter from a London physician, inserted in An Answer to the pretended Refutation of Dr Olyphant's Defence. Edinb. 1699, 8vo. "I have seen the *Melius Inquirendum*, and am too well acquainted with the stile and spelling, not to know that it is Dr Eyzat's."

[3] Information for Dr Archibald Pitcairn, against the abdicate Professor; or, a Mathematical Demonstration that Liars should have good Memories: whereby the Colledge of Physicians is vindicat from the Calumnies contain'd in Dr Stevenson's last Informa-

Other learned bodies had treated him with more respect. On the 7th of August 1699 the university of Aberdeen conferred upon him the degree of M. D. On the 16th of October 1701 the College of Surgeons admitted him a fellow. This last honour, which was unsolicited, had never been bestowed upon any other physician. He was gratified by so unusual a mark of respect, and attended the meetings of the college. He appears to have retained his station as a professor in the university. After the appointment of Carstares to the office of principal, which took place in the year 1703, he was regular in his attendance when the Latin oration was annually delivered at the opening of the session. Between the principal and the professor there was no sympathy of political feeling; but Pitcairne "used to observe that when Mr Carstares began to address his audience, he could not help fancying himself transported to the forum in the days of antient Rome."[2]

Sir Robert Sibbald was one of those who chiefly felt the edge of his sarcastic humour. He was a man considerable for his learning, and is still remembered as an industrious labourer in the department of Scottish antiquities: but he was neither conspicuous for the strength of his judgment nor the elegance of his taste; and with the weapons of wit and sarcasm he was but an unequal match for Dr Pitcairne. He was a member of the committee which prepared so strong a report against the protest; and he incurred the suspicion of having had some concern in the publication of Apollo Mathematicus. In the preface to Dr Hepburn's answer, he is designated in a manner sufficiently intelligible: "Whoever Tarrugo be, yet it's known that the papers which I call Tarrugo's were revised, corrected, and approven by one who twice in one year changed his religion, upon how honest and religious principles, I doe not determine." During the reign of the late popish king, Sibbald had been induced by the earl of Perth, lord chancellor, to change his religion; but having more maturely studied the controversy between the two churches, he returned to the profession of the faith which he had renounced.[3] To this passage of his personal history Pitcairne makes the following allusion:

Dum procul a Geneva se summovet inclyta Roma,
Quod quam sit longum scit Cyphianus iter.

Sibbald, who is thus styled Cyphianus in allusion to his villa of Kipps, was a man of too much candour and moderation to approve of all the violent measures which brought so much discredit on the College of Physicians; and when the president, Dr Sinclair, and only five fellows, had in a very summary manner suspended Stevenson and several others, he concurred with Sir Thomas Burnet in preparing a formal declaration against such unwarrantable proceedings. It is dated on the 20th of November 1699. In the year 1684 he had published a folio volume entitled "Scotia Illustrata, sive Prodromus Historiæ Naturalis." This work was attacked, with sufficient violence, in a tract of nearly a hundred pages, "Archibaldi Pitcarnii Dissertatio de Legibus Historiæ Naturalis." Edinb. 1696, 8vo. As this title includes the author's name at length, it is not easy to explain the origin of Dr Webster's statement that the work was published anonymously. Charges of plagiarism, ignorance, and something little short of stupidity, are plentifully scattered through the dissertation. Nor is the knight of Kipps the only individual who is here subjected to his animadversion: he has likewise bestowed some castigation on Dr Cockburn, of whose treatise on the animal economy he avers, that it contains nothing new but what the author has either borrowed from Bellini or himself, although he has never mentioned the name of the one or of the other. After a long interval appeared "A Letter from Sir R—— S—— to Dr Archibald Pitcairn." Edinb. 1709, 8vo. The author, whoever he may have been, attacks various positions in the medical dissertations of his antagonist. This publication was speedily followed by "A Letter from Dr James Walkinshaw to Sir Robert Sibbald." Lond. 1709, 8vo. The writer's name is known to be supposititious; and, according to a contemporary notice preserved in a copy of the pamphlet, it was understood to be written by Dr Bower with the assistance of Dr Pitcairne. The internal evidence is sufficient to convince us that the other tract was not written by Sibbald, of whose name it exhibits the initials. This answer ascribes it in the most unequivocal terms to Dr Cockburn, of whose reputation as a medical writer it indeed contains a zealous defence. Both tracts include various topics of mathematical controversy. Sibbald at length interfered in the controversy, by publishing "Vindiciæ Scotiæ Illustratæ, sive Prodromi Naturalis Historiæ Scotiæ, contra Prodromomastiges, sub larva Libelli de Legibus Historiæ Naturalis latentes." Edinb. 1710, fol. According to a statement contained in this work, Dr Pitcairne's dissertation had been so carefully suppressed, that for twelve years after its first impression, his antagonist was unable to procure a copy either for love or money. He mentions it as the joint production of several individuals; and moreover avers, what is pointedly denied in a private letter,[4] that Pitcairne disavowed being the author; "nihil unquam a se editum fuisse in meum Historiæ Naturalis Prodromum." If indeed the printed copies were carefully withheld from circulation, he might

Autobiography of Sir Robert Sibbald, p. 35. Edinb. 1833, 8vo. On Sibbald's conversion, an English poem of Dr Pitcairne may be found in the Scotish Pasquils, b. iii. p. 62.

[4] This letter accompanied a copy of Sibbald's Vindiciæ, sent to Dr Gray of London: "Sir, you know the bearer: he brings you the rarest piece of lies and nonsense I ever saw. 'Scribit et in tergo, necdum finivit.' The author gave me 3 copies in a compliment, of which I send one to you, and one to Dr Arbuthnot as an answer to his modest examination. The author told me that by my telling him I was not author of the Dissertatio de Legibus Historiæ Naturalis (which he tels indeed, and lyes), he meant, in alledging this upon me, onlie to hinder me from answering him, since he in his Vindiciæ had commended me so much: an excellent reasoning, and which made me smile in place of being angrie. He told me he would let no body else see it till he had got the approbation of all the learned to it. My papers are in the press on the first of this year. Your

"Edr. 6 Jan. 1711. A. PITCAIRNE."

with a safe conscience aver that he had published no such work. It however suited his adversary's plan to consider this as the work of some person or persons unknown; and that plan he even carried so far as to prefix a parenetic ode, not very poetical, in which the talents of Pitcairne are mentioned in terms of no parcimonious commendation.

Dr Pitcairne had published seven medical dissertations in a separate form; and to these he added another, and collected them into a volume, bearing the title of "Archibaldi Pitcarnii Dissertationes Medicæ." Roterodami, 1701, 4to. The volume, dedicated to Bellini, was inaccurately printed in consequence of the author's distance from the press. Not long afterwards it was assailed in a "Dissertatio de Salute quam ferunt Ægrotantibus Dissertationes Archibaldi Pitcarnii." Edinb. 1702, fol. This anonymous dissertation, it was sufficiently ascertained, was the production of Dr Oliphant, whom he had formerly ranked among his friends. An answer, written in English, was immediately published by some individual, who conceals his name, and exhibits the initials J. J. The author of the dissertation replied without delay, nor did his adversary leave him in possession of the field.[1] This adversary, we are inclined to believe, was Dr Bower. In a letter which Dr Drummond addressed to him soon after the death of Pitcairne, we find the subsequent passage: "I cannot but admire and applaud your steady and constant adherence to him in his greatest difficulties, and in the weakness and infirmities of old age. What excellent things you have done in his defence, are particularly known to me; and if they are as well understood by the learned world, they would certainly set your true merits in a clear light, and eternally recommend your unspotted fidelity and friendship." These expressions are evidently applicable to unavowed services, and they appear too strong to be merely applicable to his pamphlet against Cockburn. The two tracts in controversy with Oliphant bear internal evidence of having been written by a mathematician. On the same occasion, another tract was written by Dr Cheyne, who afterwards rose to great eminence in the profession.[2] He had been a pupil of Pitcairne, of whom he always retained a high admiration; and he now defended his master with a degree of violence, which, at more mature age, he had himself the candour to condemn.[3]

About this period of his life, he was involved in proceedings of a different nature. In a private letter addressed to his friend Dr Gray, a physician in London, he had testified his Jacobitical zeal by giving a highly-coloured and exaggerated statement of some transactions connected with a petition for assembling a parliament. This letter appears to have been intercepted, and to have been transmitted to the crown lawyers, who prosecuted the writer before that anomalous tribunal the privy council, on a charge of "leising making." According to the record, "he falsely represents that the said address for the parliament goes on unanimously throw the whole nation, and that only a few courtiers and presbyterian ministers oppose it, but in vain, and that twice so many have signed since the proclamation anent petitioning as signed it before; and bids him take notice that there is one sent to court with a title different, to beguile the elect of the court, if it were possible; and that all the corporationes and all the gentlemen have signed the address, and himselfe among the rest; and, by Jove, it would produce a nationall and universall ———." This blank, it is subsequently stated, "cannot from such premisses be construed to have a less import then a nationall and universall overturning." On the 25th of January 1700 he appeared before the board, attended by David Dalrymple, David Cunningham, and James Nasmyth, his counsel learned in the law. The lord advocate and solicitor general were likewise present. A petition was presented by the defendant, "acknowledging his fault and folly in writing the letter lybelled upon, and declaring it was in cups, and without any design either against his Majesty or the government, and absolutely submitting to the privy councill." He received a reprimand from the lord chancellor; and having recovered the bond which he had previously given for his peaceable behaviour, and for his appearance, whenever he should be required, before the privy council, under the penalty of two hundred pounds sterling, he escaped from any further consequences of this frivolous prosecution.

In another action he appeared in the character of plaintiff. James Webster, one of the ministers of Edinburgh, and Robert Freebairn, an eminent printer and bookseller, "being accidentally in company of the magistrates, Mr Webster complained that Freebairn in his auctions sold wicked and prohibited books, and particularly Philostratus's life of Apollonius Tyanæus, wherein that vile impostor and magician is equalised, if not preferred to our blessed Saviour and his miracles, and which were greedily bought up by atheists and deists; and Mr Freebairn bidding him condescend, Mr Webster answered, Such as Doctor Pitcairn, who is known to be a professed deist; and for farther proof of it, in that same auction, many striving for that infamous book, one regretted that there were none bidding for the Bible, the doctor scoffingly answered, that it was no wonder it stuck in their hands, for 'verbum Dei manet in æternum:' which was a direct ridiculing the scriptures, and the Christian religion." When the bookseller communicated this information to Pitcairne, he lost no time in bringing an action against Webster before the sheriff, "for the redress of that atrocious injury, as tending to make him odious to all who own a God and revealed religion, and to ruin and break his employment." The action was removed by advocation to the court of session; and on the 18th of July 1712, "the Lords considered this process was managed with much zeal [apparently meaning heat, or animosity], and that Mr Webster was willing to give reasonable satisfaction; therefore, they recommend to the Justice Clerk, ordinary in the cause, to endeavour to settle the parties amicably."[4]

These judicial records furnish sufficient confirmation of the traditionary account, which imputes to Pitcairne the character of a profane jester. Dr Hutcheson has thought proper to supply us with another example of his indecent levity. "Many an orthodox Scotch presbyterian, which sect few accuse of disregard for the holy scriptures, has been put to it to preserve his gravity, upon hearing the application of scripture made by his countryman Dr Pitcairn, as he observed a croud in the streets about a mason, who had fallen along with his scaffold, and was over-whelmed with the ruins of the chimney which he had been building, and which fell immediately after the fall of the poor mason; 'Blessed are the dead which die in the Lord, for they rest from their labours, and their works follow them.'"[1] Such a story as this reflects but little credit on him who made, or who thus repeats the jest. "For the honour of the learned physician's memory," says Dr Beattie, "I hope the story is not true. Such wantonness of impiety, and such barbarity of insult, is no object of laughter, but of horror. And I confess, I should have no good opinion of any presbyterian, or of any person, who could find it difficult to preserve his gravity on hearing it."[2]

[4] Fountainhall's Decisions, vol. ii. p. 756.

From these unedifying details, we return to the prosecution of his literary history. His next publication was an ingenious lucubration, bearing the title of "Epistola Archimedis ad Regem Gelonem, Albæ Græcæ reperta anno æræ Christianæ 1688." This tract, consisting of 48 pages in octavo, has no imprint; but a copy belonging to the library of the College of Physicians contains in manuscript, "Amstelodami, typis Georgii Gallet, 1706." After this period he occupied himself with the preparation of a new edition of his dissertations; but before he could finish his task, his health was so much impaired, that he found himself incapable of effecting all that he intended. The edition was however published a few months before his death: "Archibaldi Pitcarnii Scoti Dissertationes Medicæ, quarum multæ nunc primum prodeunt. Subjuncta est Thomæ Boeri, M. D. ad Archibaldum Pitcarnium Epistola, qua respondetur Libello Astrucii Franci." Edinb. 1713, 4to. This volume contains fourteen dissertations. Prefixed is a dedication which the Jacobites must doubtless have construed in their own way: "Deo suo et Principi opus hoc consecrat Archibaldus Pitcarnius Scotus." The author's speculations on the subject of digestion had been controverted by Astruc; and here he receives an elaborate answer from Dr Bower, professor of mathematics in King's College, Aberdeen. The writer was evidently a man of learning, and Pitcairne has mentioned him in terms of particular friendship. The preface to the volume contains an extract of a letter from the second James Gregory, relating to the subject of contraction and compression, as discussed by Astruc. Of these dissertations an English translation was soon afterwards published by Dr Sewell and Dr Desaguliers.[3]

Dr Pitcairne died on Friday the 20th of October 1713, in the sixty-first year of his age. His remains were interred in Greyfriars churchyard, where his monument, a plain stone, was repaired in 1800. By his second wife, who survived till the year 1734, he left a son and four daughters. Before he attained the age of majority, the son engaged in the rebellion of 1715; and having been imprisoned in the Tower, he obtained his release in consequence of Dr Mead's very earnest intercession with Walpole. His letter, which mentions the father in terms of high admiration and gratitude, appears to have been entrusted to the distressed mother. Her son entered into the Dutch service; and, "on account of his own merit, and the memory of his father, he would probably have arrived at great promotion, had he not died soon after."[4] The second daughter, Janet, was married on the 12th of October 1731, to Alexander fifth earl of Kelly. She died on the 7th of June 1775. Two of her sons, Thomas Alexander and Archibald, succeeded to the title. The former was very eminent for his skill in music, and some of his compositions have very recently been published by Mr Sharpe.[5] His youngest brother, Andrew Erskine, was known as a man of wit and literature. All the three died unmarried; and the earldom of Kelly is now conjoined with that of Mar.

Four years after the death of the author, appeared "Archibaldi, Pitcarnii Medici celeberrimi Scoto-Britanni, Elementa Medicinæ physico-mathematica, libris duobus, quorum prior Theoriam, posterior Praxim exhibet, in Medicinæ Studiosorum gratiam delineata. Nunc primum in lucem edita." Lond. 1717, 8vo. Hagæ Com. 1718, 4to. Of the first book the concluding chapter had already been printed at the end of the Praxis Medica Boerhaaveana. The entire volume was "printed from a copy compiled out of the notes that had been taken by some of his pupils, together with some rough draughts taken from his papers, which, as they were never revised by him, he was always very careful to suppress during his life-time." It is therefore evident that this work was produced under very unfavourable circumstances. A collection of all his works in Latin prose, with the addition of a few poems, was afterwards published, under the title of "Archibaldi Pitcarnii, Medici celeberrimi Scoto-Britanni, Opera omnia Medica." Lugd. Bat. 1737, 4to.[6]

A posthumous production of a different class is commonly ascribed to the same learned author: "The Assembly; a Comedy. By a Scots Gentleman." Lond. 1722, 8vo. After an interval of many years, the same drama was again printed, and without any reference to a former edition: "The Assembly; or, Scotch Reformation; a Comedy, as it was acted by the Persons in the Drama. Done from the original manuscript, written in the year 1692." Edinb. 1766, 12mo. This edition contains a long preface, omitted in the first. Of the two editions, the Biographia Dramatica, vol. ii. p. 40, has made two distinct comedies. The preface represents this comedy as the composition of more than one author. "This play was begun just after the king of France took Mons, as is clearly intimated in the first scene; but, by reason of some gentlemens going to the country, who were concerned in it, it lay dormant four months; then it was set about again, and was very soon compleated. We confess it was hastily huddled together; for we were not a fortnight about the whole work, by reason of multitude of business the authors were entangled in." According to this account, Pitcairne is only entitled to a share in the honour or discredit of such a production. It is a rabid effusion of Jacobitism, less remarkable for wit and humour than for ribaldry and profanity. He is likewise supposed to be the author of another work, which has recently been edited by Mr Kinloch: "Babell; a Satirical Poem, on the Proceedings of the General Assembly in the year M.DC.XCII." Edinb. 1830, 4to. The manuscript copies, of which several have been preserved, bear the initials of his name. The poem relates to the same subject as the comedy, and it evinces the same spirit of animosity to the Whigs and presbyterians. The author's rhymes are sufficiently familiar and negligent.

As a writer of Latin verses, he appears to much more advantage. Many of his poems were printed in a fugitive form, but not published by himself. There is however a collection of his "Poemata Selecta," consisting of fourteen pages in folio, but without a date, and without any formal title. An edition was afterwards published by Ruddiman;[1] with whom he had accidentally become acquainted at Laurencekirk, and whom he had liberally encouraged to transfer his residence to Edinburgh. On the death of his friend and benefactor the editor has inserted an elegy, which concludes with this distich:

> Ergo vale, lux Scotigenum, princepsque medentum,
> Musarum columen deliciæque, vale.

The Latin poems of Pitcairne have been extravagantly extolled by some of his countrymen.[2] They are chiefly to be commended for their epigrammatic merit, their point and pungency. Many of his verses are elegantly turned; but they are frequently rendered obscure by his allusions to circumstances of too private a nature to admit of easy explanation, after an interval of more than a century. Some of the allusions are explained by himself, in a curious paper which has recently been printed for the first time; others by Lord Hailes, in an article communicated to a periodical work.[3] This eminent person, whose extensive learning was founded on very accurate and critical scholarship, entertained the design of publishing an edition of Pitcairne's Latin poems, with annotations; and some of the materials which he collected have fortunately been preserved in this form. Several of those poems were written in the name of Walter Danistone, who appears to have been one of the author's friends. His epitaph on Viscount Dundee was translated by Dryden. Another of his poems became very conspicuously known by the easy and elegant paraphrase of Prior, whom Dr Drummond has described as his old comrade. It commences with these verses:

> Studious the busy moments to deceive,
> That fleet between the cradle and the grave,
> I credit what the Grecian dictates say,
> And Samian sounds o'er Scotia's hills convey.[4]

The personal character of Dr Pitcairne has been variously represented. That he was a man of a liberal and benevolent disposition, is sufficiently established by the testimony of his contemporaries. "In the business of his profession," says Dr Sewell, "he was always ready to serve every one to the utmost of his power, and even to contribute to their health at the danger of his own. He was a man of too good sense to be a humourist in physic, or refuse attendance out of pique, or prejudice, or affectation: he understood the value of life too well to sacrifice it to caprice and humour. There is one thing more remarkable of him; that he was not at all concerned about fees, and frighted from his duty by the sight of poverty in his patient; nay, he went with greater chearfulness to those from whom he could expect nothing but good will, than to persons of the highest condition. Besides, in cases which seemed to require that assistance, he not only gave away his skill and medicines, but extended his generosity for the provision of other conveniences for the sick, and left the marks of his charity, as well as of the liberality of his art, behind him. The virtue of charity was really so much his own, in the use of it, that he contrived a most secret and decent manner of conveying his benevolence, and relieved many who knew not their benefactor. In short, he was one of the greatest and most useful men in his profession this age has produced; of a free and universal genius, a good orator, poet, and philosopher. He was of a pleasant, engaging humour. Life sate very easy upon him in all its circumstances. He despised many, but hated none. He loved his friends, and laughed at his enemies." This characteristic account, written in 1715, is confirmed by Dr Drummond, who soon after the death of Pitcairne wrote in the following terms to their mutual friend Dr Bower: "Though he got much money by his extraordinary skill and practice in physic, yet he did not hoard up riches, but dealt liberally to his poor friends and relations, and also gave frankly and generously to young men of good spirits, who were in narrow circumstances. So he was not only a learned man, but a Mæcenas too, and an encourager of learning through the whole course of his life. His great care and commiseration of the poor ought not to be omitted. He not only gave them medicine freely, but money too, for their relief and support; and this kind of charity is one of the best effects of pure and undefiled religion. Besides, he did not spend all his money on his pleasure and freaks, but erected a most noble library, which, for the great variety and excellent collection of books, is one of the finest I have seen belonging to any private man in the kingdom."[5] After his death, his library was purchased by the czar of Muscovy. In his personal habits, he appears to have been somewhat inclined to jovialty. At that period, professional men were more accustomed to frequent taverns than they are at present; and his poems contain various allusions to his social haunts and companions. Of the levity of his conversational wit we have already seen more than one specimen. His profane jests exposed him to the most injurious imputations, and he was very frequently represented as a professed unbeliever. But whatever doubts might be entertained as to the soundness of his creed, they are completely removed by his verses written on Christmas-day; and Dr Drummond has stated that, during his last illness, he continued in the greatest tranquillity of mind, and evinced just apprehensions of God and religion. His political sentiments do not here seem to require much notice. It is not easy to admire the political wisdom or moral perception of a man whose heroes were King James, Viscount Dundee, and Sir George Mackenzie.

As a medical practitioner, he attained to much more extensive and lucrative employment than any former physician resident in Scotland. He left behind him a reputation which was not confined to his native country. He belongs to the mathematical and mechanical school of physic; and, in the annals of medicine, his name is honourably mentioned with those of Borelli, Bellini, and other great masters of the mathematico-medical art.[6] They all contended for the application of mathematical reasoning and demonstration to subjects of anatomy and physiology. John Bernoulli, who belonged to a very distinguished family, not only adopted their method in his treatise *De Motu Musculorum*, but he even maintained in verse the cause of the mathematical physicians.

Nunc eat indoctus, doctoque is suadeat orbi,
Nullam arti medicæ ferre mathesin opem:
Scilicet ut vulpes, caudam quæ amiserat, illa
Ne pudibunda foret syrmate sola carens.
Vestrum, ait, O sociæ, deponite inutile membrum!
Ast abiit salsis exagitata jocis.

Dr Pitcairne seems to have improved both the theory and the practice of physic. He made some advances in completing Harvey's speculations on the circulation of the blood, and in explaining the process of secretion. He laboured with great energy to explode the errors of former writers, who maintained the chemical doctrines of a corrosive menstruum in the stomach, and a certain acidity in the blood that required to be corrected by an alkali. If he relied too much on the aid of mathematics as an instrument of medical science, he at least contributed, by his conspicuous example, to recommend a clear and concise mode of reasoning, to which preceding writers did not usually attain. Boerhaave, the most illustrious of his successors in the chair at Leyden, bestowed very high commendation on his first collection of dissertations;[1] and Dr Mead, whose name stood unrivalled in his own age and nation, evidently regarded his works as exhibiting a model of disquisition in their own department of science.[2] (x.)

PITCH, a tenacious oily substance, drawn chiefly from pines and firs, and used in shipping, medicine, and various arts; or it is more properly tar inspissated by boiling it over a slow fire.

PITCHING, in naval affairs, may be defined the vertical vibration which the length of a ship makes about her centre of gravity; or the movement by which she plunges her head and after-part alternately into the hollow of the sea. This motion may proceed from two causes; the waves which agitate the vessel, and the wind upon the sails, which makes her stoop to every blast. The one depends absolutely upon the agitation of the sea, and is not susceptible of inquiry; the other is occasioned by the inclination of the masts, and may be submitted to certain established maxims.

PITHIVIERS, an arrondissement of the department of the Loiret, in France, extending over 475 square miles. It comprehends five cantons, divided into 108 communes, and contains 56,800 inhabitants. The capital is the city of the same name, situated in a fertile district, watered by the River Deuf. It contains 720 houses, with 3430 inhabitants, who deal largely in wine, brandy, and other products of the surrounding country. Long. 2. 10. 4. E. Lat. 48. 10. 26. N.

PITHO, in fabulous history, the goddess of persuasion amongst the Romans. She was supposed to be the daughter of Mercury and Venus, and was represented with a diadem on her head, to intimate the influence she exercised over the hearts of men. One of her arms appeared raised in the attitude of an orator haranguing a public assembly; and in the other she held a thunderbolt and fetters, made with flowers, to signify the powers of reasoning and the attractions of eloquence. A caduceus, as a symbol of persuasion, appeared at her feet, and beside it were the writings of Demosthenes and Cicero, the two most celebrated orators amongst the ancients.

PITHOU, Peter, a Frenchman of great literary eminence, was descended from an ancient and noble family in Normandy, and born at Troyes in 1539. His taste for literature early showed itself, and his father cultivated it to the utmost. He first studied at Troyes, and was subsequently sent to Paris, where he became the scholar and friend of Turnebus. Having finished his pursuits in languages and the belles lettres, he was removed to Bourges, and placed under Cujacius to study the civil law. His father was well skilled in his profession, and has left a favourable specimen of his judgment in the advice he gave to his son as to the best method of acquiring a knowledge of law; which was, not to spend his time and labour upon commentators, but to confine his reading chiefly to original writers. The latter made so rapid a progress, that at the age of seventeen he was able to speak *extempore* upon the most difficult questions; and his master was not ashamed to own, that even he himself had learned some things of his pupil. Cujacius afterwards removed to Valence, whither Pithou followed him, and continued to profit by his lectures until the year 1560. He then returned to Paris, and frequented the bar of the parliament there, in order to combine a knowledge of practical forms and usages with his theoretical acquisitions.

In 1563, being then only twenty-four, Pithou published his *Adversaria Subcesiva*, a work highly applauded by Turnebus, Lipsius, and other learned men, and which laid the foundation of that extensive fame which he subsequently acquired. Soon after this, Henry III. advanced him to some considerable posts, in which, as well as at the bar, he acquitted himself most creditably. Pithou, being a Calvinist, narrowly escaped being involved in the massacre of St Bartholomew in 1572; for he was in Paris when this tragedy took place, and in the same lodgings with several Huguenots, who were all killed. It seems indeed to have frightened him out of his religion, which he soon afterwards abjured, at the same time openly embracing the Catholic faith. At a subsequent period, he attended the Duke of Montmorency into England; and upon his return, his great sagacity, invincible good nature, and amiable manners, rendered him a kind of oracle to his countrymen, and even to foreigners, who consulted him upon all important occasions. An instance of this we have in the conduct of Ferdinand, the Grand Duke of Tuscany, who not only consulted him, but even submitted to his determination in a point contrary to his interests. Henry III. and Henry IV. were greatly indebted to him for combating the League in the most intrepid manner, and for many other services, in which he had recourse to his pen as well as to other means.

Pithou died upon his birth-day in the year 1596, leaving a wife, whom he had married in 1579, and several children. De Thou says he was the most excellent and accomplished man of the age in which he lived; and all the learned have concurred in speaking well of him. He collected a very valuable library, containing a variety of rare manuscripts, as well as printed books; and he took many precautions, but in vain, to prevent its being dispersed after his death. He published a great number of works upon law, history, and classical literature; and he gave several new and correct editions of ancient writers. He was the first who made the world acquainted with the Fables of Phædrus, which were utterly unknown till they were published from a manuscript in his possession. His numerous works belong to the civil and the canon law, to history, and to literature properly so called. As a jurisconsult, Lefebvre observed of him, "Cujacius discipulo præripuit ne primis jurisconsultus esset; ille præceptori ne solus." He was closely connected in friendship with Cujacius, and, after the death of the latter, he published his master's Observations on the Roman Law, accompanied with Remarks and Annotations of his own. We are also indebted to him for the discovery of the laws of the Visigoths, which he published in 1579.

---

[1] "Hæc scripta optima sunt et perfecta, sive legas dissertationem de motu sanguinis per pulmones, sive alia opuscula, sive ultimum tractatum de opio." (Boerhaave Methodus Studii Medici, emaculata et accessionibus locupletata ab Haller, tom. i. p. 569. Amst. 1751, 2 tom. 4to.) Haller describes him as "acris homo et confidens, iatro-mathematicus, Jacobo II. addictissimus." (Bibliotheca Anatomica, tom. i. p. 761. Lugd. Bat. 1774–7, 2 tom. 4to.)

[2] "The Dissertations of Dr Pitcairne, the honour of the profession of Scotland, are a convincing proof of the advantage of such a mechanical way of reasoning; nor could malice itself deny this, were not ignorance in confederacy with it, which will secure any one from being benefited by the most useful demonstrations." (Mead's Mechanical Account of Poisons, p. xvii.)

His principal writings on the canon law are, 1. Corpus Juris Canonici, 1687, in two vols. folio; 2. Codex Canonum vetus ecclesiasticum, in folio; 3. Gallicæ Ecclesiæ in schismate Status, in 8vo; and, 4. A Treatise on the Liberties of the Gallican Church. Pithou also published an edition of the Capitularies, which has since been surpassed by that of Balzuc; a series of French annalists, from the eighth to the thirteenth century; Memoirs of the Counts de Champagne and de Brie; the Historical Fragments of St Hilarius, containing curious particulars respecting the Council of Rimini; and the writings of several ancient doctors of the Gallican Church, of which several had until then remained inedited. We are likewise indebted to him for editions, from the best manuscripts, of several ancient geographers, the Itinerary from Bordeaux to Jerusalem, the works of Salvian, the Declamations of the Roman rhetoricians, Juvenal and Persius, Petronius, and the moral Distichs attributed to Cato. He enriched literature, as already mentioned, with the Fables of Phædrus, the manuscript of which had been discovered by his brother, and also with the *Pervigilium Veneris*, both previously unknown. Lastly, he amused himself with paying court to the Latin muses; but his poetry, like his eloquence, had no other ornament than it derived from the thoughts.

PITISCUS, Samuel, a learned philologist, was born at Zutphen, in Dutch Gueldres, and became rector of the college of that city, and afterwards of St Jerome at Utrecht, where he died on the 1st of February 1717, at the age of ninety. He wrote, 1. Lexicon Latino-Belgicum, 1704, in 4to; 2. Lexicon Antiquitatum Romanarum, in quo ritus et antiquitates, tum Græcis et Romanis communes, tum Romanis particulares exponuntur, Leeuwarden, 1713, in two vols. folio; and he published good editions, with prefaces and notes, of Quintus Curtius, Polyhistor, Solinus, with the Observations of Salmasius on Pliny, Suetonius, Aurelius Victor, the Pantheon Mythicum, and the *Antiquitates Romanæ* of Rosini. In 1685, Pitiscus announced a *Lexicon Catullo-Tibullo-Propertianum;* but this work, which his friends regarded as a mine of erudition, never appeared.

PITKEATHLY, or Pitcaithly, a rural watering-place, much resorted to, in Perthshire.

PITOT, Henry, descended of a noble family of Languedoc, was born at Aramont, in the diocese of Usez, on the 29th of May 1695, and died there on the 27th of December 1771, aged seventy-six. He studied the mathematics without a master, and went to Paris in 1718, where he formed a close friendship with the illustrious Reaumur. In 1724 he was admitted a member of the Royal Academy of Sciences at Paris, and in a few years he rose to the rank of pensioner. Besides a great number of Memoirs printed in the collection of that society, he published in 1731 the Theory of the Working of Ships, in one volume 4to; a work of considerable merit, which was translated into English, and caused the author to be admitted into the Royal Society of London. In the year 1740, the states-general of Languedoc made choice of him as their chief engineer, and at the same time gave him the appointment of inspector-general of the canal which unites the two seas. That province is also indebted to him for several monuments of his genius, which will transmit his name with lustre to posterity. The city of Montpellier being in want of water, Pitot brought from a distance of three leagues the water of two springs, which furnish a plentiful supply of that necessary article. The water is brought to the magnificent Place du Peyron, and thence distributed throughout the city. This work is the admiration of all strangers. The celebrated Marshal de Saxe was the great patron and friend of Pitot, who had taught him the mathematics. In 1754 he was honoured with the order of St Michael. In the year 1735 he married Marie Leonine Pharambier de Sabballoua, descended of a very ancient noble family of Navarre; but by this marriage he had only one son, who became advocate-general of the court of accounts, aids, and finances of Montpellier. Pitot was a practical philosopher, and a man of uncommon probity and candour. He was also a member of the Royal Society of Sciences of Montpellier, before which his eloge was pronounced in 1772, by M. de Ratte, perpetual secretary, in presence of the states of Languedoc; and, in the Royal Academy of Sciences of Paris, the same honour was done him by the Abbé de Fouché, who was then secretary.

PITS, John, the biographer, was born in 1560, at Aulton, in Hampshire, and educated at Wykeham's school, near Winchester, where he remained until he was about eighteen years of age, when he was sent to New College, Oxford, and admitted a probationer fellow. Having continued in that university not quite two years, he left the kingdom as a voluntary exile, and retired to Douay, whence he proceeded to the English college at Rheims, where he remained about a year, and then went to Rome, where he continued a member of the English college nearly seven years, at the expiration of which he was ordained priest. In 1589 he returned to Rheims, where, during two years, he taught rhetoric and the Greek language. He then quitted Rheims on account of the civil war in France, and retired to Pont-à-Mousson, in Lorraine, where he took the degrees of master of arts and bachelor in divinity. From this he travelled into Germany, and resided a year and a half at Triers, where he commenced licentiate in his faculty. He then visited several of the principal cities in Germany, and, continuing three years at Ingoldstadt, in Bavaria, took the degree of doctor in divinity. Having made the tour of Italy, he returned once more to Lorraine, where he was patronised by the cardinal of that duchy, who preferred him to a canonry of Verdun; and about two years afterwards he became confessor to the Duchess of Cleves, daughter of the Duke of Lorraine. During the leisure he enjoyed in this employment, he wrote in Latin the lives of the kings, bishops, apostolical men, and writers of England. The last of these, commonly known and quoted by the title of *De illustribus Angliæ scriptoribus*, was published after his death. The three others still remain in manuscript amongst the archives of the collegiate church of Liverdun. The Duke of Cleves having died about twelve years after Pits had been confessor to the duchess, the latter returned to Lorraine, attended by our author, who was promoted to the deanery of Liverdun, which, with a canonry and officialship, he enjoyed till the close of his life. He died in 1616, and was buried in the collegiate church. Pits was undoubtedly a scholar, and not an inelegant writer; but he is justly accused of ingratitude to Bale, from whom he borrowed his materials, without acknowledgment. He quotes Leland with great familiarity, without ever having seen his book; his errors are innumerable, and his partiality to the Catholic writers is obvious; nevertheless we are indebted to him for his account of several Catholic authors who lived abroad at the beginning of the Reformation.

PITT, Christopher, an English poet, celebrated for his translation of Virgil's Æneid, was born in the year 1699. Having studied four years at New College, Oxford, he was presented to the living of Pimperne, in Dorsetshire, which he held during the remainder of his life. He had so poetical a turn, that whilst he was a school-boy he wrote two large folios of manuscript poems, one of which contained an entire translation of Lucan. He was much esteemed while at the university, particularly by the celebrated Dr Young, who used familiarly to call him his son. Next to his translation of Virgil, Mr Pitt gained the greatest reputation by his excellent English version of Vida's Art of Poetry. This amiable poet died in the year 1748, without leaving, it is said, one enemy behind him.

Pitt, *William*, first Earl of Chatham, a celebrated British statesman and orator, was born on the 15th of November 1708. He was the youngest son of Mr Robert Pitt of Boconnock, in Cornwall, and grandson of Mr Thomas Pitt, governor of Fort St George in the East Indies in the reign of Queen Anne, who sold an extraordinary diamond to the king of France for L.135,000, and thus obtained the name of *Diamond Pitt*. The subject of this notice was educated at Eton, whence, in January 1726, he was removed to Trinity College, Oxford, which he entered as a gentleman commoner. Here the superiority of his mind soon attracted notice, and he was also remarked for his powers of elocution; but, at the age of sixteen, he experienced the first attacks of an hereditary and incurable gout, which continued at intervals to torment him during the remainder of his life. He quitted the university without taking a degree, and visited France and Italy, whence he returned without having received much benefit from his excursion. His father was now dead, and as he had left very little to the younger children, it became necessary that William should choose a profession. He decided for the army, and a cornet's commission was procured for him in the Blues. But, small as his fortune was, his family had the power and the inclination to serve him. At the general election of 1734, his elder brother Thomas was chosen both for Old Sarum and for Oakhampton. When parliament met in 1735, Thomas made his election for Oakhampton, and William was returned for Old Sarum. At the time when he obtained a seat in parliament he was not quite twenty-one years of age. The intention of bringing him thus early into parliament was to oppose Sir Robert Walpole, who had now been fourteen years at the head of affairs. In fact, his abilities soon attracted notice, and he spoke with great vehemence against the Spanish convention in 1738. It was on the occasion of the bill for registering seamen in 1740, which he opposed as arbitrary and unjustifiable, that he is said to have made his celebrated reply to Mr Walpole, who had taunted him on account of his youth; but the language of that reply, as it now stands, is not the diction of Pitt, who may have said something like what is ascribed to him, but of Dr Johnson, who then reported, or rather wrote, the debates for the Gentleman's Magazine. In 1746 Pitt was appointed joint vice-treasurer of Ireland, and in the same year treasurer and paymaster-general of the army, and a privy-councillor. The office of paymaster he discharged with such inflexible integrity, even refusing many of the ordinary perquisites of office, that his bitterest enemies could lay nothing to his charge, and he soon became the darling of the people. At this time he was poor enough; but Heaven directed to him a portion of wealth altogether unexpected. The old Duchess of Marlborough, who carried to the grave the reputation of being decidedly the best hater of her time, and who most cordially detested Walpole and his associates, left him a legacy of L.10,000, in consideration of "the noble defence he had made for the support of the laws of England, and to prevent the ruin of his country." In the year 1755, Mr Pitt, deeming it necessary to offer a strong opposition to the continental connections then formed by the ministry, resigned his places, and remained some time out of office. But his resignation having alarmed the people, he was, in December 1756, called to fill a higher office, and appointed secretary of state. In this situation, however, he was more successful in obtaining the confidence of the public than in conciliating the favour of the king, some of whose predilections he had conceived himself bound to oppose. The consequence was, that soon afterwards Mr Pitt was removed from office, whilst Mr Legge, with some others of his friends, were at the same time dismissed. But the nation had a mind not to be deprived of his services. The most exalted notion had been formed of him throughout the country; his patriotism was believed to be as pure and disinterested as his abilities and eloquence were confessedly transcendent; and his colleagues shared in the same general favour. In a word, the opinion of the country was so strongly expressed, both directly and indirectly, that the king thought it prudent to yield; and, on the 25th of June 1757, Mr Pitt was again appointed secretary of state, Mr Legge became chancellor of the exchequer, and the other arrangements were made conformably to his wishes. Mr Pitt was now in effect prime minister; and the change which soon took place in the aspect of public affairs evinced the ability of his measures, and the vigour of his administration. His spirit animated the whole nation; and his activity pervaded every department of the public service. His plans were ably conceived, and promptly executed; and the depression, which had been occasioned by want of energy in the cabinet, and ill success in the field, was followed by exertion, confidence, and triumph. The whole fortune of the war was changed. In every quarter of the globe success attended our arms. The boldest attempts were made both by land and by sea, and almost every attempt proved fortunate. In America, the French lost Quebec; in Africa, they were deprived of their principal settlements; their power was abridged in the East Indies; in Europe their armies were defeated; and, to render their humiliation more complete, their navy, their commerce, and their finances were almost ruined. Amidst this full tide of success George II. died, on the 25th of October 1760, and was succeeded by George III., who ascended the throne at a time when the French court had just succeeded in obtaining the cooperation of Spain.

The treaty commonly called family compact had been secretly concluded; but the English minister, correctly informed of the hostile intentions of Spain, determined to anticipate that power, and strike a blow before this new enemy should be fully prepared for action. He therefore proposed in the council an immediate declaration of war against Spain; urging forcibly that the present was the favourable moment for humbling the whole house of Bourbon. But when he stated this opinion in the privy council, the other ministers, averse to so bold a measure, opposed the proposition of the premier, alleging the necessity of mature deliberation before declaring war against so powerful a state. Irritated by the unexpected opposition of his colleagues, Pitt replied, "I will not give them leave to think; this is the time, let us crush the whole house of Bourbon. But if the members of this board are of a different opinion, this is the last time I shall ever mix in its councils. I was called into the ministry by the voice of the people, and to them I hold myself answerable for my conduct. I am to thank the ministers of the late king for their support; I have served my country with success; but I will not be responsible for the conduct of the war any longer than while I have the direction of it." To this declaration the president of the council answered, "I find the gentleman is determined to leave us; nor can I say that I am sorry for it, since he would otherwise have certainly compelled us to leave him. But if he is resolved to assume the right of advising his majesty, and directing the operations of the war, to what purpose are we called to this council? When he talks of being responsible to the people, he talks the language of the House of Commons, and forgets that at this board he is responsible only to the king. However, though he may possibly have convinced himself of his infallibility, still it remains that we should be equally convinced before we can resign our understandings to his direction, or join with him in the measure he proposes." The opposition he thus encountered the nation attributed to the growing influence of Lord Bute. But however this may have been, Mr Pitt was a man of too high, not to say imperious a temper, to remain as the nominal head of a cabinet which he was no longer able to direct. Accordingly, on the 5th of October 1761, he resigned all his appointments; and, as some reward for his services, his wife was created Baroness Chatham in her own right, whilst a pension of L.3000 a year was settled on the lives of himself, his lady, and his eldest son.

No fallen minister, if fallen he could be called, ever carried with him more completely the confidence and regret of the nation, whose affairs he had so successfully administered. But at this time the king was also popular; and the war being continued by his new ministers with vigour and success, no discontent appeared until after the conclusion of the peace. The impulse given by Mr Pitt had carried them forward in the same direction which he had pursued; but they were equally incapable of profiting by the advantages which had been already gained, or of prosecuting the war until the objects for which it was originally undertaken should be accomplished. The victories gained over France and Spain having greatly elated the nation, the feeling which almost universally prevailed amongst the people was, that we should either dictate peace as conquerors, or continue the war until our adversaries were more effectually humbled. This was likewise Mr Pitt's opinion. Accordingly, when the preliminaries of peace came to be discussed in parliament, he went down to the House of Commons, though suffering severely from an attack of the gout, and spoke for nearly three hours in the debate; giving his opinion on each article of the treaty in succession, and, upon the whole, maintaining that it was inadequate to the conquests of our arms, and the just expectations of the country. Peace was, however, concluded on the 10th of February 1763, and Mr Pitt continued unemployed.

After his resignation in 1761, Mr Pitt conducted himself in a manner worthy of his high character. So far from giving a vexatious and undiscriminating opposition to the ministry which had succeeded his own, he maintained his popularity in dignified retirement, and came forward only when questions of great importance were to be discussed. One of these occurred in 1764, on the subject of general warrants, the illegality of which he denounced with all the energy and vigour of his eloquence. Another occasion, when he came forward in all his strength, was the consideration of the discontents which had arisen on account of the stamp-act. In March 1766, the repeal of that act having been proposed by the Rockingham ministry, Mr Pitt, though not connected with them, ably supported the measure, which was carried, but whether prudently or the contrary is still a matter of dispute. About this time Mr Pitt had devised to him by will a considerable estate in Somersetshire, the property of Sir William Pynsent of Burton-Pynsent in that county, who, from admiration of his public character, disinherited his own relations, in order to bequeath to him the bulk of his fortune. After the dissolution of the Rockingham ministry, a new administration was formed, and, in 1766, Mr Pitt was appointed lord privy seal. At the same time he was created a peer by the titles of Viscount Pitt of Burton-Pynsent in the county of Somerset, and Earl of Chatham in the county of Kent.

Whatever might be his motives in accepting a peerage, it is certain that it proved very prejudicial to his character, and that in consequence he sank as much in popularity as he rose in nominal dignity. The great commoner, as he was sometimes called, had formed a rank for himself, on the basis of his talents and exertions, which titular honours might obscure, but could not illustrate; and, with the example of Pulteney before him, he should have been careful to preserve it untarnished by empty distinctions, shared by the mean and the worthless as well as by the great, the gifted, and the good. Lord Chatham, however, did not long continue in office after being elevated to the peerage. On the 2d of November 1768, he resigned the place of lord privy seal, and never afterwards held any public employment; nor does he appear to have been at all desirous of returning to office. He was now sixty, and the gout, by which he had so long been afflicted, disabled him, by its frequent and violent attacks, for close and regular application to business. In the intervals of his disorder, however, he failed not to exert himself upon questions of great magnitude; and, in 1775, 1776, and 1777, he most strenuously opposed the measures pursued by the ministers in the contest with America. His last appearance in the House of Lords was on the 2d of April 1778. He was then very ill, and much debilitated; but the question was important, being a motion of the Duke of Richmond to address his majesty to remove the ministers, and to make peace with America on any terms. His lordship made a long speech, in which he summoned up all his remaining strength to pour out his disapprobation of a measure so inglorious. But the effort overcame him, for in attempting to rise a second time, he fell down in a convulsive fit; and though he recovered for the time, his disorder continued to increase until the 11th of May, when he expired at his seat at Hayes. His death was lamented as a national loss. As soon as the news reached the House of Commons, which was then sitting, Colonel Barré made a motion, that an address should be presented to his majesty, requesting that the Earl of Chatham should be buried at the public expense. But Mr Rigby having proposed the erection of a statue to his memory, as more likely to perpetuate the sense of his great merits entertained by the public, this was unanimously agreed to. A bill was soon afterwards passed, by which L.4000 a year was settled upon John, now Earl of Chatham, and the heirs of the late earl to whom that title might descend. His lordship was married in 1754 to Lady Hester, sister of Earl Temple, by whom he had three sons and two daughters.

The principal outlines of Pitt's character have been variously sketched, sometimes with, and sometimes without, any depth of shadow. The truth is, that there scarcely ever lived a person who had less claim to be painted altogether *en beau*, or who so little merited unsparing censure. "That he was a great man cannot for a moment be doubted; but his was not a complete and well-proportioned greatness. The public life of Hampden or of Somers resembles a regular drama, which can be criticised as a whole, and every scene of which is to be viewed in connection with the main action. The public life of Pitt, on the other hand, is a rude though striking piece, abounding in incongruities, and without any unity of plan, but redeemed by some noble passages, the effect of which is increased by the tameness or extravagance of what precedes and of what follows. His opinions were unfixed; and his conduct, at some of the most important conjunctures of his life, was evidently determined by pride and resentment. He had one fault, which of all human faults is most rarely found in company with true greatness. He was extremely affected. He was an almost solitary instance of a man of real genius, and of a brave, lofty, and commanding spirit, without simplicity of character. He was an actor in the closet, an actor in the council, an actor in parliament; and even in private society he could not lay aside his theatrical tones and attitudes. We know that one of the most distinguished of his partisans often complained that he could never obtain admittance to Lord Chatham's room till everything was ready for the representation;

till the light was thrown with Rembrandt-like effect on the head of the illustrious performer; till the flannels had been arranged with the air of Grecian drapery, and the crutch placed as gracefully as that of Belisarius or Lear."[1] Yet, with all his faults and affectations, he possessed, in a very extraordinary degree, many of the elements of true greatness. He had splendid talents, strong passions, quick sensibility, and vehement enthusiasm for the grand and the beautiful. There was something about him which ennobled even tergiversation itself. He often went wrong, very far wrong; but, amidst the abasement of error, he still retained what he had received from nature, "an intense and glowing mind." In an age of low and despicable prostitution, the age of Dodington and Sandys, it was something to have a man who might perhaps, under some strong excitement, have been tempted to ruin his country, but who never would have stooped to pilfer from her; a man whose errors arose, not from a sordid desire of gain, but from a fierce thirst of power, glory, and vengeance. "History owes him this attestation, that, at a time when anything short of direct embezzlement of the public money was considered as quite fair in public men, he showed the most scrupulous disinterestedness; that, at a time when it seemed to be generally taken for granted that government could be upheld only by the basest and most immoral arts, he appealed to the better and nobler parts of human nature; that he made a brave and splendid attempt to do, by means of public opinion, what no other statesman of his day thought it possible to do except by means of corruption; that he looked for support, not, like the Pelhams, to a strong aristocratical connection, not, like Bute, to the personal favour of the sovereign, but to the middle class of Englishmen; that he inspired that class with a firm confidence in his integrity and ability; that, backed by them, he forced an unwilling court and an unwilling oligarchy to admit him to an ample share of power; and that he used his power in such a manner as clearly proved that he had sought it, not for the sake of profit or patronage, but from a wish to establish for himself a great and durable reputation by means of eminent services rendered to the state."[2]

A great many unmeaning phrases have been employed, and much rhetorical exaggeration has been expended, in attempts to characterize Lord Chatham's style of eloquence. The following estimate by Mr Macaulay, from whom we have borrowed some of the foregoing observations, is at once deep, discriminating, and brilliant.

"In our time the audience of a member of parliament is the nation. The three or four hundred persons who may be present when a speech is delivered, may be pleased or disgusted by the voice and action of the orator; but in the reports which are read the next day by hundreds of thousands, the difference between the noblest and the meanest figure, between the richest and the shrillest tones, between the most graceful and the most uncouth gesture, altogether vanishes. A hundred years ago, scarcely any report of what passed within the walls of the House of Commons was suffered to get abroad. In those times, therefore, the impression which a speaker might make on the persons who actually heard him was everything. The impression out of doors was hardly worth a thought. In the parliaments of that time, therefore, as in the ancient commonwealths, those qualifications which enhance the immediate effect of a speech were far more important ingredients in the composition of an orator than they would appear to be in our time. All those qualifications Pitt possessed in the highest degree. On the stage, he would have been the finest Brutus or Coriolanus ever seen. Those who saw him in his decay, when his health was broken, when his mind was jangled, when he had been removed from that stormy assembly of which he thoroughly knew the temper, and over which he possessed unbounded influence, to a small, a torpid, and an unfriendly audience, say that his speaking was then, for the most part, a low monotonous muttering, audible only to those who sate close to him; that, when violently excited, he sometimes raised his voice for a few minutes, but that it soon sank again into an unintelligible murmur. Such was the Earl of Chatham; but such was not William Pitt. His figure, when he first appeared in parliament, was strikingly graceful and commanding, his features high and noble, his eye full of fire. His voice, even when it sank to a whisper, was heard to the remotest benches; when he strained it to its full extent, the sound rose like the swell of the organ of a great cathedral, shook the house with its peal, and was heard through lobbies and down stair-cases, to the court of requests and the precincts of Westminster Hall. He cultivated all these eminent advantages with the most assiduous care. His action is described by a very malignant observer as equal to that of Garrick. His play of countenance was wonderful; he frequently disconcerted a hostile orator by a single glance of indignation or scorn. Every tone, from the impassioned cry to the thrilling aside, was perfectly at his command. It is by no means improbable, that the pains which he took to improve his great personal advantages had, in some respects, a prejudicial operation, and tended to nourish in him that passion for theatrical effect which was one of the most conspicuous blemishes in his character.

"But it was not solely or principally to outward accomplishments that Pitt owed the vast influence which, during nearly thirty years, he exercised over the House of Commons. He was undoubtedly a great orator; and from the descriptions of his contemporaries, and the fragments of his speeches which still remain, it is not difficult to discover the nature and extent of his oratorical powers.

"He was no speaker of set speeches. His few prepared discourses were complete failures. The elaborate panegyric which he pronounced on General Wolfe was considered as the very worst of all his performances. 'No man,' says a critic, who had often heard him, 'ever knew so little what he was going to say.' Indeed, his facility amounted to a vice; he was not the master, but the slave of his own speech. So little self-command had he when once he felt the impulse, that he did not like to take part in a debate when his mind was full of an important secret of state. 'I must sit still,' he once said to Lord Shelburne on such an occasion, 'for when once I am up, everything that is in my mind comes out.'

"Yet he was not a great debater. That he should not have been so when he first entered the House of Commons, is not strange; scarcely any person has ever become so without long practice and many failures. It was by slow degrees, as Burke said, that Mr Fox became the most brilliant and powerful debater that parliament ever saw. Mr Fox himself attributed his own success to the resolution which he formed when very young, of speaking, well or ill, at least once every night. 'During five whole sessions,' he used to say, 'I spoke every night but one; and I regret only that I did not speak that night too.' Indeed it would be difficult to name any great debater who has not made himself a master of his art at the expense of his audience.

"But as this art is one which even the ablest men have seldom acquired without long practice, so it is one which men of respectable abilities, with assiduous and intrepid practice, seldom fail to acquire. It is singular that, in such an art, Pitt, a man of splendid talents, great fluency, and dauntless boldness, whose whole life was passed in parliamentary conflict, and who, during several years, was the leading minister of the crown in the House of Commons, should never have attained to high excellence. He spoke without premeditation; but his speech followed the course of his own thoughts, and not that of the previous discussion. He could, indeed, treasure up in his memory some detached expression of an hostile orator, and make it the text for sparkling ridicule or burning invective. Some of the most celebrated bursts of his eloquence were called forth by an unguarded word, a laugh, or a cheer. But this was the only sort of reply in which he appears to have excelled. He was perhaps the only great English orator who did not think it an advantage to have the last word, and who generally spoke by choice before his most formidable opponents. His merit was almost entirely rhetorical. He did not succeed either in exposition or refutation; but his speeches abounded with lively illustrations, striking apophthegms, well-told anecdotes, happy allusions, passionate appeals. His invective and sarcasm were tremendous. Perhaps no English orator was ever so much feared.

[2] Edinburgh Review, *ubi supra*.

"But that which gave most effect to his declamation, was the air of sincerity, of vehement feeling, or moral elevation, which belonged to all that he said. His style was not always in the purest taste. Several contemporary judges pronounced it too florid. Walpole, in the midst of the rapturous eulogy which he pronounces on one of Pitt's greatest orations, owns that some of the metaphors were too forced. The quotations and classical stories of the orator are sometimes too trite for a clever school-boy. But these were niceties for which the audience cared little. The enthusiasm of the orator infected all who were near him; his ardour and his noble bearing put fire into the most frigid conceit, and gave dignity to the most puerile allusion."[1]

Such is the character of this great statesman and orator, as drawn by one masterly hand. It may perhaps both instruct and interest our readers, if we present another, delineated by an artist equally distinguished for the vigour, judgment, and fidelity with which he paints such grand pieces for the gallery of history. The preceding, as we have already said, is from the pen of Mr Macaulay: the following is understood to be from that of Lord Brougham.

"The first place among the great qualities which distinguished Lord Chatham, is unquestionably due to firmness of purpose, resolute determination in the pursuit of his objects. This was the characteristic of the younger Brutus, as he said, who had spared his life to fall by his hand,—*Quicquid vult, id valde vult;* and although extremely apt to be shown in excess, it must be admitted to be the foundation of all true greatness of character. Everything, however, depends upon the endowments in whose company it is found; and in Lord Chatham these were of a very high order. The quickness with which he could ascertain his object, and discover his road to it, was fully commensurate with his perseverance and his boldness in pursuing it; the firmness of grasp with which he held his advantage was fully equalled by the rapidity of the glance with which he discovered it. Add to this a mind eminently fertile in resources, a courage which nothing could daunt in the choice of his means, a resolution equally indomitable in their application, a genius, in short, original and daring, which bounded over the petty obstacles raised by ordinary men,—their squeamishness, and their precedents, and their forms, and their regularities,—and forced away its path through the entanglements of this base undergrowth to the worthy object ever in his view, the prosperity and the renown of his country. Far superior to the paltry objects of a grovelling ambition, and regardless alike of party and of personal considerations, he constantly set before his eyes the highest duty of a public man, to further the interests of his species. In pursuing his course towards that goal, he disregarded alike the frowns of power and the gales of popular applause; exposed himself undaunted to the vengeance of the court, while he battled against its corruptions, and confronted, unabashed, the rudest shocks of public indignation, while he resisted the dictates of pernicious agitators; and could conscientiously exclaim, with an illustrious statesman of antiquity, 'Ego hoc animo semper fui ut invidiam virtute partam, gloriam non invidiam putarem.'

"Nothing could be more entangled than the foreign policy of this country at the time when he took the supreme direction of her affairs; nothing could be more disastrous than the aspect of her fortunes in every quarter of the globe. With a single ally in Europe, the king of Prussia, and him beset by a combination of all the continental powers in unnatural union to effect his destruction; with an army of insignificant amount, and commanded by men only desirous of grasping at the emoluments, without doing the duties or incurring the risks of their profession; with a navy that could hardly keep the sea, and whose chiefs vied with their comrades on shore in earning the character given them by the new minister, of being utterly unfit to be trusted in any enterprise accompanied with 'the least appearance of danger;' with a generally prevailing dislike of both services, which at once repressed all desire of joining either, and damped all public spirit in the country, by extinguishing all hope of success, and even all love of glory; it was hardly possible for a nation to be placed in circumstances more inauspicious to military exertions; and yet war raged in every quarter of the world where our dominion extended, while the territories of our only ally, as well as those of our own sovereign in Germany, were invaded by France, and her forces by sea and land menaced our shores. In the distant possessions of the crown the same want of enterprise and of spirit prevailed. Armies in the West were paralysed by the inaction of a captain who would hardly take the pains to write a despatch recording the nonentity of his operations; and in the East, while frightful disasters were brought upon our settlements by barbarian powers, the only military capacity that appeared in their defence was the accidental display of genius and valour by a merchant's clerk, who thus raised himself to celebrity.[2] In this forlorn state of affairs, rendering it as impossible to think of peace, as it seemed hopeless to continue the yet inevitable war, the base and sordid views of politicians kept pace with the mean spirit of the military caste; and parties were split or united, not upon any difference or agreement of public principle, but upon mere questions of patronage, and share in the public spoil, while all seemed alike actuated by one only passion, the thirst alternately of power and of gain.

"As soon as Mr Pitt took the helm, the steadiness of the hand that held it came to be felt in every motion of the vessel. There was no more of wavering councils, of torpid inaction, of listless expectancy, of abject despondency. His firmness gave confidence, his spirit roused courage, his vigilance secured exertion, in every department under his sway. Each man, from the first lord of the admiralty down to the most humble clerk in the victualling office; each soldier, from the commander-in-chief to the most obscure contractor or commissary; now felt assured that he was acting or indolent under the eye of one who knew his duties and his means as well as his own, and who would very certainly make all defaulters, whether through misfeasance or through nonfeasance, accountable for whatever detriment the commonwealth might sustain at their hands. Over his immediate coadjutors, his influence swiftly obtained an ascendant which it ever after retained uninterrupted. Upon his first proposition for changing the conduct of the war, he stood single among his colleagues, and tendered his resignation should they persist in their dissent; they at once succumbed, and from that hour ceased to have an opinion of their own upon any branch of the public affairs. Nay, so absolutely was he determined to have the control of those measures, of which he knew the responsibility rested upon him alone, that he insisted upon the first lord of the admiralty not having the correspondence of his own department; and no less eminent a naval character than Lord Anson, with his junior lords, were obliged to sign the orders issued by Mr Pitt, while the writing was covered over from their eyes.

[2] Mr Clive, afterwards Lord Clive.

"The effects of this change in the whole management of the public business, and in all the plans of the government, as well as in their execution, were speedily made manifest to all the world. The German troops were sent home, and a well-regulated militia being established to defend the country, a large disposable force was distributed over the various points whence the enemy might be annoyed. France, attacked on some points and menaced on others, was compelled to retire from Germany, soon afterwards suffered the most disastrous defeats, and, instead of threatening England and her allies with invasion, had to defend herself against attack, suffering severely in several of her most important naval stations. No less than sixteen islands, and settlements, and fortresses of importance were taken from her in America, and Asia, and Africa, including all her West Indian colonies except St Domingo, and all her settlements in the East. The whole important province of Canada was likewise conquered; and the Havannah was taken from Spain. Beside this, the seas were swept clear of the fleets that had so lately been insulting all our colonies, and even all our coasts. Many general actions were fought and gained; one among them the most decisive that had ever been fought by our navy. Thirty-six sail of the line were taken or destroyed, fifty frigates, forty-five sloops of war. So brilliant a course of uninterrupted success had never, in modern times, attended the arms of any nation carrying on war with other states equal to it in civilization, and nearly a match in power. But it is a more glorious feature in this unexampled administration which history has to record, when it adds, that all public distress had disappeared; all discontent in any quarter, both of the colonies and parent state, had ceased; that no oppression was anywhere practised, no abuse suffered to prevail; that no encroachments were made upon the rights of the subject, no malversations tolerated in the possessors of power; and that England, for the first time and for the last time, presented the astonishing picture of a nation supporting without murmur a widely extended and costly war, and a people, hitherto torn with conflicting parties, so united in the service of the commonwealth that the voice of faction had ceased in the land, and any discordant whisper was heard no more. 'These,' said the son of his first and most formidable adversary, Walpole, when informing his correspondent abroad, that the session, as usual, had ended without any kind of opposition, or even of debate, 'These are the doings of Mr Pitt, and they are wondrous in our eyes.'

"To genius irregularity is incident, and the greatest genius is often marked by eccentricity, as if it disdained to move in the vulgar orbit. Hence he who is fitted by his nature, and trained by his habits, to be an accomplished 'pilot in extremity,' and whose inclinations carry him forth to seek the deep when the waves run high, may be found, if not 'to steer too near the shore,' yet to despise the sunken rocks which they that can only be trusted in calm weather would have more surely avoided. To this rule it cannot be said that Lord Chatham afforded any exception; and although a plot had certainly been formed to eject him from the ministry, leaving the chief control of affairs in the feeble hands of Lord Bute, whose only support was court favour, and whose only talent lay in an expertness at intrigue, yet there can be little doubt that this scheme was only rendered practicable by the hostility which the great minister's unbending habits, his contempt of ordinary men, and his neglect of everyday matters, had raised against him among all the creatures both of Downing Street and St James's. In fact, his colleagues, who necessarily felt humbled by his superiority, were needlessly mortified by the constant display of it; and it would have betokened a still higher reach of understanding, as well as a purer fabric of patriotism, if he whose great capacity threw those subordinates into the shade, and before whose vigour in action they were sufficiently willing to yield, had united a little suavity in his demeanour with his extraordinary powers, nor made it always necessary for them to acknowledge as well as to feel their inferiority. It is certain that the insulting arrangement of the admiralty, to which reference has been already made, while it lowered that department in the public opinion, rendered all connected with him his personal enemies; and, indeed, though there have, since his days, been prime ministers whom he would never have suffered to sit even as puny lords at his boards, yet were one like himself again to govern the country, the admiralty chief who might be far inferior to Lord Anson would never submit to the humiliation inflicted upon that gallant and skilful captain. Mr Pitt's policy seemed formed upon the assumption that either each public functionary was equal to himself in boldness, activity, and resource, or that he was to preside over and animate each department in person; and his confidence was such in his own powers, that he reversed the maxim of governing, never to force your way where you can win it; and always disdained to insinuate where he could dash in, or to persuade where he could command. It thus happened that his colleagues were but nominally coadjutors, and though they durst not thwart him, yet rendered no heart-service to aid his schemes. Indeed it has clearly appeared since his time, that they were chiefly induced to yield him implicit obedience, and leave the undivided direction of all operations in his hands, by the expectation that the failure of what they were wont to sneer at as 'Mr Pitt's visions,' would turn the tide of public opinion against him, and prepare his downfall from a height of which they felt that there was no one but himself able to dispossess him."

The same powerful writer, having thus sketched the character of the statesman, proceeds next to delineate that of the orator, as far as this can now be done from the extremely scanty and imperfect materials which have been preserved. The fame of Lord Chatham's eloquence is, in truth, almost wholly traditional.

"There is indeed hardly any eloquence, of ancient or of modern times, of which so little that can be relied on as authentic has been preserved; unless perhaps that of Pericles, Julius Cæsar, and Lord Bolingbroke. Of the actions of the two first we have sufficient records, as we have of Lord Chatham's; of their speeches we have little that can be regarded as genuine; although, by unquestionable tradition, we know that each of them was second only to the greatest orator of their respective countries; while of Bolingbroke we only know, from Dean Swift, that he was the most accomplished speaker of his time; and it is related of Mr Pitt (the younger), that when the conversation rolled upon lost works, and some said they should prefer restoring the books of Livy, some of Tacitus, and some a Latin tragedy, he at once decided for a speech of Bolingbroke. What we know of his own father's oratory is much more to be gleaned from contemporary panegyrics, and accounts of its effects, than from the scanty, and for the most part doubtful, remains which have reached us.

"All accounts, however, concur in representing those effects to have been prodigious. The spirit and vehemence which animated its greater passages, their perfect application to the subject-matter of debate, the appositeness of his invective to the individual assailed, the boldness of the feats which he ventured upon, the grandeur of the ideas which he unfolded, the heart-stirring nature of his appeals, are all confessed by the united testimony of all his contemporaries; and the fragments which remain bear out to a considerable extent such representations; nor are we likely to be misled by those fragments, for the more striking portions were certainly the ones least likely to be either forgotten or fabricated. To these mighty attractions was added the imposing, the animating, the commanding power of a countenance singularly expressive; an eye so piercing that hardly any one could stand its glare; and a manner altogether singularly striking, original, and characteristic, notwithstanding a peculiarly defective and even awkward action. Latterly, indeed, his infirmities precluded all action; and he is described as standing in the House of Lords, leaning upon his crutch, and speaking for ten minutes together in an under-tone of voice scarcely audible, but raising his notes to their full pitch when he broke out into one of his grand bursts of invective or exclamation. But in his earlier time, his whole manner is represented as having been beyond conception animated and imposing. Indeed the things which he effected by it principally, or at least which nothing but a most striking and commanding tone could have made it possible to attempt, almost exceed belief. Some of these sallies are indeed examples of that approach made to the ludicrous by the sublime, which has been charged upon him as a prevailing fault, and represented under the name of *charlatanerie*,—a favourite phrase with his adversaries, as it in later times has been with the ignorant undervaluers of Lord Erskine. It is related, that once in the House of Commons he began a speech with the words, 'Sugar, Mr Speaker,'—and then, observing a smile to prevail in the audience, he paused, looking fiercely around, and with a loud voice, rising in its notes, and swelling into vehement anger, he is said to have pronounced again the word 'Sugar!' three times,—and having thus quelled the house, and extinguished every appearance of levity or laughter, turned round and disdainfully asked, 'Who will laugh at sugar now?' We have this anecdote on good traditional authority; that it was believed by those who had the best means of knowing Lord Chatham, is certain; and this of itself shows their sense of the extraordinary powers of his manner, and the reach of his audacity in trusting to those powers.

"There can be no doubt that of reasoning,—of sustained and close argument,—his speeches had but little. His statements were desultory, though striking, perhaps not very distinct, certainly not at all detailed, and as certainly every way inferior to those of his celebrated son. If he did not reason cogently, he assuredly did not compress his matter vigorously. He was anything rather than a concise or a short speaker; not that his great passages were at all diffuse, or in the least degree loaded with superfluous words; but he was prolix in the whole texture of his discourse, and he was certainly the first who introduced into our senate the practice, adopted in the American war by Mr Burke, and continued by others, of long speeches,—speeches of two and three hours, by which oratory has gained little, and business less. His discourse was, however, fully informed with matter—his allusions to analogous subjects, and his reference to the history of past events, were frequent—his expression of his own opinions was copious and free, and stood very generally in the place of any elaborate reasoning in their support. A noble statement of enlarged views, a generous avowal of dignified sentiments, a manly and somewhat severe contempt for all petty or mean views, whether their baseness proceeded from narrow understanding or from corrupt bias, always pervaded his whole discourse; and, more than any other orator since Demosthenes, he was distinguished by the nobleness of feeling with which he regarded, and the amplitude of survey which he cast upon, the subject-matters of debate. His invective was unsparing, and hard to be endured, although he was a less eminent master of sarcasm than his son, and rather overwhelmed his antagonist with the burst of words and vehement indignation, than wounded him by the edge of ridicule, or tortured him with the gall of bitter scorn, or fixed his arrow in the wound by the barb of epigram. These things seemed, as it were, to betoken too much labour and too much art, more labour than was consistent with absolute scorn, more art than could stand with heartfelt rage, or entire contempt inspired by the occasion, at the moment, and on the spot. But his great passages, those by which he has come down to us, those which gave his eloquence its peculiar character, and to which its dazzling success was owing, were as sudden and unexpected as they were natural. Every one was taken by surprise when they rolled forth; every one felt them to be so natural, that he could hardly understand why he had not thought of them himself although into no one's imagination had they ever entered. If the quality of being natural without being obvious is a pretty correct description of felicitous expression, or what is called fine writing, it is a yet more accurate representation of fine passages, or felicitous *hits* in speaking. In these all popular assemblies take boundless delight; by these, above all others, are the minds of an audience at pleasure moved or controlled. They form the grand charm of Lord Chatham's oratory; they were the distinguishing excellence of his great predecessor, and gave him at will to wield the fierce democraty of Athens, and to fulmine over Greece."[1]

Many years ago, a small volume was published by Lord Grenville, containing letters written by the Earl of Chatham to his nephew, Thomas Pitt, Lord Camelford. They are replete with excellent advice, conveyed in an easy, affectionate, and not inelegant style, having all of them been penned evidently without effort, under the simple impulse of the kindly feelings and anxious interest which they manifest throughout. At the same time they might have been written by a person vastly inferior to Lord Chatham; and indeed one can scarcely avoid surprise at the absence of every trace of that genius, power, and originality, for which the writer was so greatly distinguished. We may add, that amidst the different conjectures which have at various times been entertained and abandoned, respecting the authorship of Junius, Lord Chatham has once and again been pointed to as the writer of these celebrated and still unclaimed letters; nor can it be doubted by one who has made himself master of the question, that there are circumstances of a very striking kind which appear to give a certain colour of probability to this supposition. Indeed it would not be difficult, we think, to make out as strong a case in his favour as any that has yet been offered to the public in behalf of others, none of whom had his "motive and cue for action." But as time, the great revealer of all mysteries, will most likely, ere long, remove the veil by which this is covered, we shall not add to the mass of doubtful speculation by reviving a discussion which, by a sort of tacit consent, has for some time been abandoned as unprofitable and nugatory. (A.)

---

[1] Edinburgh Review, vol. lxviii. p. 438, et seq.

Pitt, *William*, the second son of the preceding, and his legitimate successor in talents and celebrity as a statesman and orator, was born on the 28th of May 1759. His father, having confided the care of his eldest and youngest sons to others, took William under his own inspection; and the rapid progress of the son cheered the solitude and brightened the declining days of this illustrious statesman. The school exercises of the youth were performed under the direction of a private tutor well qualified for the task assigned him; whilst his father, finding in him a capacity above his years, embraced every opportunity of conversing freely with him upon topics of interest, calculated to expand his mind and mature his judgment. It is even said that he also made him declaim from a chair or table; well knowing the importance of an easy, natural, and dignified elocution, which, in his own case, had helped to supply the deficiencies of fortune. The proficiency of the youth was such that, at the age of fourteen, he was found qualified for being sent to the university; and Cambridge was preferred to Oxford, from a decided opinion entertained by many, that the political doctrines inculcated at the former place were more liberal than those usually promulgated at the latter. He was accordingly entered at Pembroke Hall, where he was placed under the tuition of Dr Turner; whilst Dr Prettyman, afterwards Tomline, and successively bishop of Lincoln and of Winchester, officiated as his private instructor. During his residence at Cambridge, Mr Pitt was distinguished alike for the assiduity of his application, and the success that attended his efforts to acquire those branches of knowledge to which his studies were more particularly directed; nor have many young men of rank ever passed through the ordeal of an university, exposed to the contaminating influence of seductive example, with a higher character for morals, abilities, industry, and regularity. Here young Pitt took his bachelor's degree, and also that of master of arts, both in a creditable manner; and acquired a reputation for talents, diligence, and propriety of deportment, which proved eminently serviceable to him in after life. Being intended by his father for the bar and the senate, his education was regulated so as to embrace both these objects; and it is certain that his early acquisitions in various branches of knowledge must have far exceeded those of almost any of his contemporaries.

After quitting the university, he went to the Continent, and passed a short time at Rheims, the capital of Champagne. The death of his father, however, whilst he was only in his nineteenth year, could scarcely fail to throw a cloud over the prospects of the younger son; but the foundation of future distinction had been firmly laid, and it only remained for him to clear the path to eminence by his own exertions. He had already entered himself a student of Lincoln's Inn; and as soon as he came of age he was called to the bar, having received some favour on account of his degree. He made choice of the western circuit, and appeared in several causes as junior counsel; in which capacity, of course, he had few or no opportunities of distinguishing himself. The result of this short experiment, however, was thought sufficient to encourage him to pursue the career of the law, and rendered it almost certain that he would ultimately attain a high rank in his profession; but a seat in parliament, which he soon afterwards obtained, gave his ambition its proper direction, and placed him in the arena where he was best calculated to excel. At the general election in 1780, he had been induced to offer himself as a candidate for the representation of the university of Cambridge; but finding that, from want of sufficient influence, he had no chance of success, he declined the contest, and in the following year was returned for the borough of Appleby, through the interest of Sir James Lowther, afterwards Earl of Lonsdale.

This, be it observed, was during the period of most violent political opposition to the American war; which, it may be supposed, Mr Pitt regarded with hereditary aversion, and reprobated as one of the most disgraceful and ruinous contests in which the country could have engaged. He was also ardently attached to the cause of political reform, particularly in the representation of the people; which he conceived to be the best safeguard of constitutional liberty, and the only security against the recurrence of such wars as that which he so much deplored and condemned. On the 26th of February 1781, Mr Pitt made his first speech in the British senate. At the commencement of the session Mr Burke had brought forward his bill for effecting great retrenchments in the civil list; and it was in reference to this measure that Mr Pitt made his débût in the House of Commons. The attention of the house was naturally fixed upon the son of the great Chatham; but in a few moments the regards of the audience were directed to him on his own account. Unembarrassed by the novelty of his position, and master alike of his feelings and his subject, he delivered himself with an ease and grace, a richness of expression, a closeness of argument, and a classical precision of language, which not only answered, but exceeded all the expectations that had been formed of him, and elicited great applause from both sides of the house. During the same and the subsequent session, he spoke several times, particularly in favour of parliamentary reform, of which, as we have just stated, he was a zealous advocate; and, from his talents as a public speaker, it soon became evident that he was destined to perform a prominent part upon the political stage.

But although, for the most part, he ostensibly went along with the party in opposition to Lord North, yet he had not formed any decided connection with them; and hence, when his lordship was driven from power, and a new administration formed, with the Marquis of Rockingham at its head, Mr Pitt's name was not included in the list. This cabinet, however, was of short endurance. Lord Rockingham died suddenly; and his death having occasioned a fatal difference as to the choice of a new head, the Earl of Shelburne, profiting by the circumstance, formed a junction with several members of the former cabinet, and having (in July 1782) been appointed first lord of the treasury, associated with himself Mr Pitt, who had just completed his twenty-third year, as chancellor of the exchequer. A general peace with America, and the powers in alliance with the Transatlantic republic, followed soon afterwards; but this having been made a ground of severe censure by a powerful opposition, a coalition was formed between Lord North and Mr Fox, and, in April 1783, the Shelburne administration was forced to give way to this extraordinary confederacy, which had in some measure dictated its own terms to the sovereign. During his continuance in office, Mr Pitt had found but little opportunity of distinguishing himself, except as an able defender of the measures of administration, and a vigorous assailant of the principles and conduct of his antagonists. But a circumstance soon occurred which constitutes an important era in his life, and not only proved the eventual cause of his return to office, but secured to him a degree of authority with the king, and of popularity with the nation, which has seldom fallen to the lot of any minister, and which he preserved with but little diminution till the close of his life.

The coalition ministry was, both in its formation and in its character, odious to the country at large. It was regarded as an unprincipled combination for purposes purely selfish; in its formation all the old landmarks and distinctions of party had been thrown down; and as its composition was such as to afford no hopes of future benefit to the nation, its proceedings were watched with the jealous vigilance of suspicion and hatred. Whilst matters were in this state, Mr Fox introduced his bill for regulating the affairs of India. The leading provision of this famous project was to vest the whole management of Indian affairs in seven commissioners named in the bill, and to be appointed by the ministry; or, in other words, to transfer the whole patronage of India from the Crown and the Company, to the administration for the time being. In vain was it represented that this measure would prove alike advantageous to the Company and the nation; that it would introduce responsibility where there was none, or next to none; and that it would serve to prevent abuses, which were described as equally flagrant and notorious. The public generally considered it as trenching too much upon the prerogative, as creating a mass of ministerial influence which would be irresistible, and as rendering the ministry too strong for the crown. In opposing it, therefore, Mr Pitt had rather to follow than to lead public opinion, to obey the impulse already given, than to endeavour to excite and stimulate opposition; and this he did with so much skill and ability, that although the bill passed the House of Commons, it was thrown out in the Lords. This defeat decided the fate of the coalition ministry. For although it were true, as the partisans of the ministers alleged, that the rejection of the bill had been caused by secret intrigue and undue influence, this made no difference in regard to public opinion, which was decidedly adverse to the measure; and hence the country was not disposed to find fault with the means by which the end desired had been obtained. The ministry therefore resigned, and in the new arrangement Mr Pitt was made first lord of the treasury and chancellor of the exchequer.

Having thus become prime minister at the early age of twenty-four, Mr Pitt's appearance in that high and difficult station was greatly applauded by his friends, and at the same time ridiculed by his opponents, who represented it as the arrogant assumption of a stripling, indebted to accident or intrigue for a position from which he would be driven in a few months, perhaps even sooner. And at first it seemed by no means improbable that this prognostication would be fulfilled. In the House of Commons, the adherents of the coalition ministry were still so numerous, that, when Mr Pitt introduced his bill for the regulation of Indian affairs, it was rejected by a majority of eight (222 to 214); and in this state matters remained for some months. In the mean time several meetings were held by the leading men of both parties, and various projects of accommodation discussed; but Mr Pitt's previous resignation being demanded as a *conditio sine qua non*, all these attempts failed. Resolved to stand by the sovereign who confided in, and the people who supported him, Mr Pitt now took a step, the very boldness of which, perhaps, conduced to his success, we mean, dissolving parliament. This took place in March 1784, and was speedily followed by a general election, in which thirty coalitionists, including some of the leading men of the party, lost their seats; so that the minister was enabled to meet the new parliament with a decided majority, and an opposition more weakened in talent than in numbers. His India bill, which the last parliament had thrown out, was now re-introduced and passed; an addition was made to the window-tax, in order to supply the deficiency occasioned by a reduction of the principal duties upon tea; and various plans were proposed for the more effectual prevention of smuggling.

At this period, indeed, the grand object of Mr Pitt's ambition seems to have been, to acquire the reputation of an able and successful minister of finance. In 1786, he brought in and carried through a bill for establishing his famous sinking fund, upon a plan which, it seems, had been suggested to him by Dr Richard Price, and which, as modified in the bill, was long regarded by his friends and partisans as the *ne plus ultra* of financial skill and ingenuity. But all this ignorant admiration was at length dissipated by the masterly work of Dr Hamilton; and even Lord Grenville, the friend and colleague of Mr Pitt, found himself constrained to admit, in a pamphlet which he published on the subject, after his retirement from public life, that the whole scheme was bottomed upon delusion. In the year 1787, Mr Pitt concluded a commercial treaty with France; and amongst the subsequent measures in which he was personally concerned, may be mentioned his accession to the impeachment of Warren Hastings, his opposing the repeal of the corporation and test acts, his interference in behalf of the stadtholder, the affair of Oczakow, and the dispute with Spain respecting the fur-trade at Nootka Sound, several of which were extremely unpopular.

But the most important epoch of Mr Pitt's political life was now approaching. His reforming and patriotic zeal had already been sensibly cooled. Instead of seeking to strengthen himself in the affections of the people, he began to think only of establishing himself firmly in the favour of the court; and, whilst pursuing this object, a circumstance occurred which raised him to the summit of power, and enabled him, as prime minister, to exercise every function of his office without check or control. This was the illness of the king, which took place in the autumn of 1788, and incapacitated his majesty for the exercise of the royal functions. Parliament had been prorogued to the 20th of November; and as the sovereign, by whom alone it could be further prorogued, was not in a condition to exercise his prerogative, it became necessary that it should meet upon that day. A question of great nicety and delicacy now arose; namely, in whom the office of regent was to be vested. The Prince of Wales being then connected with the party in opposition, Mr Fox strenuously contended that the regency devolved upon him as a matter of course, without restriction or limitation; whilst Mr Pitt, on the other hand, maintained that it belonged to the two remaining branches of the legislature to fill up the office as they should judge proper, and impose such restrictions as they might deem necessary; at the same time admitting that, under actual circumstances, no other person than the prince could be thought of for the regency, thus limited by the two houses of parliament. The view of the prime minister prevailed, and a bill was in consequence passed, greatly restricting the power of the regent. But its provisions were soon rendered inoperative, by the convalescence of his majesty in the beginning of 1789. It is certain, however, that, upon recovering the use of his reason, the king greatly approved of the course which Mr Pitt had pursued; and the latter was in consequence established in power more firmly than ever. We may add, that on the recurrence of a similar visitation, with still more melancholy circumstances, the precedent of 1788–1789 served as a guide to the minister of the day, Mr Percival, and the Prince of Wales became regent, subject to restrictions analogous to those which had formerly been imposed by Mr Pitt.

The next great epoch in Mr Pitt's political life, and which, beyond all the preceding portions of his conduct, will determine his character as a statesman with posterity, was the French Revolution; taken in connection with the policy which the government of this country, under the sole guidance of Mr Pitt, pursued in reference to that mighty convulsion, and the astounding events to which it gave birth. But as Mr Pitt, considered individually, cannot be separated from the history of the long and sanguinary war with France, in which, principally through his means, the country became involved; and as the most ample details, both of the policy of this country, and the strange vicissitudes of the contest, have already been given under the article BRITAIN, it is only necessary to refer the reader to that head for the fullest information on these points, as well as respecting the most important domestic events of Mr Pitt's long administration, the rebellion in Ireland, and the subsequent union of that country with Great Britain. Suffice it to say, that having held the reins of government for eighteen years, Mr Pitt, and all the members of his cabinet, retired from office in 1801. The French armies had been victorious all over the continent; Prussia had, at an early period, prudently withdrawn from the contest; Austria had been completely humbled; and a successful soldier, under the denomination of First Consul, had assumed the reins of government in France. All Mr Pitt's plans for humbling that country, and, as it were, rolling back the Revolution, had most signally failed; the cry for peace was now become general; and a breathing-time, at least, had become indispensably necessary. But it was left to Mr Addington to make the experiment, and, under his auspices, the treaty of Amiens was concluded with the French government.

But, as every reflecting person had foreseen, this armistice (for it was nothing more) proved of short duration. The war broke out again in the year 1803; and Mr Pitt, having gradually withdrawn his support from the Addington administration, it fell to pieces from its own inherent fragility. In 1804, Mr Pitt, having resumed the reins of government, exerted all his ability to give a successful turn to the contest, and organized a new coalition against France. But the thunder-stroke of Austerlitz blasted all his hopes, again placed Austria at the feet of the conqueror, and left Prussia exposed to that vengeance which soon afterwards descended upon her as a just retribution for her treachery. The prime minister was at this time in a state of health ill calculated to bear up under such a blow. A gouty habit, the predisposing causes of which appear to have been hereditary, and a too liberal use of wine as part of his ordinary regimen, undermined a constitution which had never been very robust; and these, added to the cares and anxieties of office, at a period of so great excitement, brought on a premature exhaustion of the vital powers. In December 1805 he went to Bath; but the change afforded him no permanent relief. On the 11th of January 1806, he returned to his seat at Putney, much debilitated, and there lingered on till the 23d of the same month, when he expired, in the forty-seventh year of his age. A public funeral was decreed to him by parliament, and forty thousand pounds were voted to discharge those debts which he was said to have incurred in the service of the state.

Though Mr Pitt possessed no particular advantages of person or of physiognomy, yet as a speaker he was considered by many as of surpassing eminence. Happy in the choice of his words, judicious in the arrangement of his subject, and gifted with a natural flow of eloquence, his wonderful powers were acknowledged even by those who dissented from his doctrines, and remained unmoved by his arguments. When employed in a good cause, he was irresistible; in defending a bad one, he could dazzle the judgment, mislead the imagination, and seduce the heart, even when he could not overcome the understanding. In statement or exposition he was clear, perspicuous, and singularly adroit, not to say artful; in sarcasm and invective he was tremendous. But although ambition and the love of power were his ruling passions, his mind was elevated above the meanness of avarice; his personal integrity remained unimpeached; and though he died involved in debts, these are to be ascribed to negligence, and the demands of his public station, rather than to extravagance, or any fondness for splendour and parade. Though his manner, in his public deportment, was distant and reserved, not to say haughty, yet few men were ever more successful in fixing the attachment of their private and personal friends. By all those who shared his intimacy he seems to have been esteemed and beloved. "They saw the all-powerful energies of his character," says Mr Rose, "softened into the most perfect complacency and sweetness of disposition in the circles of private life, the pleasures of which no one more cheerfully enjoyed, or more agreeably promoted, when the paramount duties which he conceived himself to owe to the public admitted of his mixing in them. That indignant severity with which he met and subdued what he considered unfounded opposition, that keenness of sarcasm with which he expelled and withered, as it might be said, the powers of most of his assailants in debate, were exchanged, in the society of his intimate friends, for a kindness of heart, a gentleness of demeanour, and a playfulness of good humour, which no one ever witnessed without interest, or participated without delight." Mr Wilberforce, who knew him intimately, entertained the same opinion of his social qualities, when he moved in the circle of his particular friends. "Though less formed for general popularity than Fox," says he, "Pitt, when free from shyness, and amongst his intimate companions, was the very soul of merriment and conversation. He was the wittiest man I ever knew, and, what was quite peculiar to himself, he had at all times his wit under entire control. Others appeared struck by the unwonted association of brilliant images; but every possible combination of ideas seemed always present to his mind, and he could at once produce whatever he desired. I was one of those who met to spend an evening in memory of Shakspeare, at the Boar's Head, East Cheape. Many professed wits were present, but Pitt was the most amusing of the party, and the readiest and most apt in the required allusions."[1]

This, it will be observed, applies to an early period of his career, when his faculties were in all the freshness and vigour of youth. But from other accounts we learn, that amidst all the anxieties and disappointments of his public life, he retained to the last the reputation of being a most amiable companion in the circle of his private friends. The Marquis of Wellesley's character of him, which we subjoin, is perhaps a little overdrawn, and has something of a controversial character about it, having been written in refutation of certain statements of Sir Nathaniel Wraxall, who, amongst other things, had said that "Pitt's manners were stiff, retired, and without unction or grace;" but, making every allowance for the partialities of friendship, considerable weight must be given to the deliberate estimate of one who, himself a great statesman, an elegant scholar, and an accomplished man, enjoyed the best opportunities of appreciating the character and attainments of his friend.

"In attempting to convey to you my recollection of Mr Pitt's character in private society," says his lordship, "I cannot separate those qualities which raised him to the highest public eminence from those which rendered him a most amiable companion. Both proceeded from the same origin, and both were happily blended in the noble structure of his temper and disposition.

"Mr Pitt's mind was naturally inaccessible to any approach of dark, or low, or ignoble passion. His commanding genius and magnanimous spirit were destined to move in a region far above the reach of those jealousies, and suspicions, and animosities, which disturb the course of ordinary life. Under the eye of his illustrious father he had received that 'complete and generous education which fits a man to perform justly, skilfully, and magnanimously, all the offices, both private and public, of peace and war.' Such an education, acting on such a natural disposition, not only qualified him to adorn the most elevated stations in the counsels of his country, but furnished him with abundant resources to sustain the tranquillity and cheerfulness of his mind.

---

[1] Life of Wilberforce, vol. ii. p. 18.

"He had received regular and systematic instruction in the principles of the Christian religion, and in the doctrine and discipline of the Church of England, and in every branch of general ecclesiastical history. His knowledge in those subjects was accurate and extensive. He was completely armed against all sceptical assaults, as well as against all fanatical illusion; and, in truth, he was not merely a faithful and dutiful, but a learned member of our established church; to which he was most sincerely attached, with the most charitable indulgence for all dissenting sects. No doubt can exist in any rational mind that this early and firm settlement of his religious opinions and principles was a main cause of that cheerful equanimity which formed the great characteristic of his social intercourse, and which was never affected by adversities nor troubles.

"He was perfectly accomplished in classical literature, both Latin and Greek. The accuracy and strength of his memory surpassed every example which I have observed; but the intrinsic vigour of his understanding carried him far beyond the mere recollection of the great models of antiquity in oratory, poetry, history, and philosophy; he had drawn their essence into his own thoughts and language; and, with astonishing facility, he applied the whole spirit of ancient learning to his daily use.

"Those studies were his constant delight and resort; at Holwood, in Kent (his favourite residence), and at Walmer Castle, his apartments were strewed with Latin and Greek classics; and his conversation with those friends who delighted in similar studies frequently turned on that most attractive branch of literature; but he was so adverse to pedantry or affectation of superior knowledge, that he carefully abstained from such topics in the presence of those who could not take pleasure in them. In these pursuits his constant and congenial companion was Lord Grenville, who has often declared to me that Mr Pitt was the *best Greek scholar* he ever conversed with. Mr Pitt was also as complete a master of all English literature as he was undoubtedly of the English language. I have dwelt on this branch of Mr Pitt's accomplishments because I know not any source from which more salutary assistance can be derived, to chase from the spirits those clouds and vapours which infest vacant minds, and, by self-weariness, render retirement melancholy and intolerable.

"But Mr Pitt amply possessed every resource which could enliven retirement. No person had a more exquisite sense of the beauties of the country. He took the greatest delight in his residence at Holwood, which he enlarged and improved (it may be truly said) with his own hands. Often have I seen him working in his woods and gardens with his labourers for whole days together, undergoing considerable bodily fatigue, and with so much eagerness and assiduity, that you would suppose the cultivation of his villa to be the principal occupation of his life.

"He was very fond of exercise on horseback, and when in the country frequently joined the hounds of his neighbourhood, both at Holwood and Walmer Castle.

"At the latter place he lived most hospitably, entertaining all his neighbours, as well as the officers of the neighbouring garrisons, and of the ships in the Downs; and he was most attentive to his duties of lord warden of the cinque ports, which called him frequently to Dover, and sometimes to the other ports.

"But in all places, and at all times. his constant delight was society. There he shone with a degree of calm and steady lustre which often astonished me more than his most splendid efforts in parliament. His manners were perfectly plain, without any affectation; not only was he without presumption or arrogance, or any air of authority, but he seemed utterly unconscious of his own superiority, and much more disposed to listen than to talk. He never betrayed any symptom of anxiety to usurp the lead or to display his own powers, but rather inclined to draw forth others, and to take merely an equal share in the general conversation: then he plunged heedlessly into the mirth of the hour, with no more care than to promote the general good humour and happiness of the company. His wit was quick and ready, but it was rather lively than sharp, and never envenomed with the least taint of malignity; so that, instead of exciting admiration or terror, it was an additional ingredient in the common enjoyment. He was endowed, beyond any man of his time whom I knew, with a gay heart and a social spirit. With these qualities he was the life and soul of his own society. His appearance dispelled all care; his brow was never clouded, even in the severest public trials; and joy, and hope, and confidence beamed from his countenance in every crisis of difficulty and danger.

"He was a most affectionate, indulgent, and benevolent friend, and so easy of access, that all his acquaintance, in any embarrassment, would rather resort to him for advice than to any person who might be supposed to have more leisure. His heart was always at leisure to receive the communications of his friends, and always open to give the best advice in the most gentle and pleasant manner.

"It is a melancholy but a grateful task to pay this tribute to the memory of my departed friend. 'Aut me amor negotii suscepti fallit,' or the character which I have endeavoured to draw is not less just and true than it is amiable and excellent; and I cannot resist the conclusion, that a pure and clear conscience must have been the original source of such uniform cheerfulness and gaiety of spirit. The truth which I have asserted I possessed ample means of knowing. From the year 1783 to 1797 I lived in habits of the most confidential friendship with Mr Pitt.

"In the year 1797 I was appointed governor-general of India, and in the month of September in that year I went to Walmer Castle to meet Mr Pitt and Mr Dundas, and to receive my last instructions. I found Mr Pitt in the highest spirits, entertaining officers and country gentlemen with his usual hospitality. Amongst others, Admiral Duncan was his constant and favourite guest. His fleet was then in the Downs, preparing for the memorable victory of Camperdown. The admiral was a lively and jovial companion, and seemed to be quite delighted with Mr Pitt's society. I embarked for India early in the month of November 1797, and I returned to England in January 1806.

"Not wishing to state any thing beyond my own personal knowledge, I will not attempt to relate the history of Mr Pitt's social habits during the period of my absence; but I cannot believe that, during that time, the whole frame of his magnificent mind had been so broken and disjointed, that he could not endure the temporary loss of power, nor reconcile himself to that retirement, and to those recreations, which were his relief from the labour of official business, and his consolation in the hour of political solicitude and care. But I know that the first summer after his resignation was passed with Mr Addington at Wimbledon, and that soon afterwards Mr Pitt was closely occupied at Walmer Castle in forming a corps of volunteer cavalry, living with his officers, and passing the greater part of his time on horseback, under the firm expectation of a French invasion. This does not well agree with the story which represents him wrapped in sullen seclusion, sunk in despondency, shunning all society, and

Pitt.

yet unable to relieve the gloom of solitude by any mental resource.

"On my arrival in England in January 1806, Mr Pitt was at Bath; I wrote to him, and I received from him a very kind invitation to meet him at Putney Hill. I met him accordingly, in the second week in January, and I was received by him with his usual kindness and good humour. His spirits appeared to be as high as I had ever seen them, and his understanding quite as vigorous and clear.

"Amongst other topics, he told me, with great kindness and feeling, that, since he had seen me, he had been happy to become acquainted with my brother Arthur, of whom he spoke in the warmest terms of commendation. He said, 'I never met any military officer with whom it was so satisfactory to converse. He states every difficulty before he undertakes any service, but none after he has undertaken it.'

"But notwithstanding Mr Pitt's kindness and cheerfulness, I saw that the hand of death was fixed upon him. This melancholy truth was not known nor believed by either his friends or opponents. In the number of the latter, to my deep affliction, I found my highly respected and esteemed friend Lord Grenville, and I collected that measures of the utmost hostility to Mr Pitt were to be proposed in both houses at the meeting of parliament. I warned Lord Grenville of Mr Pitt's approaching death. He received the fatal intelligence with the utmost feeling, in an agony of tears, and immediately determined that all hostility in parliament should be suspended. Mr Pitt's death soon followed."

In a character of Lord Chatham,[1] lately published, and which is generally ascribed to Lord Brougham, that great orator and powerful writer thus contrasts the elder and younger Pitt as public men and ministers:

"The true test of a great man,—that at least which must determine his place among the highest order of great men,—is his having been in advance of his age. This it is which decides whether or not he has carried forward the grand plan of human improvement, has conformed his views, and adapted his conduct, to the existing circumstances of society, or changed those so as to better its condition; has been one of the lights of the world, or only reflected the borrowed rays of former luminaries, and sat in the same shade at the same twilight or the same dawn with the rest of his generation. Tried by this test, the younger Pitt cannot certainly be said to have lived before his time, or shed upon the age to which he belonged the illumination of a more advanced civilization and more inspired philosophy. He came far too early into public life, and was too suddenly plunged into the pool of office, to give him time for the study and the reflection which can alone open to any mind, how vigorous soever be its natural constitution, the views of a deep and original wisdom. Accordingly, it would be difficult to glean, from all his measures and all his speeches, any thing like the fruits of inventive genius; or to mark any token of his mind having gone before the very ordinary routine of the day, as if familiar with any ideas that did not pass through the most vulgar understandings. His father's intellect was of a higher order."[2]

Lord Brougham's opinion of the oratory of the younger Pitt is recorded in the conclusion of the following passage:

"Some have compared Mr Fox's eloquence to that of Demosthenes; but it resembled Lord Chatham's just as much, if not more. It was incomparably more argumentative than either the Greek or the English orator's, neither of whom carried on chains of close reasoning as he did, though both kept close to their subject. It was, however, exceedingly the reverse of the Attic oration, either in method, in diction, or in conciseness. It had nothing like arrangement of any kind. Except in the more vehement passages, its diction was perhaps as slovenly, certainly as careless, as possible,—betokening indeed a contempt of all accurate composition. It was diffuse in the highest degree, and abounded in repetitions. While the Greek was concise, almost to being jejune, the Englishman was diffuse, almost to being prolix. How the notion of comparing the two together ever could have prevailed, seems unaccountable, unless it be that men have supposed them alike because they were both vehement, and both kept the subject in view rather than run after ornament. But that the most elaborate and artificial compositions in the world should have been likened to the most careless, and natural, and unprepared that ever were delivered in public, would seem wholly incredible if it were not true. The bursts of Mr Fox, however, though less tersely and concisely composed, certainly have some resemblance to Lord Chatham's,—only that they betray far less fancy,—and, however vehement and fiery, are incomparably less bold. Mr Pitt's oratory, though admirably suited to its purpose, and as perfect a business kind of speaking as ever was heard, certainly resembled none of the three others who have been named. In point of genius, unless perhaps for sarcasm, he was greatly their inferior; although, from the unbroken fluency of his appropriate language, and the power of a most sonorous voice, he produced the most prodigious effect." (A.)

Pitt's Island || Pittacus.

PITT'S ISLAND, a small mountainous island in the South Pacific Ocean, covered with wood. Long. 193. 14. E. Lat. 11. 50. S.

PITT'S *Straits*, in the Eastern Seas, separate the islands of Salwatty and Battanta, at the western extremity of Papua or New Guinea, and extend from west-south-west to east-south-east about thirty miles, being about six in average breadth. No bottom is found in the middle with seventy-five fathoms of line.

PITTACUS, a native of Mitylene, in Lesbos, was one of the seven wise men of Greece. His father's name was Hyrradius. With the assistance of the sons of Alcæus, he delivered his country from the oppression of the tyrant Melanchrus; and, in the war which the Athenians waged against Lesbos, he appeared at the head of his countrymen, and challenged to single combat Phrynon, the enemy's general. As the event of the war seemed to depend upon this combat, Pittacus had recourse to artifice, and, when engaged, entangled his adversary in a net which he had concealed under his shield, and easily despatched him. He was amply rewarded for this victory; and his countrymen, sensible of his merit, unanimously appointed him governor of their city, with unlimited authority. In this capacity, Pittacus behaved with the greatest moderation and prudence; and after he had governed his fellow-citizens with the strictest justice, and enforced the most salutary laws, he voluntarily resigned the sovereign power after having enjoyed it for ten years; observing, that the virtues and innocence of private life were incompatible with the power and influence of a sovereign. His disinterestedness gained him many admirers; and when the Mitylenians wished to reward his public services by presenting him with an immense tract of territory, he refused to accept more land than could be contained within the space to which a javelin could be thrown. He died in the seventieth year of his age, about 579 years before Christ, after he had spent the last ten years of his life in literary ease and peaceful retirement.

[1] See Edinburgh Review, vol. lxviii. p. 436, et seq.

[2] "Mr Pitt had foibles," says Mr Wilberforce, "and of course they were not diminished by a long continuance in office; but for a clear and comprehensive view of the most complicated subject in all its relations; for that fairness of mind which disposes a man to follow out, and, when overtaken, to recognise truth; for magnanimity, which made him ready to change his measures when he thought the good of the country required it, though he knew he should be charged with inconsistency; for willingness to give a fair hearing to all that could be urged against his own opinions, and to listen to the suggestions of other men, whose understandings he knew to be inferior to his own; for personal purity, disinterestedness, integrity, and a love of his country, I have never known his equal. His strictness in regard to truth was astonishing, considering the situation he had so long filled." (Life of Wilberforce, vol. iii. p. 249, 250.)

PITTENWEEM, a royal burgh and seaport town on the Frith of Forth, in the parish of the same name, and on the east coast of Fifeshire. It is situated on gently-elevated ground, which overhangs the harbour, and consists of an irregular main street, having the form of an oblong square, from which a number of by-streets stretch out along the public roads. The houses are chiefly of old date, with the exception of a neat range of respectable cottages on the north side of the town. In the main street are situated the town-house, the parish church (an old ungainly structure, with a turreted spire), and all that remains of the ancient priory of Pittenweem. In addition to the ruins of the priory, there is a quadrangular range of most antique houses, which are stated to have been the residences of the prior and other superior officers of the establishment. This ancient edifice is now included within the private property of a gentleman, who resides in a part of it. The town derives its name from a spacious cave, called a *weem*, hollowed out, partly by the action of the waves, and partly by art, from the rock on which stands the residence alluded to. There is also a communication between the prior's house and the cave, by means of a spiral stair, the orifice of which has, however, been lately built up. Besides the established church, there is an Episcopalian chapel, and one or two dissenting places of worship. Pittenweem was erected into a royal burgh in the year 1542, and, like all the other Fifeshire burghs, had a thriving and extensive trade, which was carried on with success till the time of the union, from which date its importance and its trade have alike declined. It was also a great fishing station, and much coal was once wrought here; but both are now considerably decreased. The harbour is very much exposed to easterly winds but it has been improved so far as the means of the town will allow, and is now rather an extensive work. The revenue of the burgh amounts to above L.550, and its expenditure to nearly the same amount. In the year 1833, the town was in debt to the amount of L.1621 sterling. The burgh is governed by a council, consisting of four bailies, a treasurer, and nineteen councillors; and, with St Andrews, the two Anstruthers, Crail, Cupar, and Kilrenny, it returns a member to parliament. The population in 1821 amounted to 1200, and in 1831 to 1317.

PIUS, a name of several pontiffs distinguished in the history of the Catholic church.

Pius II. (*Æneas Sylvius Piccolomini*) was born on the 18th of October 1405, at Corsigni, in the Siennese, the name of which he afterwards changed into that of *Pienza*. Æneas was carefully educated, and made considerable proficiency in the belles lettres. After having finished his studies at Sienna, he in 1431 went to the council of Basil with Cardinal Capranica, surnamed *De Fermo*, because he was intrusted with the government of that church. Æneas, who acted as his secretary, was then only twenty-six years of age. He afterwards acted in the same capacity to some other prelates, and to Cardinal Albergati. The council of Basil honoured him with different commissions, in order to recompense him for the zeal with which he had defended that assembly against Pope Eugenius IV. He was afterwards secretary to Frederic III., who decreed to him the poetical crown, and sent him as ambassador to Rome, Milan, Naples, Bohemia, and other places. Nicholas V. advanced him to the bishopric of Trieste, which he quitted some time afterwards for that of Sienna. At last, after having distinguished himself as nuncio on various occasions, he was invested with the Roman purple by Calixtus III., whom he succeeded two years afterwards, on the 27th of August 1458. Pius II., now advanced to the holy see, exemplified the proverb, "Honores mutant mores." From the commencement of his pontificate he appeared to be jealous of the papal prerogatives. In 1460 he issued a bull, declaring appeals from the pope to a council to be null, erroneous, detestable, and contrary to the sacred canons. That bull, however, did not prevent the procurator-general of the parliament of Paris from appealing to a council in defence of the Pragmatic Sanction, which the pope had strenuously opposed. Pius was then at Mantua, whither he had gone to engage the Catholic princes to unite in a war against the Turks. The greater part of them had agreed to furnish troops or money; but others refused both, particularly France, which from that moment incurred his holiness's aversion. But his aversion abated under Louis XI., whom in 1461 he persuaded to abolish the Pragmatic Sanction, which the parliament of Paris had with so much vigour supported.

The following year, 1462, was rendered famous by a controversy which took place between the Cordeliers and Dominicans, whether or not the blood of Jesus Christ was separated from his body whilst he lay in the sepulchre. It was also made a question whether it was separated from his divinity. The Cordeliers affirmed that it was, but the Dominicans were of an opposite opinion. As usually happens in such disputes, the disputants called each other heretics; and this obliged the pontiff to issue a bull, forbidding them, under pain of censure, to brand one another with such odious epithets. The bull which his holiness published on the 26th of April, retracting what he had written to the council of Basil when he was its secretary, if it somewhat impeached his consistency, was at least highly honourable to his frankness and candour. "I am a man," says he, "and as a man I have erred. I am far from denying that a great many things which I have said and written may deserve condemnation. Like Paul, I have preached through deception, and I have persecuted the church of God through ignorance. I imitate the blessed St Augustin, who having suffered some erroneous sentiments to creep into his works, retracted them. I do the same thing; I frankly acknowledge my ignorance, from a fear lest what I have written in my younger years should be the occasion of any error that might afterwards be prejudicial to the interests of the holy see. For if it be proper for any one to defend and support the eminence and glory of the first throne of the church, it is in a peculiar manner my duty, whom God, out of his mercy and goodness alone, without any merit on my part, has raised to the dignity of vicar of Jesus Christ. For all these reasons, we exhort and admonish you in the Lord, not to give credit to those writings of ours which tend in any degree to hurt the authority of the apostolic see, and which establish opinions that are not received by the Roman church. If you find, then, any thing contrary to her doctrine, either in our dialogues, in our letters, or in other of our works, despise these opinions, reject them, and adopt our present sentiments. Believe me rather now that I am an old man, than when I addressed you in my earlier days. Esteem a sovereign pontiff more than a private person; except against Æneas Sylvius, but receive Pius II." It might perhaps be objected to his holiness, that it was his dignity alone which had made him alter his opinion. He anticipates that objection by giving a short account of his life and actions, with the whole history of the council of Basil, to which he went with Cardinal Capranica in 1431; "but," says he, "I was then a young man, and without any experience, like a bird just come from its nest." In the mean time, the Turks were threatening Christendom. Pius, ever zealous in the defence of religion against the infidels, formed the resolution of fitting out a fleet at the expense of the church, and of passing over into Asia himself, to animate the Christian princes by his example. He repaired to Ancona with a design to embark; but he there fell sick from the fatigue of the journey, and expired on the 16th of August 1464, aged fifty-nine. Pius was one of the most learned men of his time, and also one of the most zealous pontiffs; but being of an ambitious disposition, he sometimes sacrificed to that weakness. His principal works are, 1. Memoirs of the Council of Basil, from the Suspension of Eugenius to the Election of Felix; 2. The History of the Bohemians, from their origin to the year 1458; 3. Two books on Cosmography; 4. The History of Frederic III. (whose vice-chancellor he had been), published in 1785, in folio; 5. A Treatise on the Education of Children; 6. A Poem upon the Passion of Jesus Christ; 7. A Collection of four hundred and thirty-two Letters, printed at Milan, 1473, in folio, in which are found some curious anecdotes; 8. The Memoirs of his Own Life, published by John Gobelin Personne, his secretary, and printed at Rome in 1584, in 4to; 9. *Historia Rerum Ubicumque Gestarum*, of which only the first part was published at Venice in 1477, in folio. His works were printed at Helmstadt in 1700, in folio, with a life prefixed.

PIVOT, or PIVAT, a foot or shoe of iron or other metal, usually conical or terminating in a point, whereby a body, intended to turn round, bears upon another fixed at rest, and performs its revolutions. The pivot usually bears or turns round in a sole, or piece of iron or brass hollowed to receive it.

PIZARRO, FRANCIS, a celebrated Spanish general, the discoverer and conqueror of Peru, in conjunction with Diego Almagro, a famous Spanish navigator. They are both charged with having committed horrid cruelties on the inhabitants; and they fell victims to their own ambition, jealousy, and avarice. Almagro having revolted, was defeated and beheaded by Pizarro, who again was assassinated by Almagro's friends in 1541. See the article PERU.

PIZZO, a city of Italy, in the province of Calabria Ulteriore II., and kingdom of Naples. It is situated on a promontory on the south side of the Gulf of Euphemia. It was destroyed by the tremendous earthquake of 1783, but has been again rebuilt, and contains upwards of 5000 inhabitants, the most industrious of the population of Calabria. They have been freed from taxes on salt, and from some other imposts, since 1815, when they resisted the attempt of Murat, who landed near it. This has promoted the fishery, and especially the curing of fish. The country around it is highly productive of corn, oil, figs, and mulberry trees, and yields much silk.

PLACE, in *Astronomy*. The place of the sun, a planet, or a star, denotes the sign and degree of the zodiac which the luminary is in; or the degree of the ecliptic, reckoning from the beginning of Aries, which the planet's or star's circle of longitude cuts; and therefore coincides with the longitude of the sun, planet, or star. As the sine of the sun's greatest declination, 23° 30′, is to the sine of any present declination given or observed, for instance, 23° 15′; so is the radius 10 to the sine of its longitude, 81° 52′; which, if the declination were north, would give 20° 52′ of Gemini, or, if south, 20° 52′ of Capricorn, for the sun's place.

PLACENTIA, a city of Spain, in the province of Estremadura, the capital of a partido of the same name, which comprises two fruitful districts on the two sides of the river Vera. It is situated on the river Xerte, between two hills, and has been fortified, but its defences have been neglected. It has seven gates protected by towers, twenty-two streets and squares, seven churches, as many monasteries, five hospitals, two colleges, 950 houses, and 5200 inhabitants, who are occupied in tanning leather, and in making hats and pottery ware. The district around produces much honey and bees' wax, which adds to its trade. The city is supplied with water by means of a fine aqueduct of eighty arches.

PLAGIARY, the purloiner of another man's works. Amongst the Romans, *plagiarius* was properly a person who bought, sold, or retained a freeman for a slave; and was so called because, by the Flavian law, such persons were condemned *ad plagas*, or to be whipped. Thomasius has an express treatise *de plagio literario*, wherein he lays down the laws and measures of the right which authors have to use one another's writings.

PLAGUE. The terms pest, pestilence, and plague, were long employed in Great Britain, as were the corresponding terms in other languages, both in ancient and in modern times, to denote simply a disease attacking a great number of persons simultaneously and in succession, and destroying a large proportion of those whom it attacked; in short, a widely-diffused and malignant epidemic. At the present day these terms are restricted to signify a particular form of disease, of frequent occurrence in the countries bordering on the eastern extremity of the Mediterranean, the Levant and Archipelago, but occasionally appearing also in countries more or less remote from these regions.

Symptoms by which the plague is characterized.

The disease in question, the plague of the Levant, as it is often termed, exhibits, not in every individual case, but in a large proportion of those affected in the progress of its epidemic prevalence, two classes of symptoms, the constitutional and the local. Under the constitutional symptoms may be comprehended those indicatory of fever of a malignant or typhoid character, with various concomitant phenomena that are in wont to attend fever of this character in different regions of the globe; the local consist chiefly of glandular swellings, or buboes as they are termed, and of malignant or gangrenous boils, or carbuncles.

Relations of the constitutional and local symptoms.

These two classes of symptoms stand variously related to one another in different individual cases; and even, there seems reason to believe, in different periods of the same epidemic. Dr Patrick Russell, in his Treatise of the Plague, in which he has given the results of his own extensive observation of this disease during its epidemic prevalence in Aleppo in the years 1760, 1761, and 1762, mentions one class of patients who seldom or never had buboes or carbuncles; and another class, in a few of whom, when the disease proved quickly fatal, these symptoms were likewise absent. "These two eruptions," he says, "are equally diagnostics of the true plague; their presence, separately or in conjunction, leaves the nature of the distemper unequivocal; but fatal has been the error of rashly, from their absence, pronouncing a distemper not to be the plague, which in the sequel has depopulated regions, and which early precaution might probably have prevented from spreading." Dr Louis Frank, also, mentions, that though the appearance of buboes is the most constant and characteristic symptom of the plague, yet he has seen many affected with this disease, in whom buboes were altogether wanting, or appeared only at the period of death. As cases of this kind are particularly liable to occur at the commencement of an epidemic, a considerable number of persons may, it is obvious, come to be affected, before the pestilential character of the disease is ascertained, or even suspected, particularly in regions in which the plague is of rare occurrence.

But as the constitutional symptoms of plague may occur without the local, so the local may occur with little fever or constitutional disturbance of any kind. Dr Russell, under his fifth class of cases, to which he refers those of slight infection, in which all the infected recovered, and which, he says, "was very numerous," mentions, that in these the access was often attended with so little apparent disorder, that the eruptions gave the first alarm, "the buboes were often the first symptom of infection;" and the fever, which came on afterwards, was frequently so slight as not to confine the sick to the house: others found themselves indisposed for two or three days, but were not sensible of any febrile heat whatever. In these cases, and in some others in which the fever ran somewhat higher, but without the concurrence of alarming symptoms, "all the infected had buboes or carbuncles, and very often both eruptions concurred in the same subject. Persons not confined by indisposition were often, by the inguinal buboes, prevented from walking abroad."

In cases of plague in which both the constitutional and the local symptoms manifest themselves, there is considerable difference in the relative time of their appearance. "In a very large proportion of the sick," Dr Russell informs us, "the buboes made their appearance in the course of the first day; but in many instances they did not appear before the second or third day, or even later."

In the few remarks we purpose to offer relative to the plague, we shall consider some points of its natural history, as it presents itself, 1*st*, in the countries in which it is of frequent occurrence; and, 2*d*, in those countries in which it rarely shows itself.

Its occurrence on the borders of the Levant, &c.

I. In the countries bordering on the Levant and Archipelago, the plague is liable to present itself either in single, or, as they are termed by medical men, *sporadic* cases; or in a great number of cases simultaneously or in succession, so as to constitute an *epidemic*.

Its sporadic occurrence.

It is stated, indeed, by Dr Patrick Russell, that "in the intervals between the plagues of Aleppo," that is to say, between the successive epidemic prevalences of this disease, "the city remains absolutely free; and the plague is never sporadic there, except in its beginning and decline; it never subsists for any length of time in a few scattered cases without consequence." But this statement is not conformable with the reports of others. M. Pugnet, who accompanied Bonaparte's expedition to Egypt, affirms, in his *Mémoire sur les Fièvres du mauvais caractère du Lévant*, that that country is seldom absolutely free from the plague during several successive years; and that in almost every month of every year there occur a number of cases, though these are not noted when they do not occasion its epidemic prevalence. Sir James M'Grigor, who had the medical charge of the army which was brought from India to Egypt in 1801, in like manner expresses his belief that "the contagion of plague is seldom or never out of Egypt." Dr Murdoch Mackenzie, in his Letters concerning the Plague at Constantinople, published in the Philosophical Transactions, vol. xlvii. remarks, that during the twenty years he had lived at Constantinople and Smyrna, there had scarcely been a year, excepting three, in which the plague did not threaten more or less, with little or no perceptible difference in the character of the season to explain it. The late Sir Thomas Maitland, who had occasion, whilst governor-general of Malta and the Ionian Islands, to apply his vigorous mind to the investigation of the natural history of the plague, came to the conclusion, that, though subject to variations in respect of prevalence in the countries in question, this disease is never wholly extinct in any of them. "We find," says Sir Thomas, "that, whether it be in Egypt, at Smyrna, or Constantinople, an effort has been made to convince the world that the plague stops in these places at certain seasons, and commences at others. For my own part, I can only say, that he would be a bold man who would venture to assert that the plague ever is eradicated at any season of the year, in any one of the three places just mentioned; on the contrary, I hold nothing more certain, than that it constantly exists in them all, showing itself with greater violence at one time than at another, and hardly taken notice of till it arrives at such a height as to be seriously alarming to the whole community."[1]

Frequency of its epidemic prevalence.

Various estimates have been given of the frequency of plague epidemics in the principal towns of Egypt, Syria, and Turkey. Prosper Alpinus, who resided in Egypt between 1580 and 1584, refers to a belief of its recurring in that country every seventh year, but represents this belief as being incorrect. Dr Alexander Russell mentions it as the common opinion of the inhabitants of Aleppo, that they are visited with the plague about once in ten years; which opinion, he observes, seems in some measure to be founded on experience. Dr Mackenzie, writing from Constantinople in 1763, says, that "the plague is now more frequent in the Levant than it was when I first came into this country, about thirty years ago; for then they were almost strangers to it in Aleppo and Tripoli of Syria, and they had it but seldom at Smyrna; whereas now they have it frequently at Aleppo, and summer and winter in Smyrna, which," he adds, "must be owing to the great communication by commerce all over the Levant, and more extended into the country villages than it used to be."

Disappearance during a particular part of the year.

When the plague assumes an epidemic character in the countries in which it is common, the epidemic frequently continues for several years; not, however, uninterruptedly, for in general it is observed, that for a part of the year the disease in a great measure or altogether disappears, breaking out again after an interval of various duration. In the same way, in non-epidemic seasons, sporadic cases of plague are seldom or never met with during a particular portion of the year. It seems reasonable to conclude that this disappearance of plague, or great abatement in its prevalence, during a particular portion of the year, must be connected with some peculiar condition of the weather then prevailing, and consequently that the period must be liable to variations, not only in different countries, but also to some extent in the same country in different years.

Season at which this occurs.

Dr L. Frank mentions his having been assured that at Cairo the time of year in which the operation of the plague-poison is suspended uniformly commences with the summer solstice (21st June), as stated by Prosper Alpinus with regard both to that city and to Egypt generally; but that at Alexandria, Rosetta, and Damietta, that is, in the towns along the coast, the plague terminates about the feast of St John (24th June), though not uniformly every year, as it sometimes continues till about the middle of July. In respect to the period of the plague's terminating at Cairo, Dr P. Russell mentions, that several accounts which, on making strict inquiry, he received from persons long resident in that city, Europeans as well as natives, all concurred in the fact of the plague's declining rapidly in June, but not ceasing entirely; and he particularly refers to information which he had received of the Europeans having remained, in 1759, shut up till the middle of July, "which was considered as very extraordinary." Dr Russell also remarks, that in most places in the Levant, a popular tradition is to be found of the extinction of the plague at a certain fixed period, which varies, however, at different places. At Aleppo, he adds, it is fixed nearly a month later than at Cairo. His brother, Dr A. Russell, states, that at Aleppo the plague comes to its height in June, decreases greatly in July, and certainly disappears in August. Mr Dawes, chaplain to the factory at Aleppo, says, that in all the plagues with which Aleppo had been visited in the eighteenth century up to that of 1761, the contagion is said to have regularly and constantly ceased in August and September. But that which prevailed in the year last mentioned proved the fallacy of general observations on this subject; for, from the end of March 1761, to the middle of September 1762 (that is, for a continued period of seventeen and a half months), scarcely a day passed without some deaths or fresh attacks from the distemper; and though its violence ceased in autumn, yet on an average he believes it was fatal to at least thirty persons in every week, from that time to the end of the winter. Dr P. Russell, in reference to the same epidemic, says,—"The natives all agreed in declaring the plague had never before been so formidable in the winter; and many went so far as to affirm that it was the first instance of the plague's having been ever known at all at that season. But what happened in the year 1742 was entirely forgotten; and the cases in the present winter, however strongly marked, will probably, in the course of a few years more, be obliterated from the memory of the people of Aleppo, leaving them as tenacious as before of a traditionary opinion, that the city stands secure from the plague in the winter." At Smyrna, according to Mr Hayes, the virulence of the disorder is almost invariably over by August. From the statement of Dr Mackenzie, it appears that the plague began at Constantinople in 1751 about the middle of May, and continued uninterruptedly more than sixteen months, that is, up to the latter end of September 1752. In 1753, it began the last day of May, and continued uninterruptedly till the middle of September 1754.

---

[1] Dispatch to Earl Bathurst, of date the 8th April 1819; ordered to be printed the 17th June 1825.

Season of its re-appearance.

Admitting that, in general, though certainly not universally, plague disappears in Egypt soon after the 21st of June, in Syria about a month later, and probably at a still more advanced period of the year in Asia Minor and Turkey, is there any constancy in regard of its re-appearance? Sir J. M'Grigor mentions that the month of November, or more usually of December, is the time of year in which the plague is wont to re-appear in Egypt, and that, according to the observation of the natives, when it breaks out before December, they have always a generally prevailing and very destructive disease. According to Pugnet, there are three periods in the prevalence of the plague in Egypt: its *invasion*, which occupies the months of December, January, and February; its *acme*, which occupies March, April, and May; and its *extinction*, which occurs suddenly during the second half of June. Frank says, that, according to the general accounts, the plague seldom occurs in Egypt in the months of September, October, November, December, and January, but usually appears in the months of February, March, and April; and he adds, conformably with Sir J. M'Grigor's statement, that "it is well ascertained, that when it begins in September or October, it is more terrible than if it appears later, because it then continues for a longer time, and is the cause of greater mortality. Perhaps, also, the pestilential miasma becomes more deadly." At Aleppo, according to Dr A. Russell, the plague is constantly moderated during the winter, and grows more violent as the spring advances. Mr Hayes mentions the months of March and April as the period at which the plague usually begins at Smyrna. Timone states in regard to the plague at Constantinople, that it is pretty soundly lulled by the cold of winter, emitting, however, here and there sparks during that season as well as in spring; it increases in summer, and rages with the greatest violence in August. The spread of the infection is not stopped by the coldish north winds blowing at stated times of the summer; but if the south winds blow during that season, constantly and of sufficient warmth, they suppress the plague.

We shall presently have occasion to see the application of these facts relative to the periods at which the plague subsides and revives in Egypt, Syria, and Turkey, to the explanations that have been proposed of the causes or agencies by which this disease is produced.

Nature of the agent by which it is produced.

Great difference of opinion has subsisted as to the nature of the agent which, by its operation on the animal economy, produces this form of disease; whether the plague is generated by a particular state of the atmosphere, itself the result of the reciprocal action of various concurrent agents, and which is sufficient to produce the disease in a large proportion of those who are exposed to its influence, as is the case in respect of ague or intermittent fever; or whether the disease is communicated from person to person through the medium of some impalpable effluvium from the body, as in the cases of measles and scarlet fever? Whether, in the language of medical men, the plague depends on terrestrial or atmospheric miasm, improperly named infection by some, or upon human contagion.

The quarantine laws.

The laws of quarantine, so far as they refer to the plague, obviously proceed on the supposition that this disease is capable of being communicated by person to person; and also that the plague-poison is capable of being imbibed by substances that have come in contact with the bodies of those affected, or that have been exposed to the air which they breathe; of remaining attached to such substances for a considerable space of time, when excluded from free ventilation; of mixing with the atmosphere when exposed to it, and infecting those who breathe it; or of communicating the disease to persons who touch or handle the articles to which it is attached. The inconvenience with which the enforcement of the quarantine laws is necessarily attended, particularly to those engaged in commerce, has naturally rendered many anxious for their repeal or modification. The grounds upon which those who have represented them as unnecessary have rested their case, may be referred to the two following: 1*st*, That the plague always depends on miasm, and consequently, where the circumstances necessary for the production of plague-miasm concur, the disease will happen in spite of all quarantine regulations; and, 2*d*, that supposing the disease to be contagious, there are climates in which its contagion cannot be received and propagated, and consequently, as regards these, quarantine laws must be superfluous.

Dependence on contagion satisfactorily established.

The evidence in favour of the contagious character of the plague in Egypt, Syria, Turkey, &c. and of its dissemination both by person and by fomites, as deduced from the places and individuals that escape, as well as from the places and individuals that become affected, is so ample and complete, as to leave room for doubt only in minds pre-occupied with theoretical dogmata, or considerations of personal advantage. Accordingly, the opinion adverse to the contagious character of plague in these countries, seems to be now very generally abandoned by those who can be regarded as impartial and competent judges of the fact. When a select committee was appointed by the House of Commons in 1819, to consider the validity of the doctrine of contagion in the plague, all the medical men examined, with the exception of two, were in favour of the received doctrine, that the plague is a disease communicable by contagion. One of these anti-contagionists in plague was Dr Charles Maclean, the other Dr Mitchell. Of the medical officers of the French and English armies in Egypt between 1799 and 1802, who have published an account of the diseases which presented themselves to their observation during that campaign, Assalini seems to have been the only one who came to the conclusion that the plague is not a truly contagious disease, and that it is produced solely by local causes.

Whether also dependent on terrestrial miasma.

By some, however, it has been supposed that both terrestrial miasm and human contagion are concerned in spreading the plague, the disease being first generated by miasm, but subsequently diffusing itself, by contagion, both in the districts in which the miasm is produced, and in countries to which it does not extend, and in which it cannot be supposed to be generated. Amongst those holding this doctrine, there has been a difference of opinion as to the number of districts in which the supposed plague-miasm may be produced. Some conceive that there is one particular portion of the globe only in which the circumstances essential for the development of plague-miasm occur in combination; an opinion readily adopted by the different nations and provinces among whom the disease frequently prevails, though they differ very much as to the parent soil, each being desirous to transfer that odium from itself to its neighbour. M. Fodéré, who, though he had never personally seen the plague, had bestowed much pains in studying its history, maintains that the plague is a production of the soil of Lower Egypt alone; that is to say, of the combination of the waters of the Nile, and of the materials brought down by that river, with the vegetable earth of the Delta, when, after the inundation, the heat causes these waters to be volatilized, and gives rise to the creation of an immense multitude of insects and of reptiles. When the disease has once been produced in the human body by this miasm, he has no doubt as to its being capable of being communicated from person to person. He holds, therefore, that in Lower Egypt, the plague is both an endemic and a contagious disease; whilst, when it occurs in Upper Egypt, in Syria, and the other countries of Turkey, and in Europe, it is simply a contagious disease, being transported to them from Lower Egypt.

Dependence on atmospheric conditions;

Others, again, are of opinion, that in Egypt, as elsewhere, the plague always requires a human effluvium for its production and communication; but that the propagation of this contagious effluvium is greatly influenced by, if not dependent upon, particular conditions of the atmosphere. This unknown condition of the atmosphere is supposed either to cause the effluvia of non-pestilential diseases to assume a pestilential character, or the plague-effluvium to be generated of a peculiarly virulent character, or to render the human body more susceptible of its action. The influence of the atmosphere in promoting and in checking plague seems sufficiently established by the circumstances already stated relative to the variations in its prevalence in the different seasons of the year; but in what manner or by what qualities the atmosphere exerts this influence, is a matter of the greatest uncertainty.

on temperature;

Some authors have been of opinion, that it is simply the *temperature* of the atmosphere which determines the prevalence of plague in the countries along the shores of the Mediterranean; that the atmosphere may be either too hot or too cold for its propagation. Thus Dr A. Russell mentions, that the season wherein the plague always ceases at Aleppo, is that in which the heats are the most excessive. "Extreme heat," he says, "seems to check the progress of the disease; for though, during the few first hot days, the mortality, as well as the number of those newly infected, increase, yet a few days' longer continuance of that weather greatly diminishes the number of the sick." Mr Dawes, in mentioning August and September as the months in which the plague usually, though not constantly, ceases at Aleppo, notices them as being the hottest months in the year. Conformably with the same view, the occurrence of the hot winds is conceived by some to be the agent which puts a stop to the prevalence of the plague in Egypt. From the statements of Timone, and of several other authors, as we have already seen, it appears that, at Constantinople, the cold of winter generally exercises a great influence in suppressing or diminishing the extension of this disease. Dr James Frank, who was upon the expedition with Sir Ralph Abercromby in the year 1800, and had the first establishment of the Plague Hospital at Aboukir, says, in his evidence before the committee of the House of Commons in 1819, "the great cold of Constantinople puts an end to it, and the great heat of Cairo puts an end to it." And to the same effect Mr Edward Hayes, a native of Smyrna, and who had resided there nearly forty-four years, on being asked by the committee, "When does the plague generally subside in your country?" replied, "When the great cold or the great heat destroys it."

on heat and moisture conjointly.

M. Pugnet, again, affirms that the prevalence of the plague in Egypt is always proportional to the *moisture* of the atmosphere taken in connection with its *heat*, whether the moisture shall depend on a greater than usual inundation of the Nile, or on the fall of rain; and explains by these different sources of moisture the plague making its appearance in different districts of Egypt in different years. The circumstance of the heat bearing either a very great or a very small proportion to the moisture of the atmosphere, is, according to Pugnet, unfavourable to the extension of plague; but at the same time he holds, that besides moisture and heat, the germ of the disease, as he terms the contagious principle, is requisite for its development. In noticing that most of those who have travelled in Egypt say the plague is brought there from Greece, and those who have travelled in Greece pretend that that country only receives it from Egypt, M. Pugnet remarks,—"I think that the defenders of Egypt and those of Greece are equally in the right; the plague comes no less from Egypt than from Greece, or from Greece than from Egypt. It has established itself a durable focus in these two opposite points; and when one of them seems to become extinguished, the other revives it."

Supposed connection with the overflowing of the Nile.

Dr L. Frank, who, after sojourning with the French army in Egypt, subsequently resided for a year in Tunis, and travelled for six years over the continent of Greece, principally for the purpose of investigating everything connected with the plague, is adverse to the idea of the production of the pestilential poison being in any way connected with the overflowing of the Nile. The Nile begins to decrease in September, and in December all the waters disappear from the inundated surface. Consequently, he argues, if the putrefaction of stagnant waters could produce the plague, this disease should manifest itself chiefly in the months of October, November, and December, whilst, in fact, it very rarely occurs in these months. And as the increase of the Nile in the month of June is very small, it cannot be supposed to be the occasion of the extinction of the plague which occurs at that season. Besides, the plague occurs in some years when the increase of the river has been small, and does not occur in other years when the increase has been considerable. Frank has no doubt that the plague may be generated in Egypt; but in many instances he thinks it is imported into it from other countries, just as it is liable to be carried from it to other countries. He suggests, that when the plague manifests itself rapidly without any other epidemic having preceded it, it has probably been imported; but that when an epidemic, petechial, malignant, or nervous fever has previously occurred, it is very probable that these diseases have degenerated, and produced the contagious principle of the plague. Frank conceives, with Alpinus, that it is in the character of the *winds* that the cause of the prevalence or cessation of the plague in Egypt is to be looked for; the unhealthy season corresponding with the part of the year during which the winds and weather are variable, and the healthy season with the period during which the north wind blows steadily, that is, from June to September.

Dependence on the prevailing winds.

Supposition of plague-poison being reproduced from time to time.

Those who, in admitting the contagious character of the plague, have argued in favour of the possibility of its poison being engendered independently of human effluvia, and simply from the reciprocal action of the atmosphere and the earth upon one another, seem to have been led to this view by their believing that the plague-poison is wholly extinguished during a certain portion of the year, and consequently, that for the reproduction of the disease there must be a reproduction, or *generatio de novo*, as medical men term it, of the poison.

When by the return of the period of the year which is unfavourable to its dissemination, the plague ceases, one of two things may happen. It may remain absent from the country or district for a succession of years, or it may recur with the period of the year which is compatible with its propagation. Now it does not appear to be necessary, in either of these cases, to admit the supposition of a fresh generation of pestilential poison from terrestrial miasmata. In the case of the shorter interval, the epidemic may have slumbered, but not died; in short, there may have occurred sporadic cases of the disease, in sufficient number to maintain the stock. When, again, a more considerable interval elapses between the cessation of the plague and its re-appearance at a particular place, a fresh importation may have taken place from regions in which it has been prevailing epidemically during its absence from the country under observation.

Besides being maintained by sporadic cases during the non-epidemic season of the year, the contagion of the plague may also be maintained in the form of *fomites*, that is, attached to substances that have been in contact with the bodies of patients, or exposed to the air which they breathe. Dr Russell mentions, that at Aleppo, in 1762, several instances occurred of the revival of plague in houses which had suffered the year before, attended with circumstances highly suspicious of the contagion having been preserved several months for want of cleansing. It has very generally been believed, also, that by fomites the contagion of plague may be carried to regions very remote from that in which these substances acquired it. When the articles to which the pestiferous poison has attached itself are freely exposed to ventilation, it does not seem to be retained for any considerable length of time; but when, on the contrary, they are excluded from open communication with the air, there is good ground for suspecting that the poison may remain attached to them for a long space of time. Indeed we are not acquainted with any natural limit to its continuance, besides that of the free exposure of the fomites to the air.

Circumstances diminishing the probability of infection.

In considering the plague to be capable, at least during a certain portion of the year, of being diffused by contagion, it is not necessarily inferred that all persons who approach within a given distance of a person labouring under the disease must become affected with it. There seem to be a variety of circumstances that diminish the probability of infection, with some of which we are more or less acquainted, whilst of others we are entirely ignorant.

1*st*, It has been supposed that exposure during one period of the epidemic is attended with less risk of infection than exposure during another. 2*d*, That exposure to a mild case of plague is attended with less risk of infection than exposure to one of a very malignant character. 3*d*, That a person who is exposed to plague-contagion by degrees, runs less risk of infection than one who is suddenly brought within the sphere of its operation. 4*th*, That persons possessing equanimity of mind, of temperate habits, &c. run less risk than those who are in opposite circumstances.

Individual peculiarities in respect of the susceptibility or non-susceptibility of plague-contagion are very singular and unaccountable; but not more so than are observed in respect of other contagious diseases. A person whose exposure to the affected has been slight and of short continuance, may be seized with the disease; whilst another who has undergone a very great degree of exposure remains free. And a person who has remained free during close and long-continued exposure, may ultimately become affected, without any change of circumstances, extrinsic or intrinsic, which it is possible to detect.

Dr L. Frank conceives that the proportion of persons who pass their life in Egypt without experiencing an attack of plague, is greater than the proportion of persons who never experience an attack of small-pox, which he reckons as scarcely one in ten thousand.

Possibility of recurrence in the same individual.

It has been much disputed whether having once passed through plague renders a person unsusceptible of re-infection; and if it does not afford absolute security against more than one attack, in what proportion of cases a second or more frequent recurrence takes place. Some authors have denied the reality, if not the possibility, of a second attack of plague; others have related, as very singular events, single cases which had been noticed in particular epidemics; whilst others again represent such occurrences as by no means rare. Dr Mackenzie mentions his having been assured by the Greek Padré, who took care of the Greek hospital at Smyrna for fifty years, that he had had the plague twelve different times during that period; and it is very certain, adds Dr Mackenzie, that he died of it in 1736. The abbé who took care of the Frank Hospital at Pera, assured Dr M. that he had had the disease at Constantinople and at Smyrna four different times.

Latent period of infection.

In various respects it is extremely desirable to know what length of time may elapse between a person's exposure to plague-poison, and the appearance of the disease. On the decision of this question, it is obvious, the duration of personal quarantine should be founded. Dr P. Russell mentions, that at Aleppo, he met with no instance of the disease appearing later than the ninth or tenth day after the day of shutting up, in those who adopted that precaution. Sir J. M'Grigor, in noticing that in different people, and under different circumstances, there is the greatest variety in respect of the time the matter of the pestilential contagion takes before it comes into action, mentions one case in which ten days seemed to be the shortest period that could possibly have intervened; and another in which a person continued well till the seventeenth day after being placed in quarantine.

In other countries than those of the Levant.

II. The few remarks which we have room to offer relative to the plague, as occurring occasionally in other regions than those bordering on the Levant and Archipelago, must bear reference chiefly to the question, whether, admitting the plague to be a contagious disease in the countries we have hitherto alluded to, there is any reason to apprehend the possibility of its being introduced into the British isles; or whether the quarantine laws, as regards the plague, might be safely abolished. To justify such a measure, it would, it appears to us, be necessary to establish the correctness of one or other of the following propositions:—1*st*, That it is impossible, in the nature of things, that the plague should exist in the British isles; and that, in point of fact, it never existed in them: 2*d*, That if it ever existed in these islands, it was indigenous, not imported, and consequently could not have been prevented by quarantine laws: or, 3*d*, That if it ever was imported into these islands, it was under circumstances which cannot recur.

Possibility of plague occurring in the British isles.

1*st*, Our opinion, as to whether a particular disease can occur in any country, may rest upon two grounds; the first, our belief as to the conditions on which its prevalence in the countries it is known to infest may depend; and the second, our knowledge as to whether it has ever prevailed in the country in former times. These two considerations may reflect mutual light on each other. If we are very certain as to the conditions requisite for the existence of the particular disease, and are told that it has occurred in a country which we know not to fulfil these, we will disbelieve the correctness of the statement. And, conversely, if we are perfectly satisfied that the disease has prevailed in a country which does not fulfil the conditions we are disposed to consider requisite for its existence, our opinion as to these conditions must be modified. In respect of the plague, it is plain, from the discrepancies which we have seen to prevail in the explanations given of the causes by which it is produced and propagated in Egypt, &c. that the reality of its existence is exposed to much less dubiety than the explanation of the conditions on which that existence depends.

The fact already mentioned, of the very wide signification that used to be attached to the term plague or pest, renders it necessary, indeed, that in judging whether a particular epidemic was really plague or not, we should not trust to the mere name which it received, but inquire into the symptoms which it actually exhibited. But, with symptoms so very characteristic as those that attend true plague, or rather, as we have already said, a large proportion of the cases that occur in the course of a plague-epidemic, a very slight description of a *pestilence* must suffice for determining as to its identity with genuine plague. Accordingly, we have experienced considerable surprise, in looking over the evidence taken by the committee of the House of Commons in 1819, at the number of witnesses who either positively denied that the so-called plague in London of 1665 (to omit previous epidemics to which that title was applied) was really that disease, or expressed much doubt on the subject. If the general statement of Sydenham to that effect left any room for doubt on this head, the minute description of Dr Hodges, and particularly the portion of it that relates to the more peculiar symptoms, including buboes, carbuncles, &c. is more than sufficient, we should have thought, to remove all doubt from the minds of the most sceptical.

hether igenous mport-

2*d*, As to the plague of 1665 having been indigenous, and not imported, we have a very explicit statement of Dr Hodges as to its having been brought from Turkey to Holland, and from Holland to England. Attempts have indeed been made to point out discrepancies in his explanation of its first appearance and propagation in England; but to us the objections appear inconclusive, and the deficiencies in the chain of proofs such as might occur in tracing the diffusion of a disease universally recognised as contagious. The non-recurrence of the plague in this country since that period is certainly not more easy to explain, on the supposition of the epidemic in question having been indigenous, than on that of its having been imported.

3*d*, The circumstances favourable to the reception and dissemination of plague-contagion, which may be supposed to have existed in 1665, but to be now extinct and incapable of recurring, may be of different kinds. The beneficial change may be in the character of the climate, in the condition of the soil, or in the habits of the people. But if our immunity has depended on a change in the climate, who can be responsible for the continuance of this change? What the climate has been, it may, for any thing we know, become again. And as to any immunity that could be supposed to result from a change in the habits of society, and particularly from the superior attention paid to cleanliness and ventilation in our cities, from the introduction of public sewers, &c. to which much importance has been attached, we must confess our apprehensions, that any seeds of disease which depend for their development upon filth, will not perish for want of a hot-bed in many districts of the larger cities of the three kingdoms.

A recent occurrence in Egypt forcibly inculcates the necessity of great caution in admitting, that in a country in which plague is known to have occurred, any changes have been effected, either in the soil or in the people, incompatible with its recurrence. Mr Edward W. Lane, in his Account of the Manners and Customs of the Modern Egyptians, written in Egypt during the years 1833, 1834, and 1835, says, "The climate of Upper Egypt is more healthy, though hotter, than that of Lower Egypt. The plague seldom ascends far above Cairo, the metropolis. It is most common in the marshy parts of the country near the Mediterranean. During the last ten years, the country having been better drained, and quarantine regulations adopted to prevent or guard against the introduction of this disease from other countries, very few plague cases have occurred, excepting in the parts above mentioned; and in those parts the pestilence has not been severe." But in a note Mr Lane adds, "This remark was written before the terrible plague of the present year (1835), which was certainly introduced from Turkey, and extended throughout the whole of Egypt, though its ravages were not great in the southern parts. It has destroyed not less than eighty thousand persons in Cairo, that is, one third of the population; and far more, I believe, than two hundred thousand in all Egypt."

If, from any of the circumstances alluded to, the British isles can be supposed to be free from the risk of the importation of plague-contagion, or of its diffusion in the event of importation, it is to be presumed that it does not enjoy this as an exclusive privilege, but must share it with other countries that are similarly circumstanced. It becomes necessary, therefore, to inquire in what countries, besides those immediately bordering on the Levant and Archipelago, we have occasion to believe that the plague has existed, or is capable of existing.

In the first place, of its liability to occur in the islands, and along the coasts of the more western portions of the Mediterranean, we presume no doubt can be entertained. In two of the Greek islands now under British dominion, viz. Corfu and Cephalonia, the plague occurred in 1816, in a form which left no room for doubt as to its real nature. In Italy, Malta, and the adjoining small island of Gozo, we have equally unquestionable examples of the occurrence of plague in recent times; witness that which occurred at Noja in the kingdom of Naples in 1816, and of which accounts have been published by Morea, Onofrio, and Schönberg; and that which occurred in Malta and Gozo in 1813, of which accounts have been given by Calvert, Faulkner, and Tully. Previously to 1813, Malta appears not to have been infected with the plague for upwards of a hundred and thirty years, that is, since 1675; a circumstance not undeserving the consideration of those who are disposed to consider non-occurrence as implying impossibility of occurrence.

In Sicily, we are not aware of the plague having appeared in an epidemical form since the year 1743, when it raged at Messina.

Along the African coast we have accounts of the occurrence of the plague at Tunis in 1818, 1819, and 1820, by Passeri; and of its occurrence so far to the west as Tangier in 1818 and 1819, an account has been published by Graberg di Hemso.

Of the plague-epidemics that have occurred on the northern shores of the western portion of the Mediterranean, that of which we possess the most circumstantial account is the epidemic of Marseilles in 1720. The descriptions of that epidemic given in the works of Chicoyneau, and of Bertrand and Michel, leave, we conceive, not the smallest room for doubt as to the disease having been genuine or Levant plague.

Of the extension of the plague from Turkey into more northern latitudes, numerous examples might be adduced. Between the years 1702 and 1711, it advanced by a gradual but steady course through the different provinces of Poland and Prussia to Dantzig, and from thence extended itself to Copenhagen. (See the accounts of this epidemic by Gottwald, Chamberlayne.) Again, in the year 1769 and 1770, when the Russians and Turks were engaged in warfare, the plague passed from the Turkish confines through some of the Polish provinces, and thence into the Russian territories, and ultimately reached the city of Moscow. (De Mertens, Orræus, Samoilowitz.)

It has been generally considered as a well-established fact in regard to the plague, that it had not been seen beyond a certain degree of eastern longitude, Mecca being the limit that has usually been assigned to its extension in that direction. This fact has been supposed to confirm and to be explained by the notion of its contagious poison being rendered innocuous by a certain degree of atmospheric temperature. From recent communications from India, however, there seems too much reason to apprehend that the plague has at length made its appearance on the confines of the north-western district of Hindustan. The only accounts of the epidemic which has excited these apprehensions that we have yet had an opportunity of perusing, are contained in the first three numbers of the Quarterly Journal of the Calcutta Medical and Physical Society, published between the 1st January and the 21st July 1837. We are unable to lay extracts before our readers, but we may refer to the communications of Mr Maclean, Dr Irvine, and Dr Keir, therein contained, as leaving little room to doubt that the epidemic in question was true plague, though not in its most aggravated form. (L. L. L. L.)

PLAIN, or PLANE, in general, an appellation given to whatever is smooth and even, or simple, obvious, and easy to be understood; and, consequently, stands opposed to rough, enriched, or laboured.

A plain figure, in *Geometry*, is an uniform surface, from every point of the perimeter of which right lines may be drawn to every other point in the same. A plain angle is one contained under two lines or surfaces, in contradistinction to a solid angle. See ANGLE and GEOMETRY. The doctrine of plain triangles, as those included under three right lines, is termed *plain trigonometry*. See the article TRIGONOMETRY.

PLAN, in general, denotes the representation of something drawn upon a plane, such as maps, charts, ichnographies, and the like. The term *plan*, however, is particularly used for a draught of a building, such as it appears, or is intended to appear, on the ground, showing the extent, division, and distribution of its area or ground-plot into apartments, rooms, passages, &c. A geometrical plan is that in which the solid and vacant parts are represented in their natural proportions. The raised plan of a building is the same with what is otherwise called an *elevation* or *orthography*. A perspective plan is that exhibited by degradations or diminutions, according to the rules of perspective.

PLANE, in *Geometry*, denotes a plain surface, or one that lies evenly between its bounding lines; and as a right line is the shortest extension from one point to another, so a plane surface is the shortest extension from one line to another.

In astronomy, conic sections, &c. the term *plane* is frequently used for an imaginary surface, supposed to cut and pass through solid bodies; and on this foundation is built the whole doctrine of conic sections. In mechanics, planes are either horizontal, that is, parallel to the horizon, or inclined thereto. The determining how far any given plane deviates from an horizontal line, makes the whole business of levelling. In optics, the planes of reflection and refraction are those drawn through the incident and reflected or refracted rays. In perspective we meet with the perspective plane, which is supposed to be pellucid, and perpendicular to the horizon; the horizontal plane, supposed to pass through the spectator's eye, parallel to the horizon; and the geometrical plane, likewise parallel to the horizon, in which the object to be represented is supposed to be placed.

The plane of projection in the stereographic projection of the sphere, is that on which the projection is made, corresponding to the perspective plane.

PLANE, in joinery, an edged tool or instrument for paring and shaving wood smooth. It consists of a piece of wood very smooth at bottom, as a stock or shaft, in the midst of which is an aperture, through which passes a steel edge, or chisel, placed obliquely; and this being very sharp, takes off the inequalities of the wood along which it slides.

PLANET, a celestial body, revolving round the sun as a centre, and continually changing its position with respect to the fixed stars; whence the name *planet*, which is a Greek word signifying "wanderer." See ASTRONOMY.

PLANETARIUM, an astronomical machine, so called from its representing the motions and orbits of the planets, agreeably to the Copernican system.

PLANETARY DAYS. Amongst the ancients, the week was shared among the seven planets, each having its own day. This we learn from Dion Cassius, and also from Plutarch (*Sympos.* lib. iv. q. 7). Herodotus adds, that it was the Egyptians who first discovered what god, that is, what planet, presided over each day; for amongst this people the planets were directors. And hence it is that in most European languages the days of the week are still denominated from the planets.

PLANETARY *Years*, the periods of time in which the several planets make their revolutions round the sun or earth.

As from the proper revolution of the sun the solar year takes its origin, so from the proper revolutions of the rest of the planets about the earth, several sorts of years arise; such are the Saturnian year, which is defined by twenty-nine Egyptian years, 174 hours, fifty-eight minutes, equivalent in a round number to thirty solar years; the Jovial year, containing 317 days, fourteen hours, fifty-nine minutes; and the Martial year, containing 321 days, twenty-three hours, thirty-one minutes. With respect to Venus and Mercury, as their years, when judged of with regard to the earth, are almost equal to the solar year, so they are more usually estimated from the sun, the true centre of their motions; in which case the former is equal to 224 days, sixteen hours, forty minutes, and the latter to eighty-seven days, twenty-three hours, fourteen minutes.

PLANIMETRY, that part of geometry which considers lines and plain figures, without regard to their height or depth.

PLANISPHERE signifies a projection of the sphere and its various circles upon a plane; in which sense maps, on which are exhibited the meridians and other circles of the sphere, are planispheres.

PLANT is defined to be an inorganical body, destitute of sense and spontaneous motion, adhering to another body in such a manner as to draw from it its nourishment, and having a power of propagating itself by seeds. See ANATOMY VEGETABLE, BOTANY, PHYSICAL GEOGRAPHY, and VEGETABLE PHYSIOLOGY.

PLANTAGENET, the surname of the kings of England from Henry II. to Richard III. inclusive. Antiquaries are much at a loss to account for the origin of this name; the best derivation they can find for it being, that Fulk, the first Earl of Anjou of that name, stung with remorse for some wicked action, went, as a work of atonement, in pilgrimage to Jerusalem, where, being soundly scourged with broom twigs, which grew plentifully on the spot, he afterwards took the surname of *Plantagenet*, which was retained by his posterity.

PLANTERSHIP, in a general sense, is the business of a planter. In the West Indies, plantership denotes the management of a sugar plantation, including not only the cultivation of the cane, but the care of the various processes for the extraction of the sugar, together with the making of sugar-spirits.

PLANTING.

Planting, or the culture of trees, is a branch of agriculture necessarily of much more recent date than either the culture of grain and herbage plants, or the breeding and rearing of cattle. The culture of those plants which in every country supply the food of mankind, whether directly, or by nourishing the domestic animals used for food by man, must have exclusively occupied his attention for many ages; whilst the timber which was employed in houses, ships, and machines, or for fuel, was found in the native woods. Hence, though we hear of the culture of fruit-trees, and occasionally also of ornamental trees and shrubs, amongst the Egyptians, Greeks, and Romans, the cultivation of timber-trees on a large scale by art only took place in modern times. In the days of Charlemagne, the greater part of France and Germany was covered with immense forests; and one of the benefits conferred on France by that prince, was the rooting up of portions of these forests here and there throughout the country, and substituting in their room orchards or vineyards. Artificial plantations appear to have been formed in Germany sooner than in any other country, and apparently as early as the fifteenth century. In Britain they took place, though but sparingly, nearly a century afterwards. Planting, however, was by no means general in England till the beginning of the seventeenth century, when, in consequence of the extensive transfers of property which took place in the preceding century, on the seizure of the church-lands by Henry VIII., much timber was sold by the new owners, in order to make good their payments. The quantity of timber thus thrown into the market lowered its price considerably, insomuch, as Hollingshed informs us, that the builders of cottages, who had formerly employed willow, and other cheap and common woods, now built them of as good oak as their lords. The demand for timber thus constantly increasing, and a demand for an extended surface of farming land going on at the same time, the natural forests became everywhere greatly circumscribed, till at last timber for naval purposes and house-building began to be imported, and the proprietors of land to think, first of protecting their native woods from the inroads of cattle; afterwards of enclosing pieces of waste ground, and allowing them to become covered with young trees from seeds carried thither by the wind or other accidental circumstances; and ultimately of sowing acorns and mast in such enclosures, or of filling them with young plants collected in the woods; a practice which exists in Sussex, and some other parts of England, even at the present day. Planting received a great stimulus in Britain soon after the breaking out of the late general war, partly in consequence of a real or supposed scarcity of timber fit for naval purposes, and partly owing to the high price to which the article for general use rose, in consequence of the increased expense of obtaining supplies from other countries. Since the peace, the rage for planting, with a view to profit, has subsided; but there is still a universal taste for cultivating trees and shrubs, with a combined view to ornament and use; and there is also an increased and increasing taste for the introduction of trees and shrubs from foreign countries.

Having in this slight manner noticed the origin of planting, we shall next give a brief outline of its present practice in Britain; noticing in succession: 1. A general view of the different properties possessed by trees; 2. selections suitable for different purposes; 3. the nursery culture of trees; and, 4. the culture of trees in plantations.

It is necessary to premise, that in this article we confine ourselves entirely to trees which are well known in Britain, and quite hardy; and to the formation of such plantations as are made with a view to their timber-produce. Fruit-trees and fruit-shrubs, flowering shrubs of every kind, and ornamental plantations, we consider as belonging to gardening, and as already disposed of under the article Horticulture.

I.—*General View of the different Properties possessed by Trees which may be cultivated in Britain.*

The sort of trees which it is desirable to plant, is necessarily the first point which a proprietor will take into consideration before he commences a plantation. Trees differ from one another in many particulars: in magnitude; in slowness or rapidity of growth; in their suitableness for poor soils or rich soils, moist grounds or dry grounds, elevated exposed situations, or low and sheltered plains; in the texture, colour, and durability of their timber; in their delicacy or hardiness in any given climate; in their being difficult or easy to propagate and rear; in retaining their leaves all the year, or dropping them every autumn; in producing showy flowers or fruits; and in a great variety of other particulars. In regard to magnitude, those trees which, in the latitude of Britain, and in the same parallels of latitude throughout the northern hemisphere, attain the greatest height, are the spruce and silver fir, the larch, and the Scotch pine; and these also are the trees which, in most parts of Britain, produce the greatest quantity of timber in their trunks relatively to that contained in their branches, and that in the shortest time. The poplar, the willow, and some species of elm, are rapid-growing trees, and produce a great bulk of head in a short period; but the timber of these trees is not all contained in one straight trunk, as in the case of the pines and firs, a considerable portion of it being distributed among the branches. Hence, where the speedy production of timber is the main object of planting, the pines and firs above mentioned are decidedly the trees that ought to be preferred. The production of timber, however, is not always the sole object of planting. Effect, or, in other words, the production of the appearance of woodiness on an estate, is perhaps oftener the object than mere timber. For this purpose the Scotch and English elms, the white, black, and black Italian poplars, the Huntingdon willow, and in some situations the birch, and in others, such as on the sea-shore, the sycamore, are the most desirable trees. Where the object is to clothe a sterile surface of dry sand, the birch and the Scotch pine are among the best trees that we have; and if the situation be exposed to the sea-breeze, the common and the Norway maple may be substituted for the birch and the pine; and, in the warmer parts of the island, the evergreen oak. For moist soils which cannot be drained, there are trees that have the remarkable property of sending their horizontal roots along the surface of the ground; among these are the white, the trembling, and the Ontario poplars; and, for the marshes of the warmer parts of the island, the deciduous cypress. There are trees which will grow near water, in situations where their roots can enter into it, but which will not grow in undrained soil, such as the different species of willow, and most of the poplars. It is a remarkable fact, that there is no tree in any part of the world which is truly aquatic; that is, which will spring up from the bottom of a pond or river. Had there been such trees created, there could then have been neither rivers nor lakes, and the whole of the terrestrial globe must necessarily have been either in a state of marsh or mountain.

In general it may be observed, that trees are not so absolute in their choice of soils as for each species to require one of a different nature; on the contrary, on almost any kind of soil not beyond the average in point of moisture, dryness, or tenacity, all the known species of trees and shrubs may be grown to a tolerably mature size and age. In some soils, however, they will thrive better than in others; and the timber produced generally varies in quality according to the soil. Thus a rich soil, while it contributes to the rapid growth of the pine and fir tribe, renders their timber less durable; and the same law holds good, more or less, with regard to every other species of tree.

The influence of climate on trees is incomparably greater than that of soil; for, whilst any tree may be said to grow on any soil, every tree may be said to have its particular climate; that is, a climate in which, the soil and other circumstances being suitable, it will attain its greatest bulk, and its timber endure the longest. Hence, when we take the geographical and physical range of any particular species of tree, the oak, for example, we shall find that there is what may be called a central climate, where, when on suitable soil, it attains its largest size; and that as it recedes from this climate, whether by latitude or elevation, either into one which is colder, or one that is hotter, it gradually diminishes in size, till it at last appears in the form of a shrub. Thus the common oak, which in Britain attains its largest size in Sussex and Hampshire, dwindles into a shrub on the mountains of the Highlands of Scotland, and also in the north of Africa; its degeneracy being occasioned in the one case by extreme cold, and in the other by extreme heat. Even within the range of the climate of Britain, the absolute character of trees, relatively to climate, is made obvious. The English or narrow-leaved elm, which is supposed to be a native of Asia Minor, and also of China, attains a large size in the neighbourhood of London, producing a great bulk of timber in a short period, and ripening its seeds; while north of York it does not thrive, and in Scotland it is considered only as an ornamental tree. The Lombardy poplar, which is known in the central counties of England to attain 100 feet in height in forty or fifty years, is nowhere seen of a timber-like size in Scotland; and it may be observed of the sweet chestnut and the walnut, that though they are grown both for their fruit and their timber in many parts of England, yet that they cannot be profitably employed for either purpose north of Newcastle.

Climate, relatively to trees, may be considered in regard to its average temperature throughout the year, to its temperature in summer and winter and in spring and autumn, and to its degree of atmospheric moisture. A high average temperature is no proof that a climate is suitable for trees; but a high summer temperature is suitable for many kinds, though the temperature of the winter may be very low. Thus the oaks and many other trees of North America, attaining there a prodigious size, survive a winter as cold as that of St Petersburg, where no native oaks of any kind are ever found; but the oaks of North America enjoy a very high temperature during summer, which rapidly develops their foliage and young shoots, and fully matures the latter, so as to enable them to withstand the most rigorous frosts of winter. In England the average temperature of the year is as great as that of the oak countries of the United States; but our summers are comparatively cold, moist, and gloomy; and though our winters are so much milder than those of America, yet the spongy, unripened, young shoots are always more or less injured by the frost. Another disadvantage of a country having a mild winter is, that the trees of those countries which have a very severe winter come into leaf earlier in the spring than the indigenous trees of the mild climate; and frosts being more or less prevalent at that season, they are proportionably liable to injury from that cause.

Evergreen trees form a very important division of the ligneous kingdom; and of these there are two classes, very distinct relatively to climate and temperature. The first of these classes comprises the needle-leaved trees, such as the pine and fir tribe, which will endure a degree of cold as great as that in which any deciduous tree will thrive; and the second, the broad-leaved evergreen trees, such as the holly, the box, the laurustinus, the laurel, the evergreen oak, the cork-tree, and the evergreen mangolia, all of which are trees of comparatively mild climates, and which are always found in a natural state on islands, or on continents at low elevations, and at no great distance from the sea: hence the very considerable number of evergreen trees which will endure the open air in Britain, compared with those which stand through the winter in the same parallel of latitude on the continent.

Of the trees cultivated in Great Britain, only a small proportion are indigenous. A considerable number are natives of other parts of Europe, and about two thirds of the whole are from North America. Of these North American trees there is scarcely one that is worth cultivating in Britain for its timber; and the reason seems to be, chiefly, that our climate is not sufficiently hot and light in summer to bring that timber to maturity. The truly useful timber-trees of Britain are those which are indigenous, such as the oak, the ash, the broad-leaved elm, the Scotch pine, &c.; or those which are found in the same hemisphere and in the same parallels of latitude, such as the larch, the spruce fir, the silver fir, &c. Of all the trees which are cultivated in Europe, that which is most to be depended on for the strength and durability of its timber is the common oak; and next, and perhaps equal to it, is the larch. The trunk of the oak-tree, when freed from the soft or outer wood, and thoroughly seasoned by exposure to the atmosphere, will endure an unknown period of time in buildings and machines; and, even when split up into thin laminæ, and put up in the open air as fencing, without any painting or other preparation, it has been known to last for upwards of a century. The common European oak is found to be more durable as timber than any of the American oaks, even when grown in America, unless we except the live oak; and there is perhaps no timber in the world equal to it for ship-building, excepting the teak-wood of India. The most generally useful timber grown in Britain is the Scotch pine; but as this timber is also imported from the north of Europe, and a substitute for it from North America in great quantities, it is not planted in Britain nearly so extensively as it otherwise would be. The timber of the larch is undoubtedly of greater durability than that of the Scotch pine; but being apt to warp, and not being so easily worked, it is less convenient for the purposes of house-carpentry and joinery. The timber of the common ash is valuable in the construction of agricultural instruments and machines, and it is one of the few woods which are almost as valuable when young as when of mature age. The wood of the broad-leaved elm is strong and durable, but that of the English and Dutch elms is much less so. The wood of the poplar, and that of the willow, when exposed to constant atmospherical changes, speedily decay; but when thoroughly seasoned, and afterwards kept perfectly dry, they will last for centuries. In general, it may be observed, that every description of timber, when at maturity, if thoroughly seasoned, and preserved in an atmosphere tolerably uniform in point of dryness, will last a long period.

The great majority of trees which are planted in Britain may be considered as ornamental; for though the timber of all of them is more or less useful, yet, if the mere production of timber were the main object of planting, all trees except the oak, the larch, the Scotch pine, and two or three others, would be rejected, either on account of their slow growth, or of the inferior quality of the timber which they produce in our climate. Trees may be considered as ornamental, from their general shape, from their foliage, from their flowers or fruit, or from their rarity. In order that the shapes of trees may be displayed to advantage, it is necessary that they should stand singly; and when this is the case with some species of trees, such, for example, as the different species of the pine and fir tribe, their shapes become strikingly different from what they are when grown in masses. The Scotch pine, when drawn up in close forests, produces a clean, straight trunk, free from branches for the greater part of its height; but when by chance or design it stands singly, it throws out gigantic branches on every side, and becomes one of the most irregular and picturesque-headed of trees. But of all the trees which assume ornamental shapes in consequence of standing singly or nearly so, the most remarkable is the cedar of Lebanon. When this tree is grown in masses, it shoots up with a straight, clean trunk, and terminates in a small, spiry top; but when planted alone, and allowed to spread its branches on every side, it throws out its gigantic arms in successive tiers, and forms an irregular pyramidal mass, unequalled for grandeur, singularity, and picturesque beauty, by any other tree of the temperate regions of either hemisphere. All trees indeed become comparatively the same naked poles with scanty tops when grown in masses, and all assume irregular and picturesque forms when grown singly. Hence, whenever trees are grown chiefly for the purpose of displaying their shapes, they ought to be placed at such a distance from each other as that their branches may not touch; which in practice is effected by scattering them in groups in parks or pleasure-grounds, or planting them in hedgerows. Trees which are valued as ornamental chiefly for their foliage, fruit, or flowers, will obviously display these to the best advantage when standing singly; but for such an object isolation is much less necessary, as the ornamental foliage will be displayed even when the plantation is in masses, and seen at a distance; and the flowers and fruits by planting the trees in the margins of plantations of other sorts.

II.—*Selections of Trees for particular purposes.*

The object of the preceding remarks is to communicate some general ideas on the subject of selection, and on the properties of particular species; and we shall next pursue the same subject more in detail, by giving the names of the principal trees deserving of culture in Britain, thrown into groups characterized by some property common to the whole.

Needle-leaved or Resinous Trees are characterized by straight erect trunks, regularly furnished with branches in tiers, which never, except under particular circumstances, acquire the size of timber. They never send up shoots from the collar or stool when cut over by the surface. The leaves are narrow, or needle-shaped, without veins, and they are evergreen. The seeds are produced in cones, and the whole plant is more or less resinous. They belong to the Gymnosperms of the natural system, which form an order intermediate between the Dicotyledoneæ, and the Monocotyledoneæ.

Larix Europæa, *Dec.*, is the most valuable species for its timber, which is of great durability, both in its young and mature state. Young larches, five feet or six feet high, and the spray of larch-trees of any age, last a very long period, when intertwined with larch stakes, so as to form a dead fence. Young trees from ten feet to fifteen feet in height are found, in the neighbourhood of Farnham and other places, to form the most durable hop-poles; and the durability of the mature timber, in every department, both in civil and naval architecture, has been placed beyond all doubt, by the experience of John duke of Atholl, as recorded in the Transactions of the Highland Society of Scotland, vol. xi. p. 165; and Loudon's *Arboretum Britannicum*, vol. iv. p. 2387. The bark of the larch is also of considerable value in tanning; and the leaves being deciduous, the tree is more favourable to the growth of grass under its shade, than any other species of pine or fir. The larch is readily increased by seeds which are ripened in abundance in Britain; and it prospers best in cool, argillaceous soil, moist rather than dry, and placed at a considerable elevation above the level of the sea. The larch is subject to various diseases, and, in certain soils, to the decay of the heart-wood; but very little is known at present, either of the cause of these diseases, or of their prevention or cure. The larch cultivated in Britain is a native of the Tyrol, and of the Alps of Switzerland; but there are some other species or varieties, natives of Siberia and North America, which, however, are considered as scarcely worth culture as forest-trees.

The Scotch pine, Pinus sylvestris, *L.*, is, next to the larch, the most valuable needle-leaved tree grown in Britain. Its timber forms the yellow deal of the Baltic and Norway; and it is unequalled by any species of pine or fir timber contained in any other part of Europe, or North America. The best Scotch-pine timber grown in Britain is produced in the native Highland forests; but there is reason to believe that artificial plantations, on soils and situations as nearly similar as practicable, would produce timber of nearly equal value. It has been the practice for many years past to decry the Scotch pine grown in Britain as a timber-tree; and as we have now no difficulty in importing deal from the north of Europe, this condemnation has been assented to by many without due consideration. If, however, we could import no pine or fir deal from any other country, and were obliged to grow it ourselves, we would ask where is the tree that would produce it in so short a time, and of so good a quality, as the Scotch pine? This tree is readily increased from seeds, which, unfortunately, as is the case with several other trees, are produced in the greatest abundance on stunted trees, or, at all events, on trees not remarkable for their large size, or the durability of their timber. Hence it becomes desirable to select the seeds from the best varieties, and this is now done systematically by the principal Scotch nurserymen. The Highland variety, with horizontal branches, P. sylvestris horizontalis, *Arb. Brit.*, is the variety at present of highest repute. The Scotch pine is a native of the continent of Europe, but not of any part of America.

The spruce fir, Abies excelsa, *Dec.*, is, as a British timber-tree, next in value to the Scotch pine. The young plants and the spray are almost as durable as those of the larch; the trunk grows straighter, more erect and slender, than in that tree, and when used with the bark on, as poles or as fence-wood, it is equally durable. The spruce makes much better hop-poles than the larch; but as the trunk of full-grown trees seldom attains a diameter of above one or two feet at the ground, even in countries where it is a native, the trunk can very seldom be profitably sawn up into boards. The great value of the tree is for poles of every kind, from those fit for the hop, up to the masts for the smaller ships. In most parts of Europe, all the poles used in the scaffolding employed in erecting buildings are formed of this tree. The spruce fir ripens seeds abundantly in Britain, from which plants are as readily raised as in the case of the Scotch pine and the larch. It prefers a soft soil, rather moist, and only attains a great height in sheltered situations; but it will grow to a size fit for hop-poles or fencing in a short time, and anywhere. Like the Scotch pine, it is subject to few diseases. The spruce fir is a native of the north of Germany, Sweden, Russia, and Norway, but not of Britain or of North America. There are three or four species of spruce natives of the latter country, but they are of no value as timber-trees.

The pinaster, Pinus Pinaster, *Ait.*, is by no means adapted for general culture in Britain, and therefore scarcely merits to be ranked among our needle-leaved timber-trees. In some parts of England, however, particularly in Norfolk, considerable plantations of this tree have been raised; and it is found in deep sandy soil to produce a considerable bulk of timber in a short time. It has also the advantage of thriving better when exposed to the sea-breeze than any other pine or fir. The wood is not so durable as that of the Scotch pine; but it is of the same colour, and may be employed in the joinery of ordinary apartments. In general, however, it is by no means sufficiently strong for the roofing, joists, and other carpentry of dwelling-houses. A great use of the tree in France, and particularly in the neighbourhood of Bordeaux, where it is extensively grown on the sandy wastes, is for the production of resin, tar, and pitch, which are obtained by incisions made in the trunk, and by subjecting the wood to the action of fire. Seeds of this tree are ripened in England; but they may be obtained in any quantity, at a very moderate rate, from Bordeaux. The young plants require more care in transplanting than those of most other pines and firs, being furnished with a stronger tap-root than any of them. The pinaster is a native of the south of Europe and north of Asia, but not of America. It has been introduced, however, into most countries, probably from the large size and handsome appearance of the cones. Accordingly, specimens of this tree have been sent home from China, New Zealand, St Helena, North America, &c.; and the produce of the seeds from these places are commonly, but improperly, treated by nurserymen as varieties.

The silver fir, Picea pectinata, *Arb. Brit.*, in favourable soils and situations produces a great bulk of timber in a comparatively short period; but the timber is much less strong and durable than that of either the spruce fir or the Scotch pine. The tree is of slow growth for the first ten or twelve years of its existence, and the leading shoot is at that age very apt to be injured by spring frosts; nevertheless, even in the north and west of Scotland it has been known to attain to the height of 100 feet in sixty or seventy years. The timber is white, and makes excellent flooring for bed-rooms. The tree ripens seeds in Britain, though more sparingly than the spruce fir, and plants are easily raised. It is in general healthy, though the points of the shoots are occasionally destroyed by frost or by insects. The silver fir is a native of Central Germany, and of the Alps of Italy and Spain; but of no other country. There are other species of Picea, natives of North America and Nepaul; but relatively to Britain they can only be considered as ornamental trees.

Other needle-leaved trees might be enumerated as attaining a timber-like size in the climate of England; but there is not one of them that we think can be ranked in value along with those already mentioned as timber-trees. Of the American pines, that of which we have had most experience in this country is the Weymouth pine, Pinus Strobus, *L.*, which furnishes the white pine-wood of American commerce; but this wood, grown in any given situation in Britain, is far inferior to that of the Scotch pine grown in the same locality; and there are only a few situations in England where the Weymouth pine will produce the same bulk of timber as the Scotch pine in the same period. The other American pines, as timber-trees adapted for Britain, scarcely deserve notice. Pinus tæda, serotina, and rigida, have attained a timber size in a few places in England; but the time they have required to do this, even under the most favourable circumstances, precludes the hope of their ever becoming British timber-trees. Several Californian species of pine have recently been introduced; but half a century will be required to enable us to judge of their suitableness for this country. The Californian spruce fir, Abies Douglasii, is the most promising needle-leaved tree that has been introduced from that country; but it remains to be proved whether we shall ever be able to rank it with the common spruce. Of Nepaul pines there are two species, P. excelsa and P. Lambertiana, which resemble the Weymouth pine; and there is a spruce fir, Abies Smithiana, *Arb. Brit.*, A. Morinda, *Hort.*, which promises to be as hardy as the Norway spruce; but the other pines and firs of the Himalayas are all rather tender. The cedar of Lebanon, if planted in masses, like the larch or the Scotch pine, would, in good free soil, produce abundance of timber, but of far inferior strength and durability to what the Scotch pine would produce similarly treated. However ornamental, therefore, this tree may be, it cannot be recommended as fit to be cultivated for its timber. There are some European pines and firs which deserve to be noticed, as possibly containing some trees among them that might be cultivated as timber. Among these are the Corsican pine, Pinus laricio, *Poir.*, including several varieties, among which, as we think, may be reckoned the black pine of Austria, Pinus Austriaca, *Höss*, as well as the Pyrenean pine, Pinus Pyrenaica, *La Peyrouse*, P. Hispanica, *Cook.* All these species or varieties appear to thrive in the climate of London; and there is a Corsican pine in the arboretum at Kew which is upwards of eighty feet high. Whether the rate of growth, and the strength and durability of the timber, will ultimately prove equal to that of the Scotch pine, appears to us doubtful. We think, however, that in point of bulk of timber, the Corsican pine would equal the Pinaster. The Cembrian pine, P. Cembra, *L.*, of which there are two varieties, one a native of Switzerland and the other of Siberia, grows as rapidly even in Scotland as it does in its native localities; but it is of extremely slow growth everywhere, and not worth cultivating as a timber-tree. Specimens in the climate of London, which have been nearly 100 years planted, have trunks only forty or fifty feet high, and from a foot to eighteen inches in diameter at the ground. The yew-tree, Taxas baccata, *L.*, though it attains its full perfection in this country, being indigenous, yet, from its slow growth, and the little demand for its timber, it cannot be recommended to the planter whose main object is profit. The arbor vitæ, evergreen cypress, deciduous cypress, and juniper, all belong to the needle-leaved division of trees; but none of them are worth cultivation with a view to profit.

Broad-leaved Trees, in contradistinction to needle-leaved, are classed, according to their timber, in two subdivisions, hard-wooded trees, and soft-wooded trees. They are characterized by large trunks and widely-spreading woody branches, and broad leaves with branching veins; they send up shoots from the collar or stool when cut over by the ground; and they are deciduous. They belong to the Dicotyledoneæ of the natural system.

The *hard-wooded Timber-trees of Britain* are characterized by the comparative hardness and durability of their wood, and consist chiefly of the oak, ash, elm, beech, sweet chestnut, walnut, and locust or false acacia.

The British oak may be considered as including two species or subspecies, the stalked fruited, or most common oak, Quercus Robur pedunculata, *Arb. Brit.*, and the stalkless fruited, or less common oak, Quercus Robur sessiliflora, *Arb. Brit.* The latter species or subspecies is found to grow more erect and more rapidly than the other, more particularly if the soil be good and deep. The two sorts are found indiscriminately mixed together in many parts of England, as in Woburn Park, Bedfordshire, and in various parts of Sussex; in other places one species exclusively prevails, as at Tiberton Park, near Hereford, where there are some of the largest oaks in England, on a deep, loamy soil, and almost all Q. R. sessiliflora. At Welbeck, in Nottinghamshire, on the other hand, there are a great many oaks, almost exclusively Q. R. pedunculata. In all the places mentioned, the trees are the remains of native forests. Though the wood of the oak is the strongest and most durable of that of all British timber-trees, the tree is not always that which the planter would make choice of with a view to profit, on account of the slowness of its growth. It has, however, this advantage, that as it bears a higher price than any other British timber, so it will pay better at a distance from the market; and thus, while oak will pay after conveying it fifty or sixty miles to a seaport, elm will scarcely pay at half that distance, and the soft woods at still less. Oak plantations are also more valuable than others when in a young state, on account of the value of their bark. From the value of oak as ship-timber, the price of trees fit for that purpose is always considerable; though what is paid for the largest trunks employed in naval architecture will not remunerate any one for the number of years they must have stood on the ground. Accordingly we find that the governments both of France and England grow this description of timber exclusively in national forests. The wood of the oak has also the advantage of being applicable to a greater number of uses than that of most other trees. Houses, ships, furniture, and machines, may be formed almost entirely of oak, and consequently there is a ready sale for this kind of timber almost everywhere; hence the oak may be more planted in Britain than any other hard-wooded tree. It is easily raised from acorns, which ought to be collected from the tallest and handsomest trees. The British, or naval oak, as it may perhaps be more properly called, is a native of Britain and most parts of Europe, but not of Asia, Africa, or North America. There are several subordinate varieties, but none worth notice as timber-trees, excepting the kinds which we have noticed.

The ash, Fraxinus excelsior, *L.*, is in most parts of Britain next in value as a timber-tree to the oak. The wood is chiefly used in the manufacture of agricultural implements, such as ploughs, handles to spades, mattocks, handles to carpenters' implements, carts, waggons, threshing-machines, &c. Young ash-trees, and ash poles and suckers, are also much in demand for crate-ware, hoops, whip-handles, walking-sticks, and especially for hop-poles. Before the general introduction of cast iron in machinery, ash-wood was much more in demand than it is at present. The tree requires a good, deep, loamy soil, dry rather than moist; and a situation naturally sheltered, such as the steep banks of glens, rivers, or lakes. As the value of the timber depends chiefly on its toughness and elasticity, the tree is best grown in groves or masses, in consequence of which, where the soil is good, the growth is rapid, and the trunk is drawn up free from large side-branches. The tree is easily propagated from its seeds or keys. It is a native of Central Europe, but of no other part of the world. There are several species of ash natives of North America, and one or two of Europe; but these are of no value in this country, excepting as ornamental trees.

Of the elm there are two species, the English or narrow-leaved elm, Ulmus campestris, *L.*, and the Scotch or broad-leaved elm, Ulmus montana, *L.* Between these two species there are several varieties, or hybrids, such as the Dutch elm and the Huntingdon elm, the latter by far the most valuable timber-tree of the genus. The narrow-leaved elm can hardly be considered as a timber-tree in Scotland, but in the central districts of England its rapid growth, straight trunk, and ample spreading head, constitute it a magnificent tree; and the timber is useful for some important purposes in ship-building, as well as in the construction of machines and agricultural buildings. The Scotch elm is a hardy tree, of rapid growth; but, unless planted in masses, it seldom produces a straight handsome trunk. Its timber is much more durable than that of the English elm, or of any of the hybrids between the species. It was formerly much used in agricultural carpentry, in rural machinery, and in common household furniture. The Scotch elm produces abundance of seeds, which, if sown as soon as they are gathered, often come up the same year; but the English elm and the hybrids produce seeds very sparingly, and are almost always propagated by layers, or by grafting on the Scotch elm. One remarkable difference between the English and Scotch elms it may be useful to notice, viz. that the latter never throws up suckers from its roots; and it is therefore peculiarly valuable as a stock for the English elm, and for those varieties or hybrids between the species which do throw up suckers. There are some other species and varieties of European elms, and several kinds of American elms, but none of them are deserving of culture in Britain as timber-trees.

The beech, Fagus sylvatica, *L.*, acquires a large size, particularly on chalky or sandy soils. It is a very handsome tree in every stage of its growth, but the timber is not remarkable either for strength or durability. It was formerly much used in mill-work and turnery; but its principal use at present is in the manufacture of chairs, bedsteads, and a variety of minor articles. It is a native of England, and of various parts of the continent of Europe. There are some varieties, particularly the purple beech; and there are one or two species natives of North America, but none of them deserve notice as timber-trees. It is propagated by its mast, which it produces plentifully in fine seasons.

The hornbeam, Carpinus Betulus, *L.*, is an indigenous tree, which attains the same height, but not the same diameter of trunk, as the beech, to which it bears a general resemblance, but is in every respect greatly inferior. It is propagated by its nuts, which it produces in abundance. This tree and the beech were formerly highly valued for making lofty hedges, on account of their retaining their leaves great part of the winter.

The sweet chestnut, Castanea vesca, *Gærtn.*, is generally ranked next to the beech as a timber-tree; but in that character it has little or no merit. The tree is magnificent in appearance, rivalling, when full grown, the British oak; but it differs essentially from that tree in its timber not increasing in value as it increases in age. In Britain, and also in France, it was formerly believed that the roofs of the oldest cathedrals, and of Westminster Hall and other buildings, were of chestnut; and it was thought, in consequence, that the tree had formerly been more abundant, both in Britain and on the Continent, than it is at present. Subsequent inquiry, however, proves all this to be a mistake; and Daubenton and various others have shown that the timber called chestnut in old buildings is referable to the chestnut oak, Quercus Robur sessiliflora, *Arb. Brit.* It is worthy of remark, that some of the ancient writers describe a grove of chestnuts as extending northwards from London, and abounding in wild beasts; and that the remains of the indigenous woods at Hampstead, in the Earl of Mansfield's grounds, are of the chestnut oak. The timber of the sweet chestnut, when not more than of forty or fifty years' growth, forms very durable posts for fences and gates; being, according to some, more durable in this capacity than oak itself; but whenever the trunk of the tree becomes of larger dimensions than six or eight inches in diameter, the timber is found to be shaky; and at eighteen inches or two feet in diameter it has already begun to decay at the heart. In a young state, when the stems are not above two inches in diameter at the ground, the chestnut is found to make durable hoops for casks and props for vines; and of a larger size it makes good hop-poles, though the stem tapers rather too much for that purpose. It is a native of Asia, the north of Africa, and of North America; and some think it a native of Britain. In the south of England, in fine seasons, it ripens abundance of fruit, from which plants are easily raised. There are a number of varieties, both in Britain and on the Continent, which are highly valued for the qualities of their fruit; but none of these, nor any of the American kinds, are worthy of being cultivated for their timber.

The common sycamore, Acer Pseudo-Platanus, *L.*, is a tree of the second rank, seldom attaining the height of any of those that have been hitherto mentioned. It has, however, the merit of withstanding the sea and mountain breezes better than most other timber-trees; and its wood is valued in turnery, and for a variety of minor purposes. It produces abundance of seeds, which, like those of the ash, are called keys, and it is easily raised in the nursery; but it does little good in plantations, unless the soil be good and tolerably dry. It will neither thrive on very stiff clays, nor on dry sands or chalks. There are several species of Acer, natives of Europe and North America; and that which comes nearest to A. Pseudo-Platanus, as a timber-tree, appears to be the A. obtusatum, *Arb. Brit.*, a native of Hungary and Calabria, but it has not yet been tried in plantations made with a view to profit. The Norway maple, A. platanöides, *L.*, is a hardy and very interesting tree; but neither it, nor any of the other species, either from America or Europe, seem to deserve cultivation for their timber. If we made any exception, it would be in favour of the common field-maple, Acer campestre, *L.*, which forms a very curious wood for the cabinet-maker.

The common birch, Betula alba, *L.*, is another tree of the second rank, which is worthy of culture in inferior soils and situations, more especially as coppice-wood. The spray, in some parts of the country, is sold to the besom-maker, and makes a valuable return. The tree seeds freely, and is in every stage of its progress easy of management. There are several species of birch, natives of North America, which attain the size of timber-trees, and all of them have been introduced into this country, and tried in British plantations; but there is not one of them which can be considered otherwise than as an ornamental object, or as one of botanical interest.

The false acacia, or locust, Robinia Pseud-Acacia, *L.*, may be placed amongst the timber-trees of the second rank. It is of unquestionable beauty, and much has been said of the value of its timber. When of a certain age, this is of great hardness and durability, and it lasts a long time as posts, or as trenails or wooden pins, for bolting together ships' timbers. For the latter purpose, however, iron and copper are now generally used, both in Europe and America. The false acacia has been much recommended by Cobbett and a host of other writers for hop-poles and props for vines; but though it has been extensively tried in England for the former purpose, it is now utterly neglected, being found rarely to grow straight and clean, and, when used, being much less durable than the ash.

Amongst hard-wooded trees of the third rank, the timber of which is of some use, are the mountain ash, Sorbus domestica, *L.*; the white beam-tree, Sorbus Aria, *L.*; the wild apple, wild pear, wild cherry, and wild plum, the hawthorn, the holly, the laburnum, and perhaps one or two others. We could hardly recommend a plantation to be made solely of any of these trees; but when a few are introduced by way of variety or ornament, it is useful to know that their timber is of some value. The laburnum, the holly, the yew (which last we have included under the needle-leaved trees), are by far the most valuable of the trees of the third rank. The heart-timber of the laburnum is almost as dark and hard as that of ebony, and that of the holly is of a beautiful white. The timber of the yew is veined, and its beauty may be increased by judicious staining. The roots of the thorn, the yew, and of most of the third-rate trees, are often beautifully veined, and employed in cabinet-making and veneering.

Soft-wooded Trees are distinguished by the comparative rapidity of their growth, and the softness of their wood, its whiteness, and its limited duration. The principal of these worth cultivating in Britain as timber-trees, are the poplar, the willow, the alder, the lime, and the horse-chestnut.

The poplar, Populus, *L.* There are several species of this tree, which well deserve culture with a view to their timber, where the soil is good and deep, and where the roots can reach water without being saturated by it. The white and gray poplars, Populus alba, *L.*, and P. canescens, *L.*, are hardy, of very rapid growth, attaining a height of thirty or forty feet in most parts of Britain in ten or twelve years, and producing a beautiful, smooth, compact, white timber, well adapted for flooring bed-rooms, and for a great many minor purposes, either in its native colour, or stained black in imitation of ebony. The black Italian poplar, P. monilifera, *Dec.*, is an equally rapid-growing tree with the white poplar, and produces a beautiful pale-yellow timber. The common black poplar, P. nigra, does not grow so rapidly as the last, and seldom produces a straight trunk; but its timber is homogeneous, of a yellowish white, and takes a fine dye. The aspen, or trembling poplar, P. tremula; and the Athenian poplar, P. Græca, are of slower growth than the white or black poplars, and they have a beautiful, smooth, homogeneous, white wood. There are a number of other species of poplar, chiefly natives of America, and the Lombardy poplar, which is a native of Persia; but none of these are worthy of being planted as timber-trees in the climate of Britain.

The white willow, Salix alba, *L.*, is a rapid-growing tree, and produces a great bulk of timber in a short period. The wood is white, soft, and sometimes slightly veined with blue. When kept dry, and well ventilated, it will last a long time, and has been found in buildings which have existed upwards of a hundred years, in a perfectly sound state. The Bedford willow, Salix Russelliana, *L.*, grows with about the same rapidity as the white or Huntingdon willow, and its timber is of the same quality. The crack-willow, Salix fragilis, *L.*, is a tree of a smaller size, but its timber is useful for a variety of purposes; and the bark of this, and of most of the other species, may be used in tanning. There are a great many species and varieties of willow natives of Europe, or of North America and Asia; but, excepting the three above mentioned, we do not consider any of them as worth cultivating for timber.

The alder, Betula Alnus, *L.*; Alnus glutinosa, *Dec.*, is an indigenous tree, of smaller size and much lower growth than the poplars, or tree-willows; but its timber is more valuable from being more compact, less liable to twist, and having a fine mahogany tinge. The tree is a native of Britain, and of most parts of Europe, on moist soils by rivers; and it is readily propagated by seeds. There are some other European species; and two, Alnus incana, and Alnus cordifolia (the latter lately introduced from Naples), may probably prove useful as timber-trees, as they both grow on dry soils; but, from the experience which has yet been had respecting them, they can only at present be recommended as ornamental.

The lime-tree, Tilia Europæa, *L.*, is a well-known soft-wooded tree, of some value for its timber, which is used by musical-instrument makers and carvers. It is a native of Europe, and is generally propagated by layers. The blossoms produce the whitest and most delicate honey in the world. There are some American lime-trees, but they scarcely attain the size of timber-trees in England.

The horse-chestnut, Æsculus Hippocastanum, *L.*, is a rapid-growing tree in good soil; but its timber is perhaps the least valuable of the class to which it belongs, as it has little strength, and, unless kept dry, is far from being durable; but it is useful for some husbandry purposes, such as linings to carts, wheel-barrows, &c.; and it takes a ready dye as a substitute for ebony.

The only soft-wooded trees that can be recommended for culture with a view to profit, are the white, gray, black Italian, and common black poplars, and the white and Bedford willows.

Hedge-trees and Shrubs.—Plants which are useful for forming hedges are of as great importance to the planter as those which are valuable for their timber. Almost all trees planted in rows, with the free admission of air and light on every side, will become clothed with branches from the ground upwards; and if these are occasionally cut in, they will form gigantic hedges, more or less compact; but some trees are much better adapted for this purpose than others; and among those of the first class, the best are the beech, the hornbeam, the elm, the lime, the Lombardy poplar, and the spruce fir. The best of the second class are perhaps the common birch, Sir Charles Wager's maple (Acer eriocarpum), and the evergreen oak; and the best of the third class are the common thorn, the crab, the sloe, the wild plum, the buckthorn, the barberry, the holly, and the yew. By far the best of these for British field-hedges is the common hawthorn, and the next best is the wild crab. The sloe or black thorn makes an excellent hedge; but it throws up so many suckers, that it requires constant attention to keep it within bounds. It forms, however, an excellent barrier for picturesque plantations, where it is allowed to spread itself in every direction. The holly, were it not for the slowness of its growth, would form the best of all hedges, both for gardens and fields, as its leaves are little liable to be injured by insects; and, being an evergreen, it neither harbours weeds nor vermin at its roots. Birds are also much less apt to build in it than they are in deciduous hedges. It has only two disadvantages that we are aware of, viz. the slowness of its growth, and its imperviousness to wind in the winter season. On this last account, when on damp clayey soil, it has a tendency to prevent the drying of arable lands in spring. Were holly hedges occasionally introduced among those of the common thorn, they would add very greatly to the beauty of the country in the winter season; and, on dry uplands, they would form excellent shelter for stock. The common furze sown on the top of a high bank forms an effective hedge in a short period, but it is of no great duration. On moist soils fences may be made for planting rows of willows or poplars, and in situations exposed to the sea-breeze the elder may be planted; but such fences can be hardly considered as hedges, from their want of compactness and density of foliage.

Trees and Shrubs suitable for Coppice-wood and Undergrowth.—One property required for all these plants is, that they should stole or spring up from the collar or stool when they are cut over; and the true undergrowths are only to be found among such shrubs as will grow under the shade of trees. There are a great many woody plants which may be cultivated as coppice-wood; indeed there are few of the broad-leaved trees and shrubs which will not answer for this purpose, but the locality must determine the preference. In soft, wet soils, the birch, the alder, and the apple-leaved willow, are amongst the most common and useful trees. In drier soils, the ash forms a most valuable coppice-wood, supplying handles for agricultural implements, stuff for hurdles, hoops, wattles, and a great many other useful articles. In good, deep, loamy soil, the oak forms an excellent underwood; and if the situation be at a distance from a market, it is by far the most valuable that can be employed, as the bark alone will produce a sufficient profit, and, from its portable nature, it can be sent to a greater distance than timber.

Ornamental Trees and Shrubs include by far the greater number of woody plants in cultivation; though many, perhaps the whole of them, produce wood which, when it can be obtained of sufficient size, may be applied to some useful purpose. As already observed, we exclude altogether from consideration in this article, flowering and fruit-bearing trees and shrubs. We also exclude all those that are rather delicate, or require particular kinds of soil; and shall confine ourselves to trees and shrubs which are considered ornamental from their general form, and which may be introduced into the margins of ordinary plantations in most parts of Britain. We shall arrange these under the heads of evergreen and deciduous.

Evergreen ornamental Trees and Shrubs.—The most ornamental of these, and one which will thrive in every part of Great Britain, is undoubtedly the cedar of Lebanon. It is somewhat delicate when young; but, if brought forward in pots, placed where it is finally to remain when of the height of eighteen inches or two feet, and carefully planted, and protected from cattle and vermin, it soon makes a vigorous growth, and becomes a handsome tree, even in the Highlands of Scotland. The seeds of the cedar of Lebanon, when left in the cones, retain their vitality for a number of years; the cones are sometimes imported from the Levant, but more generally obtained from English trees. Where proper care can be bestowed on the seeds and the soil, it would be an improvement to sow them where they are finally to remain; because the cedar, and all the pine and fir tribe, depending principally on their surface-roots, suffer more from confinement in a pot, or transplanting from the open nursery, than trees having powerful tap-roots. The Deodar cedar differs in general aspect from the cedar of Lebanon, in having foliage of a whitish or glaucous hue. It appears to be as hardy as the other, and will probably soon become as common. Cones are imported from the Himalaya Mountains, where the tree is indigenous; or it may be grafted on the common cedar, or raised from cuttings. All the pine and fir tribe may be described as highly ornamental, and a great many of them will endure the open air in the coldest parts of Britain. The Weymouth pine, Pinus Strobus, is a very hardy ornamental tree; and still more so is the Pinus Cembra, which is of slow and erect growth, and retains the beauty of youth longer than any other pine. The Pinus excelsa is a very hardy and very ornamental species, but it is at present rare. Pinus Banksiana, and P. inops, are curious and very ornamental species. Some of the Californian pines, particularly P. ponderosa and P. Sabiniana, appear to be quite hardy. Among the ornamental spruce firs may be mentioned Abies Smithiana (A. Morinda, *Hort.*), a native of the Himalayas, which closely resembles the common spruce, and is apparently as hardy; it is readily propagated by cuttings, and by herbaceous grafting on the common spruce; and the trees already planted will probably very soon produce cones. The largest tree of this species in Britain is probably that at Hopetoun House, near Edinburgh. The Douglas fir, Abies Douglasii, is a very handsome tree, apparently as hardy as the common spruce, but differing in the dark-green colour and somewhat two-rowed disposition of its leaves, from which it appears intermediate between the common spruce and the silver fir. It has already attained the height of eighteen or twenty feet in different parts of Britain, and has produced cones. The Cephalonian fir, Abies Cephalonica, *Arb. Brit*, is a very handsome tree of the same kind, and of recent introduction; and which, having withstood the winter of 1837–38, is probably hardy enough to become an ornamental British tree. It is very readily propagated by cuttings, and cones might doubtless be imported from Cephalonia. The black and white spruces of North America are well known ornaments in our shrubberies; and there are some Californian species, such as Abies

Menziesii, which will probably soon be added to their number. The hemlock spruce (Abies Canadensis, *Mich.*) is one of the most ornamental of fir-trees; it is very hardy, and ripens seeds in different parts of England. One of the finest specimens is at Strathfieldsaye, in Hampshire, the seat of the Duke of Wellington. Among the ornamental silver firs, the first in point of grandeur is the Picea Webbiana, *Arb. Brit.;* but, even in the climate of London, it suffers so much from the spring frosts, that it is doubtful whether it will ever become a very ornamental tree in England. Nevertheless, though the severe winter of 1837–38 seriously injured this tree, it did not kill it; and probably, as it increases in age, it may be later in protruding its young shoots, and thus be more likely to escape the spring frosts. Even the silver fir, which attains the height of 100 feet and upwards in many parts of Britain, is yet frequently injured by frosts during the first twenty years of its growth. Picea pichta Fraseri, and some other species and varieties, natives of Siberia or North America, are as hardy as the balm of Gilead fir, Picea balsama, *Arb. Brit.* The Chili pine, Araucaria imbricata, is a noble tree in its native country, and appears to be much hardier in the climate of Britain than has generally been imagined. Young plants which have been two or three years established in the open ground passed the severe winter of 1837–38 without any injury, which renders it not improbable that it may ultimately prove as hardy as the common cedar. The evergreen oak, Quercus Ilex, *L.*, is a hardy evergreen tree, of which there are several varieties. It is readily propagated from its acorns, which are ripened in abundance in this country, or may be imported from the Continent. It will thrive in any deep dry soil, and forms excellent hedges, or shelter to a dwelling-house. The cork-tree, Quercus Suber, *L.*, is of a corresponding character, but rather more tender. The holly, the common yew, the Irish yew, and the box-tree, are evergreens universally known and admired. They are perfectly hardy in every part of Britain, and deserve a place in every plantation.

The Portugal laurel and the common laurel form very ornamental trees, or large shrubs; and, from their glossy foliage, they are particularly beautiful in winter. The alaternus and the phillyrea form large bodies very ornamental. The arbor vitæ, of which there are two species, is very hardy, and forms a permanent fastigiate low tree. The red cedar, Juniperus Virginiana, *L.*, the Phœnician juniper, and some other species of juniper, are at once hardy and ornamental. The cedar of Goa, Cupressus lusitanica, *L.*, is a beautiful evergreen, with glaucous foliage, but somewhat tender; nevertheless, in Ireland it has attained a great size. The common cypress, Cupressus semper virens, *L.*, grows vigorously in the central districts of England, but scarcely thrives in the northern counties. The Arbutus is one of the handsomest of evergreens, and is admired for its flowers and fruit, no less than for its foliage and general form. There are several varieties and species which endure the open air in the climate of London, but which are found rather tender farther north. The sweet bay, Laurus nobilis, *L.*, forms a bushy low tree in the climate of London, and in the south of England has attained the height of sixty feet; but it suffered much from the severe winter of 1837–38, and may be considered, on the whole, as rather tender.

Sub-evergreens are trees which retain their leaves through the winter in a green state, and drop them late in spring, immediately before the development of the new leaves. The principal British trees of this description are certain varieties of the Turkey oak, and more especially the Fulham oak, and the Lucombe oak. These are trees of the first rank, and in the central districts of England become magnificent objects. Turner's oak, Quercus Turneri, is also sub-evergreen, and forms a handsome tree of the second size. Quercus virens, the live oak of America, forms a sub-evergreen tree in the climate of London, but farther north it is to be feared that it will be found rather tender.

The common privet, especially when cultivated in good soil, becomes a sub-evergreen bush, and, when trimmed to a single stem, a handsome small tree; and to it might be added some others, such as Cratægus Mexicana, Photinia serrulata, Berberis aristata, Aristotelia Macqui, and Cotoneaster frigida, affinis, acuminata, and nummularia, all of which are quite hardy in the climate of London, and also in Ireland, but rather tender in the north of England, and in some parts of Scotland.

Deciduous ornamental Trees and Shrubs.—We shall notice the hardiest of these in the order in which they occur in the natural system. Magnolia acuminata is perhaps the only species of Magnolia that can be considered truly hardy in most parts of Britain; and, from its large leaves, and curious greenish-blue flowers which afterwards change to yellow, it well deserves a place either on the lawn, or in the margin of plantations. M. cordata, tripetala, and conspicua, are quite hardy in moderate climates; but M. conspicua flowers so early that it is apt to be injured by spring frosts. The tulip tree, Liriodendron Tulipifera, *L.*, forms a tree of the first rank in the climate of London, and attains a considerable size in the milder parts of Scotland; for the beauty of its foliage, independently altogether of its flowers, it deserves a place in every collection. The Hungarian or white-leaved lime-tree, Tilia Europæa alba, *Arb. Brit.*, is a tree of the second rank, of very great beauty, and nearly as hardy as the common lime-tree. From the effect of its mass of white foliage among the green leaves of other trees, it becomes useful for breaking formal lines, directing attention to particular objects, or harmonizing white buildings with verdant scenery. The red-wooded and yellow-wooded lime-trees are very ornamental, and also the cut-leaved variety. The American limes are sufficiently hardy to attain the size of trees in the climate of London, and, from their leaves being much larger than those of the European limes, they are very ornamental. The maple, Acer, *L.*, is a genus which contains some of the finest ornamental trees that occur in British plantations. They are all valuable for coming early into leaf and early into flower, as well as for the many angled forms of their leaves, and the beauty of their buds. The variegated leaved varieties of the common sycamore form very ornamental objects, but, like all variegated leaved trees, their greatest beauty is in spring, when the leaves first expand. The variety with white striped leaves is well known, and is very generally planted; but the yellow-leaved variety, or Corstorphine plane, though by far the most beautiful, is scarcely known, except in the neighbourhood of the original tree. The purple-leaved variety is a very striking one, having the under surface of the leaves, more especially when they first come out in spring, of a dark purple. The hairy fruited, or Sir Charles Wager's maple, Acer eriocarpum, is a very elegantly shaped tree, with beautifully cut leaves, and conspicuous reddish flowers, which appear in February; it ought never to be omitted in plantations having the slightest pretensions to ornament. The red flowering or scarlet maple, A. rubrum, resembles the last tree in foliage; but its flowers are of a much darker red, and the tree is of less vigorous growth. In autumn the leaves die off of an intensely deep red, insomuch that the tree attracts attention even at the distance of a mile or two. Where it thrives, it may certainly be considered as the most ornamental of all the maples. A. Tataricum and spicatum are low trees, the first a native of Tartary, and the last of North America; they are remarkably hardy, come early into flower, and their keys and leaves die off of a fine yellow or red. The snake-barked maple, A. striatum, is a beautiful tree, whether we regard its leaves or its bark; it is a native of Pennsylvania, and therefore quite hardy in Britain. A. macrophyllum, the large-leaved maple, is a remarkably fine tree, with leaves sometimes nearly a foot in diameter; it appears to be as hardy as the common or the Norway maple, and its growth when young is very rapid; though, having been only lately introduced from North America, it is as yet scarcely known in Europe. The Norway maple, A. platanöides, is so hardy that it might almost be considered as a timber-tree; but being inferior in this respect to the common maple, it, and its different varieties, are more generally to be ranked as ornamental. The sugar maple, A. saccharinum, in Britain, is one of the most tender North American maples; it bears a close resemblance to the Norway maple, and, like it, its foliage dies off of a very rich yellow. A. obtusatum, a native of Hungary and of Calabria, is a remarkably fine vigorous-growing tree, bearing a considerable resemblance to the sycamore, Acer Pseudo-Platanus. A. Opalus is a very handsome small tree, with round, coriaceous leaves, finely cut at the edges; this tree is little known and seldom planted, though few objects are better adapted for a small lawn. The round plaited-leaved maple, A. circinatum, is a rare species from North America; but one of great beauty of foliage, and apparently quite hardy. A. Monspessulanum is a small tree of great beauty, and in some situations sub-evergreen. The common or field maple, A. campestre, is one of the hardiest and most beautiful of small British trees: the most ornamental tree of this species is the Austrian variety, A. campestre Austriacum, *Arb. Brit.*, which forms a beautiful single object on a lawn, and also very good garden hedges. The Negundo, or box-elder, Negundo fraxinifolium, *Dec.*, a native of North America, is a beautiful tree, with its leaves cut in the manner of those of the ash, and a fine, smooth, dark-green bark. The foliage, when it first appears, is of a fine yellow, and when mature it is of a pale green. It is a desirable object, as a single tree, or in the margin of plantations. The different species or varieties of the horse-chestnut are all trees remarkable for the beauty of their foliage, but more especially for that of their flowers. The common species is known to every one, but the scarlet and red flowered varieties, and the yellow and pale flowered kinds, all comparatively of recent introduction, only require to be seen to be ardently desired by all lovers of trees. The pavias, or smooth-fruited horse-chestnuts, are much smaller trees than the rough-fruited kinds, and they are all extremely beautiful. P. rubra, flava, discolor, hybrida, neglecta, macrocarpa, and macrostachya, deserve to be in every collection. Kœlreuteria paniculata, a native of China, is a hardy tree, very ornamental from its foliage as well as its flowers. There are fine specimens both in England and Ireland, yet the tree is not generally met with in pleasure-grounds. The toothache-tree, Xanthoxylum fraxineum, is a small tree or large shrub, a native of North America, hardy and ornamental both from its foliage and flowers. The same may be said of the shrubby trefoil, Ptelea trifoliata. The ailanto, Ailantus glandulosa, is a native of China, but perfectly hardy in most parts of England. It forms a stately tree of the first rank, with a straight trunk, ample head, and magnificent foliage, the leaves, which are compound, being sometimes three feet in length. In some parts of France it is planted as a timber-tree, and is found to thrive particularly well on chalky soils. The bladder-nut tree, Staphylea, *L.*, is a hardy bush, which may be trained to a very handsome low tree, ornamental from its foliage, its white flowers, and its curious bladder-like capsules. There are two species, S. trifoliata and S. pinnata, both deserving a place in the shrubbery. The spindle-tree, Euonymus, *L.*, is a genus of which there are several species, quite hardy, and singularly ornamental when in fruit. The common spindle-tree, E. Europæus, and the broad-leaved spindle-tree, E. latifolius, are the handsomest hardy species of the genus, and, when trained up to single trees on a deep loamy soil, with ample space, they form in autumn, when their capsules are ripe, objects altogether unique in the arboricultural world. Though these species are commonly seen as shrubs drawn up among others, or growing in hedges, and forming bushes perhaps not more than six or eight feet in height, yet, when properly treated, they will form trees thirty feet high, as may be seen in some of the London gardens, and even as far north as Forfarshire, where the spindle-tree produces a timber much sought after by coopers. The different varieties of the common holly are so well known for the beauty of their foliage, that the reader only requires to be reminded of them. The Minorca holly, Ilex balearica, and the opake-leaved holly, I. opaca, are very handsome kinds, which ought not to be forgotten. The winter-berry, Prinos, is a deciduous shrub, a native of North America, which, like the holly, produces fine scarlet berries, and retains them through the winter. There are several species, all quite hardy, and one or more of them deserve a place in every collection. Christ's thorn, Paliurus aculeatus, is a native of Asia, and is used as a hedge-plant in the north of Italy. It is altogether a most elegant bush or tree, there being something quite unique in its branches, bark, and thorns, which are very numerous; and in its leaves, flowers, and seeds. The buckthorn, Rhamnus, is a hardy genus of shrubs or low trees, of which there are many species; but we shall confine ourselves to those which are decidedly hardy. Rhamnus Alaternus is a well-known evergreen, of which there are varieties having broad and narrow leaves, and leaves blotched or variegated with yellow, and also with white. R. hybridus, a native of France, is a sub-evergreen, resembling the alaternus. R. catharticus, the purging buckthorn of Britain, and the white thorn of the modern Greeks, forms a very hardy and handsome small tree. R. alnifolius, alpinus, and frangula, are also very handsome small trees; and there are several other species which, if they can be procured, well deserve a place in the shrubbery. R. latifolius, a native of the Azores, is a very handsome kind, and quite hardy both in the gardens of London and Edinburgh. The different species of rhus are very hardy and very ornamental. R. Cotinus is a particularly interesting object when its seeds are ripe. R. typhina, viridiflora, and glabra, are curious from the stag's-horn appearance of the ends of the branches; and their leaves, before they drop, assume a fine yellow, rich scarlet, or dark-red hue. Sophora Japonica forms a splendid tree in the climate of London, and there is a pendulous-branched variety which is very ornamental. One property of this tree is, that in dry and warm seasons, when the leaves of most other trees become of a paler green than usual, those of this tree assume a darker hue. Virgilia lutea is a North American tree, with fine large foliage, hardy in most parts of Britain; and, in America, valued for the yellow colour of its wood. The laburnum has already been mentioned both as a useful and an ornamental tree. The purple laburnum is a hybrid between the Scotch laburnum and the Cytisus purpureus, of vigorous growth, but more curious than beautiful. Robinia viscosa is a variety of the false acacia, or locust-tree, with a glutinous bark, and flowers slightly tinged with pink. It is a beautiful object, both in foliage and when in blossom, and is as hardy as the common robinia or locust. There are a number of other varieties of Robinia pseud-acacia, and in particular the parasol-acacia, all of which are very ornamental. The rose-acacia, Robinia hispida, of which there are several varieties, is highly prized for its rose-coloured flowers. The Siberian pea-tree, Caragana arborescens, and a number of other varieties or species of Caragana, are all very ornamental, and quite hardy; and the same may be said of the salt-tree, Halimodendron, and of the different species of Colutea, or bladder-senna. The three-thorned Gleditschia, or honey-locust, Gleditschia, *L.*, is a genus of which there are seven species in cultivation in British nurseries, besides varieties. Some of the Gleditschias attain the size of trees of the first rank, and others are middle-sized or small trees; but they are all deserving of culture, on account of the beauty of their foliage, and their very remarkable spines. The Kentucky coffee-tree, Gymnocladus Canadensis, is a curious-looking object in winter; but in summer it is clothed with a magnificent foliage. It is a native of Canada, easily propagated by cuttings of the roots, and consequently hardy enough for any part of Great Britain; though, strange as it may appear, it is far from being common in collections. The Judas trees, Cercis Siliquastrum and Canadensis, are very handsome small trees, both when in leaf and in flower; the flowers have an agreeable acid, and they are used in Paris in salads, and fried in batter for fritters. The almond, the peach, the apricot, the plum, and the cherry, in their single or comparatively wild state, and also the varieties of these species having double flowers, are fine ornamental objects in plantations or on lawns, and are quite hardy. Cerasus semperflorens and serrulata, the Allsaint, and Chinese double-blossomed cherries, are very desirable ornamental trees. The perfumed cherry, Cerasus mahaleb, is a most valuable tree, coming early into flower, diffusing its odour in every direction, and soon afterwards becoming covered with berries, which are generally of a glossy black, but in some varieties yellow. The bird-cherry, Cerasus padus, is a native of the woods both of Scotland and Sweden, and one of the most ornamental of low trees when in flower. Its beautiful spikes of white blossoms are succeeded by black or red fruit, which is very ornamental while it remains on the tree, but when ripe is soon devoured by birds, by whom it is greedily sought after. The Cornwall bird-cherry, Cerasus padus rubra, and the pendulous branched bird-cherry, Cerasus padus bracteosa, are interesting varieties. C. Virginiana, serotina, and capollin, are species of bird-cherry resembling one another, surpassing the European bird-cherry in the smoothness and glossiness of their foliage, and equaling it in the beauty and profusion of their flowers. C. Virginiana is so hardy, and produces fruit in such abundance, that in some parts of England it may be considered as naturalized, having come up in the native copses from seeds carried thither by the birds from artificial plantations. There are about twenty other species of Cerasus, all quite hardy; and though some of them are of very humble growth, and adapted for planting on the faces of rocks, rather than amongst other shrubs, yet they are all deserving of culture.

The genus Cratægus consists of twenty-eight species, and about double that number of varieties, each of which forms a beautiful small tree. There is not perhaps any other genus of hardy ligneous plants in which so many beautiful small trees are to be found. They are all remarkable for having an irregular, picturesque character of outline, and for assuming this character at the growth of even five or six years. They all come into flower at an early age, produce flowers profusely, and all ripen abundance of fruit. The flowers are, for the most part, white and fragrant, but in some varieties they are tinged with red and purple; and in one, the scarlet hawthorn, C. oxyacantha rosea, they are of a fine rose colour. The flowers appear at various periods from March till the middle of July; and one variety, the Glastonbury thorn, often comes into bloom at Christmas. The earliest flowering species are Cratægus purpurea and nigra, and the latest C. cordifolia and Virginica. The colour of the fruit is for the most part red, as in the common hawthorn; but in some it is yellow, as in C. Aronia; black, as in C. nigra; or greenish-yellow, as in C. Mexicana. In C. coccinea the fruit is large, and of a scarlet colour. In C. Douglasii it is of rich glossy purple-black; and in C. orientalis sanguinea, *Arb. Brit.*, it is of an intensely deep port-wine colour. Of the common hawthorn of our hedges, C. oxyacantha, *L.*, there are no fewer than thirty recognised varieties, each of which would form a very beautiful and distinct tree. One of the varieties has the fruit white, another has double white flowers, another, C. oxyacantha phœnicea flore pleno, double red, another a fine single pink. One has black fruit, another yellow, and a third white. In one the entire tree takes the upright narrow form of a cypress, and in another the branches are pendulous, like those of the weeping willow; one has leaves like those of the oak, another leaves like those of the fern, and so on. All the species of Cratægus may be readily propagated by grafting them on the common thorn, by which means, when stocks standard high are used, they become trees fit for planting out where they are finally to remain, at the end of the third season. The species may be propagated either by grafting, by seeds, or by cuttings of the roots. Much ornament might be conferred on the country, and especially on the roads which pass through a hedged estate, if the proprietor were to allow some thorns in his hedgerows to grow to the average height of two or three feet above the top of the hedge, and at that height to bud, or graft these with some of the more tree-growing of the ornamental species. Cotoneaster frigida, affinis, acuminata, and nummularia, are Nepaul small trees of very great beauty, both on account of their foliage and their fruit; so much so, that though we have already mentioned them under the head of sub-evergreens, we have here repeated their names. Amelanchier vulgaris, Botryapium, sanguinea, ovalis, and florida, are very beautiful low trees, which bear a profusion of white flowers early in spring, and are succeeded by brown or black berries, which, though commonly left to the birds, are not disagreeable to eat. The common medlar, and Smith's medlar, Mespilus Smithii, *Dec.*, M. grandiflora, *Hort.*, are ornamental trees: the former is valued also for its fruit, and the latter for the profusion of white blossoms with which it is covered in April. There are a great many very ornamental species and varieties of the genus Pyrus, which is now so far extended as to include species formerly considered as belonging to Sorbus, Cratægus, Mespilus, &c. P. nivalis, sinaica, salicifolia, elæagnifolia, and amygdaliformis, may be considered as white woolly-leaved varieties of the common wild pear, and P. sinensis as a distinct variety of the common cultivated pear. P Bollwylliana appears to be a hybrid between the apple or crab, and Pyrus Aria. P. variolosa, a native of Nepaul, is a remarkable tree, with leaves sometimes like those of the common cultivated pear, and at other times cut, like those of Pyrus spuria sambucifolia. Pyrus prunifolia, baccata, and Astracanica, are crab-apples with handsome blossoms and small beautiful fruit; and there are a number of sub-varieties, which may be obtained in the nurseries. Among these, the white astracan or transparent crab of Moscow, the supreme crab, and Biggs's everlasting crab, deserve the preference. P. coronaria, and P. angustifolia, are American wild apples, with sweet-scented flowers. P. spectabilis, a native of China, but quite hardy, is remarkable for its showy pink and white blossoms, which are produced in great profusion. P. Aria, the white-beam tree, and all its varieties, deserve culture, as compact, low, or small trees; P. vestita, a native of Nepaul, is remarkable for its large woolly foliage, which dies off of a fine yellow. P. torminalis, though indigenous, is a most ornamental tree. Pyrus Sorbus, and all its different varieties, are very ornamental. Pyrus spuria, a native of Kamtschatka, forms a very beautiful little tree, with a profusion of white flowers and black fruit; and Pyrus arbutifolia, Mespilus arbutifolia, *L.* with its varieties, melanocarpa, floribunda, and depressa, are beautiful low shrubs, and, when grafted standard high on the common thorn, form very ornamental objects, whether in blossom, when covered with their fine dark fruit, or when their leaves are dying off, and have become of an intensely dark red, shaded with yellow and purple.

The common and Chinese quinces form handsome low trees; the former more particularly so when in flower and fruit, and the latter when in full leaf. The Japan quince, Cydonia Japonica (Pyrus Japonica, *L.*), is well known as one of the most ornamental spring-flowering shrubs in cultivation. Hamamelis Virginica, the Wych hazel, is valuable from its beginning to flower in November, and retaining its blossoms till February or March: though rarely seen in collections, it is very hardy, and forms a very handsome small tree. The different species of dogwood are ornamental, and, with the exception of C. florida, quite hardy. C. alba sibirica has the shoots of a fine scarlet colour, and is singularly ornamental in the winter season. The common elder, Sambucus nigra, will thrive, and form a handsome low tree, in a variety of situations, where many other trees and shrubs will scarcely grow: on a mountain side, and in the coal-smoke of cities or factories. There is a very handsome variety with cut leaves, one with white fruit, and another with green fruit. S. racemosa is a native of Spain, which grows vigorously in this country. The leaves are finely cut; and the fruit, with which it is generally profusely covered, is of the most brilliant scarlet: being very little known among gardeners, it is scarcely ever seen in collections. The different species of Viburnum are hardy, and all more or less ornamental, both when in flower and in fruit. The leaves also die off of a fine yellow-red, sometimes tinged with purple. V. Lentago, pyrifolium, prunifolium, and nudum, when trained to a single stem, form compact-growing, neat, little trees. The common wayfaring tree, V. Lantana, and the American wayfaring tree, V. lantanöides, form very neat bushes. V. Opulus is well known as the Guelder rose; and the American variety, V. O. oxycoccos, has fruit as large as the cranberry, which is used in America for the same purpose; as is the fruit of V. O. edule, another American variety. The fly-honeysuckle, Lonicera xylosteum, and the Alpine upright honeysuckle, Lonicera alpigena, are the only two species which are sufficiently woody and large to be noticed in this selection; the other species belong to flowering shrubs. The snow-drop tree, Halesia tetraptera, is one of the hardiest of North American trees, and, when in flower, one of the most beautiful: it ripens abundance of seeds in this country, by which it is readily propagated; so much so, that in some parts of England it is, like the American bird-cherry, naturalized in the copses. It is rarely to be met with in Scotland, though few trees so well adapted for the climate of that country are so ornamental. The date-plum, Diospyros Lotus, though it ripens fruit as a standard in the climate of London, is perhaps rather tender for the northern counties; but where the climate is moderate, it forms a very beautiful small tree. The Virginian snow-flower, or fringe-tree, Chionanthus Virginica, is nearly as hardy as the snow-drop tree; and when planted in a moist soil, and trained to a single stem, its head is ornamental from its large, deep-green foliage, independently of the fine, white, fringe-like flowers which are suspended from the axils of the leaves. The common purple and the common white lilacs, Syringa vulgaris, and S. vulgaris alba, are very hardy, and make very neat small trees when trained to a single stem. The common ash is the parent of several varieties which are very ornamental. One of the oldest of these is the simple-leaved ash, of which there is a variety lately discovered in Ireland, with the leaves variegated. The pendulous-branched or weeping ash is a well-known variety, as are the yellow barked and the striped barked. There are several other varieties not in our opinion worth cultivating, though from these we except F. excelsior parvifolia, F. e. p. argentia, and F. e. p. oxycarpa. The lentiscus-leaved ash, F. Lentiscifolia, is an elegant tree; and there is a pendulous variety of it, which forms by far the most graceful tree of the genus. There are several species or varieties of American ash, very ornamental in their foliage, most of them hardy in the climate of London, but few of them adapted for the northern counties. The flowering ash, Ornus Europæa, is a very handsome tree, nearly as hardy as the common ash, and it ought on no account to be omitted in ornamental plantations. Few trees have a finer effect when standing singly on a lawn. Catalpa syringæfolia is a splendid tree when in flower: it attains the height of thirty or forty feet, and sometimes ripens its seeds in the climate of London; but in the northern counties it seldom does much good. It is one of those trees which will bear an immense deal of cold in winter, provided there has been heat and bright sunshine enough in summer to ripen its wood. The tupelo tree, Nyssa, is nearly as hardy as the Diospyros Lotus, and is more beautiful than that tree in autumn, when its leaves change to an intensely deep rich scarlet. The Oleaster or wild olive, and the Hudson's Bay olive, Elæagnus hortensis and argentea, are handsome silvery-leaved low trees; the former, however, rather tender, and the latter rather shrubby. The sea-buckthorn is a very handsome and a very hardy willow-leaved little tree, which has the great advantage of standing the sea-breeze without injury. Hippophæ salicifolia, a native of the mountains of Nepaul, is of more vigorous growth than the European sea-buckthorns, and appears to be nearly as hardy as they are. Shepherdia argentea, the Missouri silver-tree, is an elegant silvery-leaved tree, a native of North America, where it produces an edible fruit: it forms a suitable companion to Hippophæ and Elæagnus, which are also more or less silvery in their foliage. The black, the white, the red, and the tartarian mulberries, are all ornamental trees, but rather tender in the northern counties. The paper mulberry, Broussonetia papyrifera, is an interesting object, but more tender than the common mulberry. Maclura aurantiaca, the American bow-wood, or Osage orange, is a tree of very vigorous growth in the climate of London; but as it continues growing till late in the season, its wood is often not ripened so far as the points of the shoots, and the tree is therefore probably unfit for those parts of the island where the atmosphere is almost constantly charged with fog. The elm comprises many ornamental species and varieties. Of the English or narrow-leaved elm, those which we prefer are U. campestris viminalis, U. c. foliis variegatis, and U. c. virens. U. c. planifolia, and U. c. chinensis, are very beautiful as elms, but difficult to procure. Ulmus effusa is, in our opinion, by far the handsomest species of the European elms when it is in a young state; but it does not grow up to a handsome tree. The most beautiful variety of Scotch elm is the weeping elm, Ulmus montana pendula, which is remarkable for the vigour of its growth, and the picturesque manner in which its branches are thrown about. There are some American elms which are tolerably hardy in the climate of London, but which cannot be recommended for colder districts. Planera Richardi is an Asiatic tree, and attains the first rank even in the climate of London, where it sometimes ripens seeds; it deserves a place along with the elms, and along with the southern and eastern nettle-trees, Celtis australis and Tournefortii. The common walnut-tree, Juglans regia, though it becomes a tree of the first rank in the climate of London, and is cultivated for its fruit both there and in Devonshire, yet in the north has generally the points of its young shoots blackened by the spring frosts. Of the willow there are a great many species and varieties, all of which are highly ornamental when in flower. Of these we may recommend the almond-leaved willow, S. amygdalina; the sweet-scented bay-leaved willow, S. pentandra; the weeping willow, S. Babylonica; the golden willow, S. vitellina; and the purple-barked willow, S. atropurpurea. The poplar genus contains several ornamental species. The first we shall mention is Populus tremula grandidentata, *Arb. Brit.*, the North American large aspen, of which there is a pendulous branched variety. P. heterophylla is an American poplar, little known and rarely met with in British nurseries. The balsam poplar, P. balsamifera, is one of the earliest trees, which sends out its leaves in spring; and it and the Lonicera Tatarica, in the climate of London, are found clothed with leaves a week or a fortnight sooner than any other tree or shrub whatever. The leaves of the balsam poplar, when they first come out, are of a rich yellow, and they perfume the air with their fragrance for some distance around; as the summer advances, they become darker, till in the autumn they are of a black or bluish green. It may give some idea of the extreme hardiness of this tree to mention, that Captain Franklin found it as far north as the Great Slave Lake; and that the greatest part of the drift-timber which he observed on the shores of the Arctic Sea was of this species. It is one of those poplars that send up suckers, and it is consequently readily propagated by cuttings of the roots. It prefers a moist soil, and though the Cree name for this species means ugly poplar, yet when full grown on such a soil, it forms a very massive round-headed tree, which at a distance might be mistaken for an oak or a chestnut, as is proved by two fine specimens in the grounds at Syon. The Ontario poplar, P. candicans, bears a close general resemblance to the balsam poplar; it has the rigid fastigiate habit of that tree, the same habit of sending out its foliage before all other poplars, its fine fragrance, and its property of throwing up suckers from the roots; but it differs from the balsam poplar in having very large heart-shaped leaves. It is rather more difficult to propagate than the balsam poplar, and, in British nurseries, is commonly raised from layers. The genus Alnus, the alder, contains some very ornamental trees. A. glutinosa laciniata has finely-cut foliage, and, what is remarkable, is in general a more free-growing tree than the species. A. cordifolia is a native of Calabria, and by far the handsomest species of the genus. We have already mentioned it as probably fit to be grown for its timber. A. incana, the hoary-leaved alder, is a very handsome tree, and has the advantage of preferring dry soil. A. oblongata, serrulata, undulata, and viridis, are low trees or large shrubs, quite hardy, and deserving of introduction into collections. The birch is a genus of which the greater number of species are natives of North America; and, though they are valuable timber-trees there, none of them in this country have yet proved anything more than ornamental. The finest American species is B. nigra, distinguished by the beautiful paper-white of its bark, which cracks, separates into thin laminæ, and rolls up, even when the tree is young and only two or three inches in diameter. B. populifolia is a handsome species, very much resembling the common birch, and in our opinion only a variety of it, as are B. pubescens, urticifolia, pontica, Darlecarlica, and others. There is a cut-leaved, pendulous variety of the common birch, which is very ornamental. The paper-birch, B. papyracea, is a fine tree; as are B. glandulosa and B. Däurica. B. fruticosa, pumila, and nana, are shrubs.

Of oaks there are upwards of forty species introduced into British gardens; the greater number of them, with many varieties, being purchasable in British nurseries. All these, with the exception of the two varieties of the common oak and the Turkey oak, may be considered as solely or principally ornamental. Of the common oak, Q. pedunculata, there are three varieties, very distinctly marked, viz. the cypress oak, Q. p. fastigiata; the weeping oak, Q. p. pendula; and the cut-leaved oak, Q. p. heterophylla. These three varieties often ripen acorns, and of the plants raised from them a number are found to have the same habit as the parent. There are several varieties of Q. sessiliflora, which differ in the size of the acorns, in the size of the leaves, in the greater or lesser degree in which these are cut, and in the presence or absence of pubescence; none of these varieties, however, have yet been propagated by the nurseryman, excepting Q. s. pubescens. The Pyrenæan oak, Q. Pyrenaica, is a very handsome and distinct species, of low growth. Q. Apennina is also a low tree. Q. Esculus, the Italian oak, is a tree under the middle size, which thrives well, and ripens its acorns in the climate of London: there are fine specimens at Whitton Park. Of the Turkey oak, Quercus Cerris, there are ten or twelve very distinct varieties. The first of these is the pendulous variety, the next the Austrian, then the Ragnal, the Fulham, and the Lucombe. Of the latter there are five very distinct sub-varieties, all sub-evergreen, and all well deserving of culture wherever the common Turkey oak will thrive. Quercus Ægilops, the Velonia oak, thrives in the climate of London; but is probably too tender for the northern counties. The American oaks, which are deciduous, may be classed as the white, red, black, and willow oaks. The white oak best worth cultivating in Britain as an ornamental tree is Q. alba; but Q. olivæformis and macrocarpa are remarkable for their fruit, and Q. obtusifolia and lyrata for their leaves. The chestnut oak, Q. Prinus, and its several varieties, also deserve culture: the leaves of these oaks resemble those of the sweet chestnut, and the species is to the other deciduous American oaks what Q. sessiliflora is to the deciduous oaks of Europe. Q. alba bears the closest resemblance to Q. pedunculata, and may be considered as being the American form of that species. All the red oaks are beautiful in the form and colour of their foliage; and some of them attain the size of timber-trees in Britain, though their wood is of little value either here or in America. Q. rubra, and coccinea, and tinctoria (the Quercitron), are perhaps the most ornamental; and Q. palustris is the hardiest, the most rapid growing, and the handsomest in point of general form. The black American oaks are all remarkable trees. The black-jack oak, Q. nigra, *L.*, is the most extraordinary species, from the very singular form of its leaves; and next to it is Q. aquatica. Q. illicifolia, heterophylla, and agrifolia, belong to this division. The willow oaks, Q. Phellos, imbricata, and laurifolia, have entire leaves, which die off without changing colour; and this group may be considered the least ornamental of the American oaks.

The American hornbeam, Carpinus Americana, and the common and Virginian hop hornbeams, Ostyra vulgaris and Virginica, deserve a place in collections, more especially the hop hornbeams, from the singular appearance of their fruit. Of the common hazel there are some ornamental varieties, such as that with purple leaves, and another with cut leaves. The Constantinople hazel, Corylus Colurna, forms a very handsome middle-sized tree; and C. rostrata and Americana are hardy, and well deserving a place in ornamental plantations. The oriental and occidental planes are highly ornamental trees of the first rank, and Platanus Orientalis acerifolia, *Arb. Brit.*, and P. O. cuneata, *Arb. Brit.*, are fine varieties, the latter forming a curiously-twisted low tree. The Liquidambar is a splendid tree, remarkable for the beauty of its foliage and its refreshing fragrance. Liquidambar imberbe is a small tree, also very ornamental. The Ginkgo or maidenhair tree, Salisburia adiantifolia, *Sm.*, is remarkable for the singularity of its foliage: it is a native of China, but is quite hardy in most parts of Britain; and it is propagated without difficulty by cuttings made in autumn. Of the larch there are some species and several varieties, which are chiefly ornamental; those best deserving of culture are L. Europæa pendula, L. Americana pendula, and L. Americana rubra. The deciduous cypress is rather tender in the northern parts of the island; but in the climate of London, when planted where its roots are within reach of water, it forms a magnificent tree of the first rank.

III.—*The Nursery Culture of Trees.*

We have now gone through the whole of the hardy trees and shrubs of Britain, and have indicated those which we think best deserving of culture, where the objects are either timber-produce or general effect, and where no extraordinary care is proposed to be bestowed on the soil. The reader cannot fail to be surprised at the very small number of species which merit to be planted for the sake of their timber, and at the great number which we have enumerated as ornamental. That number would have been more than doubled had we included the flowering shrubs, and such foreign trees and shrubs as will only thrive in the southern parts of the island; but we have confined ourselves as much as possible to those which will thrive both in the climate of London and in that of Edinburgh. It must be recollected that all the ornamental trees produce timber of some sort; and some of them, such as the box, crab, common maple, &c., timber of considerable value. Every ornamental tree, therefore, may be considered a useful tree, even with respect to the wood which it produces; though, from the length of time it takes to produce that wood, it may not be a profitable tree to cultivate for that purpose. Having treated on the trees worth cultivating, we shall now enter on the subject of their cultivation.

The cultivation of trees and shrubs includes their propagation and rearing in the nursery, and their culture and management in plantations.

Nursery Culture.—A nursery is any plot of ground devoted to the propagation and rearing of trees and shrubs. To be perfect, it ought to contain the principal kinds of soil in which trees and shrubs grow, and to possess different climates, according to the countries of which the plants are natives; but as these requisites cannot be always obtained, particularly with respect to climate, all that art can do is to make the nearest approach to them that circumstances will admit. It may be laid down as a general principle, that all seeds will germinate, and all plants grow, in any kind of soil whatever, provided it contain some vegetable matter, be in a state of minute division, and be retentive, to a certain extent, of water. All plants, therefore, may be reared in a nursery containing only one kind of soil; but in such a nursery all will not be equally well reared; for some plants, such as all those which have hair-like roots (as the ericaceæ, including the heaths, rhododendrons, arbutuses, &c.), and in general all that are called peat-earth plants, will only thrive in a peaty-soil; or a soil composed of a mixture of very fine sand, and thoroughly decomposed leaves, or woody matter. Other plants, such as all those which attain a large size, and have strong tap-roots, will only thrive in deep loams or in deep fertile sands, though they will grow for a time very well in peat. A nursery, therefore, that contains the three leading soils of sand, loam, and peat, will suffice for all the purposes for which the most extensive nursery can be required; and, for raising such trees and shrubs as have been treated of in this article, a piece of ground containing sandy loam in one place, and clayey loam in another, or even sandy loam throughout, will be quite sufficient, as far as regards soil. With respect to climate, all the deficiencies which can occur in Britain may be made up by glazed frames, in which the more tender kinds can be raised; and in which those which are grown in pots can be kept through the winter. A nursery may be considered in two points of view: with reference to the nurserymen, and with reference to the climate and soil where the trees are finally to be planted. As matters stand at present, it is the interest of the nurseryman to have his nursery in a fine climate, and in deep, fertile soil, in order that he may raise large vigorous plants in the shortest possible period: but it is the interest of the purchaser to have the plants reared in a climate and soil inferior to that into which they are to be transplanted; because, when this is done, instead of the plants receiving a check from the operation of transplanting, as is usually the case, they will be improved by it. It is the interest of the nurseryman to have his nursery trenched and manured to the depth of two or three feet; in order that it may contain abundance of nourishment, and be retentive of moisture during the summer season, so as to cause the plants to produce long and vigorous shoots. On the other hand, it is the interest of the purchaser that the soil should not be cultivated to more than eight or ten inches in depth, in order that the nourishment and the moisture, and consequently the roots, may be concentrated in a very limited space; so that, when the plants are taken up, the whole of the roots may be taken up with them, which, where the ground has been trenched, is impossible, from the great depth to which they will have penetrated. It is for the interest of the nurseryman that the summer should be moist, in order that the shoots produced may be long and strong; but it is for the interest of the purchaser that the summer should be dry, in order that the shoots may be short, and thoroughly ripened; and that the roots should cease to grow early in the autumn, in order that their spongioles, having had time to harden, which they cannot do till they have ceased elongating, may receive the less injury when the plants are taken up. In short, it is the interest of the purchaser to concentrate all the forces of the plant within such limits as he can thoroughly command, that is, can take up and carry away. The advantages of then sowing and planting to the planter, therefore, are obvious, though the reverse is for the interest of the nurseryman; as by thick planting the plants are drawn up taller and straighter, and a greater number will grow on a given surface. We are fully aware of the arguments which are opposed to this doctrine by nurserymen; viz. that the stronger a plant is, and the greater the number of its fibrous roots, the more likely will it be to succeed after being transplanted to a new situation; and that this strength of shoot, and abundance of fibrous roots, can only be produced in deep, rich soil. But we deny that this vigorous appearance in the shoots of plants is strength; and assert that, so far from a deep soil being favourable to the production of fibrous roots, it is directly the reverse. The strength of a plant, and its suitableness for being removed from one situation to another, and for growing vigorously after it is removed, consists in all its parts having arrived at maturity, in the thorough ripening of its wood, and in the completely dormant state of its fibrous roots; and these requisites, we assert, can only be obtained by concentrating the nourishment contained in the soil into a limited space, by the soil being compact, and by no more moisture being admitted to the roots than what is absolutely necessary to complete the growth of the season in sufficient time to allow of the thorough ripening of the young wood. If by any mode of culture these requisites can be obtained, together with the long and thick shoots which are produced by growing the plants in deep, rich soil, so much the better; but we contend, that, in the climate of Britain, this is impossible. If the purchasers of plants in nurseries will observe what takes place in the case of layers, as in those of the elm, the lime, the platanus, the white poplar, the vine, &c. they will see the justice of our statement. Such layers made in spring have generally at the end of the season shoots of three or more feet in length, which have continued growing till they were checked by frost; the consequence of which is, that neither the wood nor the fibrous shoots have ripened. The first year after removal, such plants make scarcely any growth; and if they survive the first year, it requires two or three years more before they are firmly established. Nearly the same thing may be said of almost all one-year grafted or budded fruit-trees, which, having seldom ripened their wood thoroughly, from being planted in deeply trenched rich soil, and half of their roots having been left in the ground after they are taken up, are consequently obliged to be cut in when planted. These considerations show, as a general principle, the advantage of growing all plants that are to be transplanted, in such a manner as that they may thoroughly ripen their wood and roots, and so that the whole of the roots may be taken up with the plant. On a large scale, the only mode of effecting this is by having the soil shallow and rich, but not too moist. On a small scale, the same end is attained in a very complete manner by growing the plants in pots; and, were it not for the expense, this would be the best mode of growing all nursery articles. The plants, however, should not be kept too long in pots, because, when so treated, many species, after a time, acquire a stunted habit, and the roots, when the tree is transplanted, instead of being in a state to allow of their being unwound from the ball, and stretched out in lines radiating in every direction from the stool, are so long and slender, and the circulation through them is so languid, that they require to be cut off or shortened. In general, it may be observed, that a weak plant, with the wood and roots thoroughly ripened, is much more likely to thrive when transplanted, than a strong one from which a great part of the roots have been cut off; and hence, of two young Huntingdon elms, budded on the Scotch elm, one of which had been grown in a pot, and had its leading shoot only two feet long, and another which had been grown in the free soil, and had its leading shoot five or six feet long, as is often the case—the former, when transplanted where it was finally to remain, would far sooner attain the height of twenty or thirty feet than the latter. We do not expect that all commercial nurserymen will subscribe to these opinions, but private gentlemen who raise their own trees will find it their interest to attend to them. Hence those who plant in mountainous districts will always find it better to have their nurseries on the sides of the mountains than in the valleys.

Propagation.—Trees, like other plants, are chiefly propagated by seeds; but they are also increased by cuttings, layers, budding, and grafting. The timber-trees of all countries are raised from seeds, with the exception of a very few, such as the poplar and the willow, which are raised from cuttings; and some species of elms, limes, and a few others, which are raised from layers, or by grafting. The greater number of ornamental trees and shrubs are raised by some of these artificial methods; because in this country they seldom ripen seeds, and because varieties are always perpetuated by artificial modes. Thus, all the American oaks are, or may be, grafted on the common British oak. Most of the foreign acers and birches are raised by layers, most of the ornamental thorns by budding and grafting, and almost all the ornamental willows and poplars by cuttings. All plants which do not ripen seeds readily are propagated by some of these artificial modes; and that mode is preferred by the nurseryman, which, experience has proved, will produce the largest and most vigorous-looking plants in the shortest time. Thus, though more suitable plants for the planter would be produced by raising the platanus and the white poplar from cuttings, because in that case nature would adjust the tops to the power of the roots; yet, as much larger plants are produced by layers, that mode is everywhere preferred in the commercial nurseries. The lime-tree ripens its seeds in this country, and also the English elm; but large plants are much more rapidly procured in the first case by layers, and in the second by grafting. We do not say that in every case the mode by which the largest plants are most rapidly produced should give way to the slower mode; but merely that, in most cases, it would be advantageous to the purchaser that the slower mode should be adopted. According to some writers, plants which are raised from cuttings, or by any other mode than by seeds, are of less durability than seminal plants; but though this may be true, or appear so, in a few instances, it can never be adopted as a general principle; since, from all that we are taught by physiology, a bud contains as perfect an embryo of a plant as a seed: the only difference being, that the bud is more powerfully imbued with the peculiarities of the individual which produced it than the seed is. This doctrine is confirmed by experience; since the poplar, the willow, the vine, &c., have been propagated by cuttings from time immemorial, and, for any thing that is known to the contrary, possess respectively the same properties now that they did in the days of the Romans.

Propagating by Seeds.—The seeds should be collected from the handsomest individuals of the species, when they are quite mature; and they should either be sown immediately, or preserved in a place where they will undergo few changes in regard to heat or moisture, till the proper sowing season, which, in almost every case, will be the following spring. Nature, it may be observed, sows all her seeds soon after they are fully matured; that is, they drop from the tree upon the ground in autumn, or the beginning of winter, or, in the case of some trees, such as the pines and firs, not till the following spring; but as, when seeds are thus left to chance, the greater part of them are destroyed by vermin, by being placed in a condition not favourable for germination, or by imperfect or premature germination, only a moderate number of them produce plants. It is the business of art, therefore, to study what is favourable and unfavourable in nature's mode of sowing seeds, and to imitate only the former. The result of this study is, that by far the greater number of seeds may be kept with advantage from the time they ripen, till early in the following spring, that is, till February or March, and then be committed to the soil. There are a few exceptions, as in the case of poplar and willow seeds, which ripen early, and which, when sown immediately that they drop from the tree, often come up in the course of a few weeks; whereas, if they are kept till the following spring, the greater number do not come up at all; and also in the case of seeds which lie two years in the ground before coming up, such as those of the hawthorn, the holly, &c. and which may be kept till the second spring after being ripened before they are sown. In order to show the treatment required for the seeds of different kinds of trees, and the plants raised from them in the nurseries, it will be convenient to throw them into groups; and these may be as follow: the pine and fir tribe; the trees producing nuts, acorns, masts, and keys; trees producing pomes with kernels, berries with stones, berries in capsules, small seeds, leguminous seeds, and cottony or papery seeds.

The seeds of the pine and fir tribe ripen from October till January, and if the cones are allowed to remain on the tree throughout the winter, the seeds do not in general drop out till the following April or May; soon after which, such of them as drop into a favourable soil, where there is a certain degree of moisture and shade, come up in five or six weeks. The nurseryman collects the cones of each species immediately after they are ripe (which, with the pinaster, and a few others, is as early as the month of October), and he lays them by in a dry place till he has leisure to extract the seeds. This he does by exposing the cones to the heat of the sun under a glass case, by which the heat is retained, and raised to a higher degree than it would be in the open air; or he subjects them to artificial heat before an open fire, or on a kiln. The seeds, when taken out, are sown in April, in soil dug over, and rendered fine by raking; and over them is laid a covering of soil, which, in general, need not be deeper than the thickness of the seed to be covered, where the soil is loamy;

but it may be twice that thickness where the soil is a coarse sand. In order to retain a uniform degree of moisture on the surface, the beds, after the sowing is completed, should be shaded from the sun, by covering them slightly with the branches of trees, and especially with those of evergreens, such as the spruce fir. In cold moist climates, such as that of Aberdeen, this shading may be dispensed with; but in the climate of London it is, in most seasons, essentially necessary, and may be effected by hoops and mats, by fronds of fern, by straw, or by pea haulm. For greater convenience, the seeds are generally sown in beds, a slight excavation being made in the beds by drawing some of the earth to the sides; and in order that the seeds may be evenly deposited on a somewhat firm surface, the bottom of this excavation is rolled with a light roller. After the seeds are distributed over the beds, at such distances as that the plants, after they have come up, and have grown to the end of the season, may not touch each other, the beds are again rolled, and afterwards the covering of earth is thrown over them which was drawn off before rolling and sowing. It may be observed here, that the rolling in of the seeds, by bringing them in close contact with comparatively firm soil, renders a much thinner covering of earth necessary than if the seeds had been sown on a loose surface. It is also more favourable to the vegetation of the seeds; it being found that close contact with the soil, both in the case of seeds, and the spongioles of the roots, is a powerful stimulus to vegetation. Some of the more tender species of pines and firs, such as the stone pine, the cedar of Lebanon, the cypress, &c. are commonly sown in pots, or in flat earthen pans, for the convenience of making them germinate under glass, and in order to facilitate future transplantation; but the process of preparation, sowing, and covering, is exactly the same as when the seeds are raised in beds. The plants, after they have come up, require nothing but the usual routine culture of the nursery for two summers; at the end of which period they should be taken up, and, if possible, transplanted where they are finally to remain; but as this cannot always be done, the next best practice is to plant them in the nursery, either in lines, which is the most convenient mode, or scattered over beds; in either case keeping the plants so far apart that there may be a clear space round each plant, of from three to six inches, according to its height and the length of its leaves. Thus, for the Scotch pine and the spruce fir, which grow slowly when young, and have comparatively short leaves, three inches will be sufficient; whilst for the larch, which grows rapidly the second year, and for the pinaster, which has long leaves, six inches will be required. Here the plants may remain another two years, and afterwards be transplanted on the same principle; unless they are in the mean time removed to where they are finally to remain. Unless this has been the case, they will have little chance of doing good as timber-trees; for experience has proved, that after two years' growth, or at most four years', all the pine and fir timber are materially checked by transplanting; and that this check is of a kind which cannot, like that given to broad-leaved trees, in a similar case, be counteracted by cutting them down to the ground; but, on the contrary, remains for many years, and materially affects the future growth and habit of the tree.

Trees bearing Nuts, Acorns, Masts, Keys, &c.—These, on British timber-trees, ripen from October to December. The greater part of oaks ripen their acorns in November; but the beech, the horse-chestnut, the walnut, and the hazel, ripen their mast and nuts in October; and most of the sycamores and maples their keys in September. All these seeds ought to be gathered as soon as they are ripe; because, as they form an important part of the food of wild animals, the best are liable to be picked up by them as soon as they drop. They may either be sown immediately or kept till February, as in neither case will they come up till April or May. They should be sown in a sandy loam, in drills, the seeds being deposited at such a distance from each other, that the leaves of the plants springing from them may not touch at the end of the first season; they should be trodden into the drill with the foot, or pressed down with the back of a wooden rake; and they may be covered to the depth of twice or thrice the thickness of the seed. The reason why drills are recommended for this description of tree-seeds is, that in the intervals between the rows, a spade may be inserted obliquely, so as to cut through the tap-roots of the plant, and force it to throw out lateral roots. This operation is commonly performed early in the spring of the second year: it does not prevent a second tap-root being formed from the mutilated extremity of the first; but it throws a greater proportion of the energies of the plant into the lateral roots, which, by increasing these and their fibres, renders the tree better adapted for transplanting. At the end of the second year, plants so treated may be taken up, and either planted where they are finally to remain; or, their tap-roots being shortened, they may be transplanted into nursery lines, at distances adjusted according to the principles laid down for transplanting the pine and fir tribe. In this situation they may remain two years longer, and then be taken up and again replanted in the nursery; because all broad-leaved tap-rooted trees differ from needle-leaved trees in this important particular, that the larger and stronger they are, up to a certain point, before they are removed from the nursery, and planted where they are finally to remain, the more vigorously will they grow there. The point or limit to the size which they may be allowed to attain in the nursery must be regulated by the condition of the soil into which they are to be transplanted, relatively to moisture. If this be abundant, so as to supply all the fibrils with water during the first summer, even if the removed plant has a stem an inch in diameter, so much the better; it being clearly understood that it has been transplanted in the nursery every two years, and is consequently abundantly supplied with fibrous roots, and has all its wood perfectly ripe. If, on the other hand, the soil into which the plant is to be transplanted is naturally dry, and perhaps also thin and poor, the plants should be removed from the nursery thither at the end of the second year. The reason is sufficiently obvious; such plants, being of small size, have few leaves to exhale moisture, and before they grow large they will have adjusted their roots and annual growths to the locality.

Trees producing Pomes with Kernels.—This class includes the genera Pyrus, Cydonia, Amelanchier, Cotoneaster, Viburnum, &c. The fruits of the different species of these genera ripen at various periods from September to November. They should be gathered when ripe, and each kind should be mixed with sand, and laid up in a heap, in order to rot away the pulp. This heap may be turned over several times in the course of the winter; and in the month of February it may be sifted, and the seeds separated from it, and sown in beds, exactly in the same manner as is done with the seeds of the pine and fir tribe. After the plants have been two years in the seed-bed, they may be transplanted into nursery lines, on the same general principles as already described.

Berries having Stones.—This class includes the genera Cratægus, Ilex, Taxus, Prunus, Cerasus, Rhamnus, and some others. The fruit ripens from August (as is the case with some species of Cratægus) to December. It should be gathered as soon as it is thoroughly ripe; and after having been mixed with sand or sandy soil, the mixture should be laid up in moderate-sized heaps, exposed to the weather, and turned over frequently for two years, after which it may be taken, along with the sand, and sown in beds; and when the plants come up, and have grown two years, they may be transplanted, and treated like the others. In general, all the plants belonging to this class, whichever way the seeds may be treated, whether they are sown immediately that they are ripe, or kept in a rot-heap two summers, will not come up till the spring of the third year; but there are some positive and some accidental exceptions. Amongst the former are the yew, the berries of which generally come up at the end of the first year, and the wild cherry, which, if sown in July, immediately after the fruit is ripe, will come up the following spring; whereas, if kept till August before it is sown, it will not come up for two years. As casual exceptions, we may mention that the holly and hawthorn, when the berries are macerated in water as soon as they are gathered, and sown immediately afterwards, will, in some seasons, come up the following spring in considerable numbers; though the same treatment in other seasons, in the same nursery, will not be attended with the same results.

Berries and Capsules having small Seeds.—This class includes the elders, the privet, the spindle-tree, the barberries, and some others. The fruit may be treated like the pomes; and great care should be taken, after it is rotten, either that the seeds are completely separated from the sand before they are sown, or that the sand and seed, when sown together, should be so distributed over the bed as that the plants may come up at regular distances, and sufficiently far apart. The covering of soil should be very thin, more especially if the seeds are rolled in; and the beds should be shaded by branches or matting till the plants are fairly above ground. At the end of the second season they may be transplanted into nursery lines as before.

Leguminous Seeds.—These include the genera Cytisus, Robinia, Gleditschia, Caragana, &c. The pods generally ripen in September or October; but some of them, such as the Gleditschia, not till November or December. The seeds may be kept in the pods till February, and then taken out and sown in beds, on the principles before laid down. At the end of two years the young trees may be transplanted as before.

Cottony, Papery, Feathery, and other soft Seeds.—These include the genera Populus, Salix, Alnus, Betula, Ulmus, &c. The seeds ripen from May to November; all the poplars ripen their seeds in May; all the willows and elms in June; the alders in November; and the birches in October. The seed of the alder and the birch may be kept in a cool, dry, airy situation till the following spring, or it may be sown immediately after it is gathered. In either case it comes up in the May or June following; but it is preferable that the seeds of the elm. the poplar, and the willow, should be sown immediately, because in that case they are much more certain of coming up. Many of these seeds will come up the same autumn, and the remainder the following April and May. The seeds may be dried and preserved in bags for a year; but in this case the greater part of those of the poplars and willows will not vegetate. The reason may be, that the seeds, when preserved, are kept too warm; which must necessarily deprive them of their moisture, through the absorption of the cottony substance with which they are enveloped. Poplar and willow seeds require to be sown on a surface rendered quite even, and slightly firm, by rolling. Afterwards the seeds should be evenly distributed over it, and they should be covered with very light, sandy soil, or peat or vegetable mould, if either can be procured, no thicker than barely to conceal the seed from the eye. After this the beds should be watered, and effectually shaded, by being hooped over and matted; and they should be kept in a uniform state of moisture, by occasional supplies of water, when the plants make their appearance. Of all the seedling trees raised in British nurseries, none come up and grow with so much vigour, the first year, as the common broad-leaved elm; and, therefore, the seeds of this tree require to be placed at a greater distance from each other in the seed-bed than those of any other kind. The seeds of the elm also keep much better till the following spring than those of the poplar and willow, and they are generally so kept by Scotch nurserymen.

IV.—*The Culture of Trees in the Plantations. The Formation and Management of Plantations.*

Whether plantations of forest-trees should be sown or planted, is a question which has been agitated and discussed by different writers. It is readily allowed, that sowing is the natural mode; but it is the business of art to improve upon nature, and to attain the same ends which she does, by more definite means. If this general principle be correct, it affords at once a decisive answer as to the respective eligibility of sowing or planting; unless, indeed, it can be shown, which some have attempted to do, that the timber of transplanted trees is never so valuable as that of sown ones. The only reason alleged for this is, that the transplanted trees have lost their tap-roots; and although a more frivolous one could hardly be imagined, yet it has been maintained by a number of writers, and is still insisted on by a few. On examining the roots of full-grown trees, however, either in natural forests or artificial plantations, no tap-root is ever found; on the contrary, those roots which proceed either directly or obliquely downwards from the base of the trunk, are uniformly found much smaller than those which proceed from the base of the trunk horizontally, at a few inches distance under the surface of the ground. The tap-root, therefore, is chiefly of use to the tree whilst in a young state; and if we trace a seedling oak through the first ten years of its progress, we shall find that, in the first year, the tap-root is larger in proportion to the part of the plant above ground, than it is in any succeeding year; and that as the top of the tree and the lateral roots increase in size, the tap-root ceases to increase, till at last, even at so short a period as ten or twelve years' growth, it is found to be the smallest of all the main roots of the tree. We assume it, therefore, as agreed on by the most intelligent planters, that a transplanted tree, other circumstances being the same, is in all respects as good as a seedling one. Hence we conclude, that all artificial plantations ought to be made by planting the trees, and for a similar reason we would plant these in rows at regular distances; and, in short, treat them, as far as is practicable, like a crop of herbaceous vegetables, when reared in the kitchen-garden or in the field. We would prepare the soil, and even manure it for the trees, with as great care as we would for a crop of turnips or cabbages; and we would stir the surface afterwards for two or three years, till it began to be covered with the branches of the trees; in which state we should leave it during the whole period of the growth of the plantation, only taking care to remove large weeds. We admit, however, that this kind of tree culture can only take place with advantage on a tolerably even surface, and where the soil is of the same nature throughout; but we think it right to lay it down as a general principle of guidance, in so far as it can be followed, for planters in all other soils and situations. With the exception of the ground destined for ornamental plantations about country houses, the great majority of cases in which plantations are to be formed with a view to profit must necessarily be on hilly and irregular surfaces; and where there is probably a considerable variety of soil, even in a very limited space. The only preparation that in cases of this kind can be given, is under-draining; for to dig or trench the surface would render it liable to be washed away by heavy rains and thawing snow. Plantations under such circumstances must be formed by digging pits for each particular tree, and by making use of such kinds as are thought to be best adapted to the particular soil and situation. This will frequently occasion the use of a considerable variety of trees in the same plantation; but the effect will be as much more interesting in point of beauty, as the result will be advantageous in point of timber produce. We have already stated, that needle-leaved trees should, if possible, be transplanted when they are not older than two years; but that broad-leaved trees may be transplanted at four, six, eight, or ten years' growth; provided they have been removed every two years in the nursery, and that the soil in which they are placed is sufficiently deep and moist to bring all the fibrous roots into full action the first summer. In the planting of irregular surfaces, which cannot be done by digging, when strong plants of this kind are used they overcome the natural herbage immediately; and, if carefully planted, not one in a score will fail. Smaller plants, on the other hand, are apt to be choked by the grass or herbage, and to have their leaves and young shoots injured by the insects which never fail to abound in such situations. When such surfaces have naturally a very dry soil and subsoil, plants with such a mass of roots as those which we have mentioned cannot subsist on them the first year; and therefore smaller plants, or such as have been only once transplanted, are preferable.

Notwithstanding these arguments in favour of planting instead of sowing as a general practice, there are circumstances under which sowing is either the preferable, or perhaps the only mode, that can be adopted. In every case of making plantations of the pinaster, or of the cedar of Lebanon, unless we could procure a sufficient number of plants of two years old in pots, we should prefer sowing a patch of seeds in every place where a plant was intended finally to remain. Three seeds in a patch would be sufficient; and if more than one came up, the rest should be removed the second or third year. In cases of this kind the plants require to be looked over two or three times every year, to prevent the surrounding herbage from choking them. When steep rocky cliffs, or the sides of hills, consisting of loose naked stones, are to be covered with wood, then sowing is the only mode that can be resorted to. The kind of rock having been ascertained, in order to discover the nature of the debris or soil collected in its clefts, or under the loose stones, the kinds of seeds to be sown may be selected accordingly. Where the soil is good, acorns, ash-keys, maple and sycamore keys, and beech mast, may be introduced; but where it is poor, the safer mode will be to sow seeds of the Scotch pine, the larch, the birch, the mountain ash, the white-beam tree, and the elder. Where there is no visible soil, each seed, or two or three seeds, may be enveloped in a composition of common green moss, cow-dung, and loam, and these balls being deposited in clefts or crevices, or among loose stones, and left to be acted upon by the rain, will swell and burst, and the seeds which they contained will vegetate, and find nourishment in the fragments of the ball in which they were enveloped. When the object is to cover drift sand with wood, the practice followed in the downs or landes of Bordeaux may be adopted, with suitable variations. A zone of the downs, or sandy surface, on that side from which the prevalent winds blow, is first to be sheltered by a fence of boards three or four feet in height. This will protect a zone of twenty or thirty feet in width; that is, it will prevent the drifting sands from covering this space to any great thickness. On this zone the seeds of broom, as being a plant that will grow on the poorest soil, are to be sown; and, among these, the seeds of the tree which is considered the most suitable for the particular situation. Near the sea this will generally be found to be the pinaster; but in the interior of the country, where the sands are not deep, perhaps the birch or the Scotch pine may be found eligible.

Two of the most important points connected with the formation of plantations, are the distance at which the trees ought to be planted from each other, and the introduction or non-introduction among them of nurse-trees. When both these points were first settled by professional planters, the important uses of the leaves of plants were not at all understood by practical men. Hence they gave directions for planting the trees at such distances as that they might draw up one another; without considering the loss of the leaves on the sides of each plant which this drawing up will produce. As the strength of every plant depends on the number of its leaves, and on the full exposure of these to the light, it follows that the strongest young trees will be those which are clothed with branches and leaves from the ground upwards, and which have their leaves fully exposed on every side to the perpendicular light. In regard to the distance from each other at which trees can be planted in a plantation, we should say, begin by planting at a greater or less distance, according to the size of the plants and the nature of the soil and situation; but do not neglect to cut down, or thin out, the moment the lower branches of the plants interfere with one another. Continue this practice year after year, till the lower branches begin to show symptoms of decay at their extremities; when, instead of thinning out the trees, the process of pruning them may be commenced. The lower tier of branches may then be cut off close to the stem, it being understood that such pruning shall take place before the branches are more than an inch in diameter at the point where they join the stem, even if the extremities of the branches have not begun to decay. The trees may then be left to grow, either till another tier of branches begins to show symptoms of decay, when, of course, that tier must be cut off immediately; or till the points of the healthy branches interfere with those of the healthy branches of the surrounding trees, in which case thinning must be resorted to as before. In this way the process of thinning and pruning ought to go hand in hand, till the trees have attained their average height; by which time the different species will be found standing at distances differing according to the height of each tree and the nature of its branches. Thus those trees which will be found standing closest together when full grown, will be the pine and fir tribe; because in them the branches never attain a timber size, and the lower tiers begin to decay at their extremities sooner than in any other trees. On the other hand, the oak has more widely-spreading and durable branches than any of the other broad-leaved trees; and hence, when plantations of this tree are fully grown, the individuals will be found at a greater distance apart than those of any other species of broad-leaved tree whatever. What this distance will be must depend on the soil and situation; because in some localities the common British oak will attain double the height and breadth of head which it does in others. Our business here is to illustrate a principle; and we shall leave it to planters who approve of it, to deduce the rules from it which will apply to their particular cases.

The next point which we have to discuss is the advantage or disadvantage of introducing nurse-plants into plantations. That these have a tendency to accelerate the growth of trees in an upward direction for a number of years after the plantation is made, there can be no doubt; but this is always at the expense of the side-branches and side-leaves, and consequently of the thickness of the trunk of the tree to be nursed. The question, therefore, is, what is gained by the nursing? Is there any advantage in having a young tree with a tall, slender stem, and few or no side-branches, rather than a tree of half the height, with a short, stiff stem, clothed with branches and leaves from the ground upwards? We admit that evergreen nurses, such as the Scotch pine and the spruce fir, considerably improve the climate of a plantation, by preventing the radiation of heat from the ground; and that, provided they did not do injury in other respects, in this respect they would do good. The question as to nurses or no nurses may, we think, be satisfactorily answered in the following manner: Suppose we adopt the principle already laid down, that all trees in plantations intended to produce timber should be kept at such distances by thinning and pruning, as that the extremities of their lowest branches should never interfere. Then, having fixed on the kind of tree the growth of which is to be the main object of the plantation, and the number of these that, when full grown, can stand upon an acre, or any given surface, plant them in their proper places, and fill up the intervals with the trees intended to serve as nurses. As the nurses increase in size, and their branches touch their principals, let them be pruned or thinned; so as in no way to prevent the principals from being clothed with branches from the ground upwards on every side, or to prevent the leaves on these branches from being fully exposed to the sun. In this way the climate of a plantation will be improved by evergreen nurses; and the nurses will protect the trees from high winds till they have attained to such a size and vigour of growth, that the annual shoots produced on the top of the tree will be so short that they can be ripened in a colder climate than would be required to ripen a longer shoot produced by a young tree. This mode of nursing trees, it may be observed, is widely different from the practice of letting nurses and principals draw up one another, in which case both will be alike without side-branches; and consequently, when the nurses are removed, the principals, weakened by having their stems unprotected by branches exposed to the cold in winter and to the heat in summer, will remain stationary a number of years; in some cases dying away altogether, and in others making so little progress, that nearly as much would be gained in the produce of timber by cutting them down, and training up a single shoot from the stools, or by trenching the ground and replanting, as by letting them grow.

We have now taken a cursory glance at the principal points which require to be considered in the culture of trees, and in the formation and management of plantations; but the subject is of very great extent, and could not be entered into in all the requisite details in even double or treble the space which can be allotted to this article. Our object in writing it has been rather to direct attention to general principles, than to lay down specific rules; satisfied as we are that, in every department of agriculture and gardening, too much deference is paid to routine practices, and too little recourse is had to the principles on which these practices are founded. Above all, planters do not seem sufficiently aware of the important agency of leaves and light, not only in the production of quantity of timber, but of quality also.

It may be necessary to observe, that in this article the botanic names are generally those adopted in Loudon's *Arboretum et Fruticetum Britannicum*, to which work we would refer for more ample information upon all the points which have been here touched on, and on many others directly or indirectly connected with the subject. (V. V. V. V.)

PLANUDES, Maximus, a Greek monk of Constantinople, who, towards the end of the fourteenth century, published a collection of epigrams entitled *Anthologia;* a Greek translation of Ovid's Metamorphoses; a Life of Æsop, which is rather a romance than a history; and some other works. We know nothing more of him, than that he suffered some persecution on account of his attachment to the Latin church.

PLASSEY, a town of Hindustan, in the province of Bengal, and district of Nuddea, situated on the eastern bank of the Bhaggarutty or Hoogly River. Here was fought, in June 1757, between the British under Colonel Clive, and the army of the Nabob Suraje-ud-Dowlah, the battle of Plassey, which ultimately decided the fate of Bengal. Long. 88. 15. E. Lat. 23. 45. N.

PLASTER, or Emplaster, in *Pharmacy*, an external application, of a harder consistence than an ointment, and which is, according to the different circumstances of the wound, place, or patient, spread either upon linen or upon leather.

Plaster, or *Plaister*, in building, a composition of lime, sometimes with sand, or other substance, to parget or cover the nudities of a building.

Plaster of Paris, a preparation of several species of gypsum dug near Montmartre, a village in the neighbourhood of Paris, and hence the name.

The best sort is hard, white, shining, and marbly, being known by the name of *plaster-stone* or *parget of Montmartre.* It will neither give fire with steel, nor ferment with aquafortis; but it calcines very freely and readily into a fine plaster, the use of which in building and casting statues is well known.

The method of representing a face truly in plaster of Paris is this. The person whose figure is designed is laid on his back, with any convenient thing to keep off the hair. Into each nostril is conveyed a conical piece of stiff paper, open at both ends, to allow of respiration. These tubes being anointed with oil, are supported by the hand of an assistant; then the face is lightly oiled over, and the eyes being kept shut, alabaster fresh calcined, and tempered to a thinnish consistence with water, is by spoonfuls nimbly thrown all over the face, till it lies near the thickness of an inch. This matter grows sensibly hot, and in about a quarter of an hour hardens into a kind of stony concretion; which being gently taken off, represents, on its concave surface, the minutest part of the original face. In this a head of good clay may be moulded; and therein the eyes are to be opened, and other necessary amendments made. This second face being anointed with oil, a second mould of calcined alabaster is made, consisting of two parts joined lengthwise along the ridge of the nose; and herein may be cast, with the same matter, a face extremely like the original.

If finely powdered alabaster, or plaster of Paris, be put into a basin over a fire, it will, when heated, assume the appearance of a fluid, by rolling in waves, yielding to the touch, and steaming, all which properties it again loses on the departure of the heat; and being thrown upon paper, it will not at all wet it, but immediately discover itself to be as motionless as before it was set over the fire; wherefore it appears, that a heap of such little bodies as are neither spherical nor otherwise regularly shaped, nor small enough to be below the discernment of the eye, may, without fusion, be made fluid by a sufficiently strong and various agitation of the particles which compose it, and may lose its fluidity when the agitation is discontinued.

Two or three spoonfuls of burned alabaster, mixed up thin with water, in a short time coagulate into a hard lump at the bottom of a vessel full of water. Artificers observe, that the coagulating property of burned alabaster will be very much impaired or lost if the powder be kept too long, especially in the open air, before it is made use of; and when it has been once tempered with water, and suffered to grow hard, they cannot, by any new burning or powdering of it, make it serviceable for their purpose as before.

This matter, when wrought into vessels, or other forms, is still of so loose and spongy a texture, that the air finds an easy passage through it. Mr Boyle, in relating his experiments with the air-pump, gives an account of his preparing a tube of this plaster, closed at one end and open at the other; and on applying the open end to the cement, as is usually done with the receivers, it was found utterly impossible to exhaust all the air out of it; for fresh air from without pressed in as fast as the internal air was exhausted, although the sides of the tube were of considerable thickness. A tube of iron was then put on the engine, so that being filled with water, the tube of plaster of Paris was covered with it; and on using the pump, it was immediately seen that the water passed through into it as easily as the air had done when that was the ambient fluid. After this, trying it with Venice turpentine instead of water, the thing succeeded very well; the tube might be perfectly exhausted, and would remain in that state for several hours. But on pouring some hot oil upon the turpentine, the case was much altered; for the turpentine melting, became a thinner fluid, and in this state was capable of passing like water into the pores of the plaster. On taking away the tube, however, it was remarked that the turpentine, which had pervaded and filled its pores, rendered it transparent, in the manner that water gives transparency to that singular stone called *oculus mundi.* In this manner, the weight of air, under proper management, becomes capable of making several sorts of glues penetrate plaster of Paris; and not only so, but also baked earth, wood, and all other bodies porous enough to admit water.

PLASTIC denotes a thing endowed with a formative power, or a faculty of forming or fashioning a mass of matter after the likeness of a living being.

Plastic *Nature*, a certain power, by which, as an instrument, many philosophers, both ancient and modern, supposed that the great motions in the corporeal world, and the various processes of generation and corruption, were perpetually carried on.

Amongst the philosophers of Greece, such a power was almost universally admitted. It seems, indeed, to have been rejected only by the followers of Democritus and Epicurus, who talk as if they had thought gravity essential to matter, and the fortuitous motion of atoms, which they held to have been from eternity the source, not only of all the regular motions in the universe, but also of the organization of all corporeal systems, and even of sensation and intellection in brutes and in men. It is needless to say, that those men, whatever they might profess, were in reality atheists; and Democritus, it is universally known, avowed his disbelief of a God.

The greater part of the philosophers who held the existence of a plastic nature, considered it not as an agent in the strict sense of the word, but merely as an instrument in the hand of the Deity; although even amongst them there were some who held no superior power, and were of course as gross atheists as Democritus himself. Such was Strato of Lampsacus, a man originally of the peripatetic school, over which he presided many years, with no small degree of reputation for learning and eloquence. He was the first and chief asserter of what has been termed *Hylozoic Atheism;* a system which admits of no power superior to a certain natural or plastic life, essential, ungenerated, and incorruptible, inherent in matter, but without sense and consciousness. That such was his doctrine we learn from Cicero, who makes Velleius the Epicurean say, "Nec audiendus Strato qui Physicus appellatur, qui omnem vim divinam in Natura sitam esse censet, quæ causas gignendi, augendi, minuendive habeat, sed careat omni sensu."[1] That Strato, in admitting this plastic principle, differed very widely from Democritus, is apparent from the following account of him by the same author: "Strato Lampsacenus negat opera deorum se uti ad fabricandum mundum; quæcunque sint, docet omnia esse effecta naturæ, nec ut ille, qui asperis, et levibus, et hamatis uncinatisque corporibus concreta hæc esse dicat, interjecta inani; somnia censet hæc esse Democriti, non docentis sed optantis."[2]

That the rough and smooth, the hooked and crooked, atoms of Democritus, were indeed dreams and dotages, is a position which no man will controvert; but surely Strato was himself as great a dreamer when he made sensation and intelligence result from a certain plastic or spermatic life in matter, which is itself devoid of sense and consciousness. To use the emphatic language of Cudworth, it is indeed inconceivable "how any one in his senses should admit such a monstrous paradox as this, that every atom of dust has in itself as much wisdom as the greatest politician and most profound philosopher, and yet is neither conscious nor intelligent." It is likewise to be observed of Strato, that though he attributed a certain kind of life to matter, he by no means allowed of one common life as ruling over the whole material universe. He supposed the several parts of matter to have so many several plastic lives of their own, and appears[3] to have attributed something to chance in the production and preservation of the mundane system.

In denying the existence of a God, perpetually directing his plastic principle, and in supposing as many of these principles as there are atoms of matter, Strato deviated far from the doctrine of Aristotle. The great founder of the peripatetic school, as well as his apostate disciple, taught that mundane things are not effected by fortuitous mechanism, but by such a nature as acts regularly and artificially for certain ends; yet he never considers this nature as the highest principle, or supreme *Numen*, but as subordinate to a perfect mind or intellect; and he expressly affirms, that "mind, together with nature, formed or fashioned this universe." He evidently considers mind as the principal and intelligent agent, and nature as the subservient and executive instrument. Indeed, we are strongly inclined to adopt the opinion of Mosheim, who thinks that by nature Aristotle meant nothing more than that ϑεϱμοτης ψυχιϰη, or *animal heat*, to which he attributes immortality, and of which he expressly says[4] that all things are full. Be this as it may, he always joins together God and nature, and affirms that they do nothing in vain. The same doctrine was taught before him by Plato, who affirms that "nature, together with reason, and according to it, orders all things." It must not, however, be concealed, that Plato seems to have attributed intelligence to the principle by which he supposed the world to be animated; for Chalcidius, commenting on the *Timæus*,[5] thus expresses himself: "Hæc est illa rationabilis anima mundi, quæ gemina juxta meliorem naturam veneratione tutelam præbet inferioribus, divinis dispositionibus obsequens, providentiam nativis impertiens, æternorum similitudine propter cognationem beata." Apuleius, too, tells us,[6] "Illam cœlestem animam, fontem animarum omnium, optimam virtutum esse genetricem, subserviri etiam Fabricatori Deo, et præsto esse ad omnia inventa ejus."

The doctrine of Plato has been adopted by many moderns of great eminence both for genius and for learning. The celebrated Berkeley, bishop of Cloyne, after describing Plato's *anima mundi*, thus recommends the study of his philosophy:[7] "If that philosopher himself was not read only, but studied also with care, and made his own interpreter, I believe the prejudice that now lies against him would soon wear off, or be even converted into high esteem, for those exalted notions, and fine hints, that sparkle and shine throughout his writings; which seem to contain not only the most valuable learning of Athens and Greece, but also a treasure of the most remote traditions and early science of the east." Cudworth, and the learned author of Ancient Metaphysics, are likewise strenuous advocates for the Aristotelian doctrine of a plastic nature diffused throughout the material world; and a notion very similar occurred to a subsequent writer, who does not appear to have borrowed it either from the Lyceum or the Academy.

This writer is Mr Young, of whose *active substance*, and its agency in moving bodies, some account has elsewhere been given (see MOTION). As a mere unconscious agent, immaterial, and, as he expresses himself, immental, it bears a striking resemblance to the plastic nature or vegetable life of Cudworth. But the author holds it to be not only the principle of motion, but also the basis or substratum of matter itself; in the production of which, by certain motions, it may be said to be more strictly plastic than the hylarchical principle, or *vis genitrix*, of any other philosopher with whose writings we have any acquaintance. Though this opinion be singular, yet as its author is evidently a man who thinks for himself, unawed by the authority of celebrated names, and as one great part of the utility of such works as ours consists in their serving as indices to science and literature, we shall lay before our readers a short abstract of the reasonings by which Mr Young endeavours to support his hypothesis, and we shall take the liberty of remarking upon those reasonings as we proceed.

The author, after a short introduction, enters upon his work,[1] in a chapter entitled Analysis of Matter in general. In that chapter there is little novelty. He treats, as others have done, of primary and secondary qualities, and adheres too closely to the language of Locke, when he says, that "the nature of bodies signifies the aggregate of all those ideas with which they furnish us, and by which they are made known." To say the best of it, this sentence is inaccurately expressed. An aggregate of ideas may be occasioned by the impulse of bodies on the organs of sense, but the effect of impulse cannot be that which impels. We should not have made this remark, which may perhaps be deemed captious, were we not persuaded that the vague and inaccurate use of terms is the source of those mistakes into which we cannot help thinking that the very ingenious author has sometimes fallen. Having justly observed that we know nothing directly of bodies but their qualities, he proceeds to investigate the nature of solidity.

"Solidity," he says, "is the quality of body which principally requires our notice. It is that which fills extension, and which resists other solids, occupying the place which it occupies; thus making extension and figure real, and different from mere space and vacuity. If the secondary qualities of bodies, or their powers variously to affect our senses, depend on their primary qualities, it is chiefly on this of solidity; which is therefore the most important of the primary qualities, and that in which the essence of body is by some conceived to consist. This idea of solidity has been judged to be incapable of any analysis; but it appears evident to me," continues our author, "that the idea of solidity may be resolved into another idea, which is that of the power of resisting within the extension of body. Hence it becomes unnecessary, and even inadmissible, to suppose that solidity in the body is at all a pattern or archetype of our sensation."

That solidity in the body, and we know nothing of solidity anywhere else, is no pattern of any sensation of ours, is indeed most true, as we have shown at large in another place (see METAPHYSICS); but to reconcile this with what our author asserts immediately afterwards, that "solidity is no more in bodies than colours and flavours are, and that it is equally with them a sensation and an idea," would be a task to which our ingenuity is by no means equal. He affirms, indeed, that solidity, as it is said to be in bodies, is utterly incomprehensible; that we can perfectly comprehend it as a sensation in ourselves, but that in bodies nothing more is required than a power of active resistance to make upon our senses those impressions from which we infer the reality of primary and secondary qualities. This power of resistance, whether it ought to be called active or passive, we apprehend to be that which all other philosophers have meant by the word *solidity;* and though Locke, who uses the words *idea* and *notion* indiscriminately, often talks of the idea of solidity, we believe our author to be the first writer who has thought of treating solidity as a sensation in the mind.

Though it is wrong to innovate in language, when writing on subjects which require much attention, we must, however, acknowledge it to be unworthy of inquirers after truth to dispute about the proper or improper use of terms, so long as the meaning of him who employs them can be easily discovered. We shall, therefore, follow our author in his endeavours to ascertain what this power of resistance is which is commonly known by the name of solidity. All power he justly holds to be active; and having, by an argument[2] of which we do not perceive the force, attempted to prove that it is by an inward power, and not by its *inertia*, that one body prevents another from occupying the same place with itself, he naturally enough infers matter to be essentially active. "But the activity of matter is to be considered in a certain limited sense, and its inertness is to be regarded in another limited sense; so that these are compatible within their respective limits. The activity of body may be considered as belonging to the parts of a compound; its inertia as the inertia formed of those parts. The actions of the parts are everywhere opposed to each other, and equal; and hence results the inactivity of the whole."

Solidity alone of the primary qualities being positive, and peculiar to bodies, and our author having resolved this into *action* or *power*, it follows, by his analysis, that the *essence* of *body* is reduced to power likewise. But, as he properly observes, power is an idea of reflection, not acquired by the senses, but suggested by thought. Hence our knowledge of real existence in body must be such as is suggested to us by our thoughts exercised about our sensations. "We are capable of acting and producing changes in appearances; and this faculty, which we experience to exist in ourselves, we call power. We are conscious of the exertion of our own power; and, therefore, when we see *action* or *change* happen without any exertion of ours, we refer this to other powers without us, and necessarily conclude the power to exist where the change begins or the action is exerted. This power, then, referred to bodies, must exist in them, or it can exist nowhere."

---

[1] An Essay on the Powers and Mechanism of Nature.

[2] "We can only conceive of solidity as being a resistance of the parts of any body, to a power which endeavours to separate them, or to bring them nearer together. Now that which resists any power, and prevents its effect, is also a power. By resistance, I mean here an active resistance, such as an animal can employ against an animal. If a horse pulls against a load, he draws it along; but if he draws against another horse, he is put to a stand, and his endeavour is defeated. When any endeavour to change the situation of the parts of any solid is in like manner prevented from taking effect, and the parts retain their situation, the situation has plainly been preserved by an active resistance or power, equivalent to that which was fruitlessly exerted on them."

Such is our author's reasoning to prove that matter is essentially active, and that from this activity results our notion of its solidity; but does he not here confound solidity with hardness, and impenetrability with cohesion? He certainly does; for water is as solid, in the proper sense of the word, as adamant, and the particles of air as the particles of iron. The parts of water are, indeed, separated with ease, and those of adamant with difficulty; but it is not because the latter have more solidity than the former, but because the power of cohesion, whatever it may be, operates upon them with greater force. Solidity is an attribute of a whole; hardness and softness result from the cohesion of parts. We do not at all perceive the propriety of the simile of the horse pulling a load, and afterwards pulling against another horse. Is it because both horses are active that one of them cannot prevail against the other, and because the load is inactive that either of them may drag along a mass of iron of half a ton weight? If so, double or triple the mass, and a very strange phenomenon will be the result; for we shall have an active whole compounded of two or three inactive parts, even though those parts should not be in contact.

In two chapters, which might easily have been compressed into one not so long as the shortest of them, our author analyses atoms or the primary particles of matter, and strenuously opposes their impenetrability. He allows that there are atoms of matter not divisible by any known force; but as these, however small, must still be conceived as having extension, each of them must be composed of parts held together by the same power which binds together many atoms in the same body. This power, indeed, he acknowledges to operate much more forcibly when it cements the parts of a primary atom, than when it makes many atoms cohere in one mass; but still it operates in the same manner; and as the ideal analysis may be carried on *in infinitum*, the only possible idea which is suggested by atoms, or the parts of atoms, is the idea of a resisting power. That this power of resistance, which constitutes what is vulgarly called the solidity of bodies, may not be absolutely impenetrable, he attempts to prove, by showing that resistance does in fact take place in cases where impenetrability, and even solidity, are not supposed by any man.

"Let us endeavour," says he, "to bring together two like poles of a magnet, and we shall experience a resistance to their approximation. Why, then, may not a piece of iron, which between our fingers resists their coming together, resist by an efficacy perfectly similar, though more strongly exerted? If magnetism were to act upon our bodies as upon iron, we should feel it; or were magnets endowed with sensation, they would feel that which resists their nearer approach. The resisting extension between the two magnets is permeable to all the rays of light, and, reflecting none, is therefore unseen; but it is easy to conceive that the same power which resists the approach of the iron might resist and reflect some rays of light. We should then have a visible object interposed between the two magnets, as we have before supposed it might be a tangible one. It is likewise easy to conceive that which is tangible and visible so applied to our organs of tasting, of smelling, and of hearing, as to excite ideas of flavours, odours, and sounds. Thus we see that an action, in which no supposition of solidity or impenetrability is involved, may be conceived to assume all the qualities of matter, by only supposing a familiar effect extended in its operation."

This reasoning is exceedingly ingenious, though perhaps not original; but, what is of more importance, it does not approach so near to demonstration as the author seems to imagine. If magnets operate by means of a fluid issuing from them (see MAGNETISM), those who hold the solidity or impenetrability of matter will maintain, that each atom of the magnetic fluid is solid and impenetrable. That we do not see nor feel these atoms, will be considered as no argument that they do not exist; for we do not see, nor in a close room feel, the atoms of the surrounding atmosphere; which yet Mr Young will acknowledge to have a real existence, and to be capable of operating upon our senses of hearing and smelling. Let us, however, suppose that by this reasoning he has established the non-existence of everything in the primary atoms of matter except active powers of resistance, and let us see how he conceives the actions of these powers to constitute what gives us the notion of inert and solid body; for that we have such a notion cannot be denied.

To *act* he allows to be an attribute, and justly observes, that we cannot conceive an attribute to exist without a substance. "But," says he, "we have traced all phenomena to action as to a generic idea, comprehending under it all forms of matter and motion as species of that genus. By this analysis, that complex idea we have usually denominated matter, and considered as the substance or substratum to which motion appertained as an attribute, is found to change its character, and to be itself an attribute of a substance essentially active, of which one modification of motion produces matter and another generates motion." The action of this substance Mr Young determines to be motion; and he proceeds to inquire by what kind of motion it produces matter, or inert and resisting atoms.

"Whatever portion of the *active substance* is given to form an atom, the following things are necessary to be united in such portion of active substance. *First*, It must in some respect continually move; for otherwise it would lose its nature, and cease to be active. *Secondly*, It must also in some other respect be at rest, for otherwise it could not form an inactive atom. *Thirdly*, It must preserve unity within itself." The author's proof of the first of these positions we have given elsewhere; the second he holds to be self-evident; and the third he thinks established by the following reasoning. "Solidity is the result of those actions among the parts of any whole, whereby the unity of the whole is preserved within itself. Several uncohering things may be united by an external bond; this does not constitute these one solid; it may be one bundle; but if several things cohere, and have an unity preserved within themselves, they become one solid. An atom is the least and most simple solid."

Having thus proved the necessity of these three requisites to the formation of an atom, he observes that "the two first can only be united in a rotation of the portion of active substance about a centre or axis at rest. By such a motion, all the parts successively occupy different places in the orbit of rotation, and therefore move; the centre round which they revolve being at rest, the whole portion is also at rest; and thus the portion is at once moving and quiescent, as is required. The same kind of motion will also fulfil the terms of the third requisite; for a substance having a revolving motion around its own centre, preserves its unity by reason of all the parts preserving the same relation to the centre; and further, a motion of the active substance about a centre or axis will be an activity in the same orbit, which will act upon and resist whatever shall interfere to oppose its activity, or destroy the unity of the sphere, by diverting the course of the revolving motions. The activity or motion of a portion of *active substance* about a centre will, therefore, give solidity to such portion; for it will give it unity and resistance, and in a manner tie together all the parts, forming them into one mass about their common centre; for they move or are active, not towards the centre, in which case they would be lost in non-extension; nor from the centre, where they would dissipate in boundless space; but about the centre, preserving the same limits of extension. And being in this way active, they in this way resist any other activity opposed to them, that is, they resist any action which tends to penetrate or divide this sphere of revolving activity. Therefore, since any portion of active substance does, by revolving about a centre, become an united, resisting, and quiescent whole, the smallest portions of the *active substance* which have such motions will become atoms, or make the smallest portions of matter."

Having thus shown to his own satisfaction how atoms of matter are formed, he next explains, what at first he confesses may appear to be a paradox, "how the *active substance*, retaining its own nature and essential properties, continuing immaterial, unsolid, and active, puts on at the same time the form of matter, and becomes material, solid, and inert. A sphere of revolving active substance, as it revolves constantly about a centre, and as parts of the substance are considered as successively passing through every point in the orbit; considered thus in its parts, and in its motions, it is *active substance*, immaterial, and unsolid; but the whole sphere, considered unitically, collectively, and as quiescent, is in this point of view a solid atom, material and inert."

Such is the active substance of Mr Young, and such his theory of the formation of matter. That he has not with servility copied from the ancients, every reader of his book, who is not an absolute stranger to Greek and Roman literature, will readily acknowledge; and yet, if his theory be well founded, he has discovered a middle substance between mind and matter, more properly plastic than Aristotle or Plato, Cudworth or Berkeley, ever conceived. But truth compels us to add, that to us his theory appears to labour under insuperable objections. That there may be in the universe a substance essentially active, and at the same time not intelligent, is a proposition which we are by no means inclined to controvert. Various phenomena, both in vegetable and in animal life, lead us to suspect that there is such a substance; but it does not follow that we are inclined to adopt our author's doctrine respecting the formation of matter. He conceives his proof indeed to be "in its nature not at all imperfect, or to fall short of demonstration; and if any one refuse it, he thinks it will be necessary for him to show, either that the explanation offered is not sufficient, or that some other explanation will serve equally well."

To show that the explanation which this writer has offered is not sufficient, will not, we apprehend, be a very arduous task; but we have ourselves no inclination to attempt another explanation, because we believe that of the formation of matter no other account can be given than that which resolves it into the fiat of the Creator. That it cannot be formed by the motion of an immaterial substance, in the manner which our author has very clearly described, seems to be a truth so evident as not to admit of proof; for if motion, as he defines it, be a change of place, everything that is moved must have the quality of extension. But all the parts of this active substance which are given to form an atom, move round a centre, and are expressly said to occupy successively different places in the orbit of rotation. Every one of these parts, therefore, is an extended being: And since, according to our author, solidity is nothing but an active power of resistance, and the parts of this active substance, in their rotation round their centre, act upon and resist whatever interferes to oppose their activity, it follows that each of these parts is likewise a solid being. But, in the opinion of Mr Young himself, and of all mankind, whatever is extended and solid is material. This theory, therefore, exhibits a process in which atoms are formed of a substance which, though it is said to be active, immaterial, and unsolid, appears, when narrowly inspected, to be nothing else than a collection of those very atoms of which the author pretends to explain the formation. Mr Young, who examines and very freely censures some of the doctrines of Newton and others, can scarcely have expected that others would refrain from stating objections to a theory which is quite new, to a transformation which he himself acknowledges may to many "appear not only problematical and difficult to conceive, but wholly impossible, and implying contradictions absolutely and for ever irreconcileable." Whether this be a just character of it our readers must determine; but if we had not believed the author to be a man of ingenuity, we should not have introduced him or his work to the notice of the public.
